Abstract

Background: Multidisciplinary care management teams must rapidly prioritize interventions for patients with complex medical and social needs. Current approaches rely on individual training, judgment, and experience, missing opportunities to learn from longitudinal trajectories and prevent adverse outcomes through recommender systems.

Objective: This study aims to evaluate whether a reinforcement learning approach could outperform standard care management practices in recommending optimal interventions for patients with complex needs.

Methods: Using data from 3175 Medicaid beneficiaries in care management programs across 2 states from 2023 to 2024, we compared alternative approaches for recommending "next best step" interventions: the standard experience-based approach (status quo) and a state-action-reward-state-action (SARSA) reinforcement learning model. We evaluated performance using clinical impact metrics, conducted counterfactual causal inference analyses to estimate reductions in acute care events, assessed fairness across demographic subgroups, and performed qualitative chart reviews where the models differed.

Results: In counterfactual analyses, SARSA-guided care management reduced acute care events by 12 percentage points (95% CI 2.2-21.8 percentage points, a 20.7% relative reduction; *P*=.02) compared to the status quo approach, with a number needed to treat of 8.3 (95% CI 4.6-45.2) to prevent 1 acute event. The approach showed improved fairness across demographic groups, including gender (3.8% vs 5.3% disparity in acute event rates, reduction 1.5%, 95% CI 0.3%-2.7%) and race and ethnicity (5.6% vs 8.9% disparity, reduction 3.3%, 95% CI 1.1%-5.5%). In qualitative reviews, the SARSA model detected and recommended interventions for specific medical-social interactions, such as respiratory issues associated with poor housing quality or food insecurity in individuals with diabetes.

Conclusions: SARSA-guided care management shows potential to reduce acute care use compared to standard practice. The approach demonstrates how reinforcement learning can improve complex decision-making in situations where patients face concurrent clinical and social factors while maintaining safety and fairness across demographic subgroups.

Introduction

Background

Health care delivery increasingly relies on multidisciplinary teams, including care coordinators and community health workers, to support patients with complex medical and social needs [1]. These care management programs are now mandated components of state Medicaid programs serving more than 80 million Americans and are widely implemented in Medicare Advantage plans serving an additional 30 million beneficiaries [1]. These programs aim to reduce acute care use through proactive outreach, offering services such as care coordination,

XSL•FO
RenderX

medication adherence counseling, and social needs assistance. While physicians and nurses typically follow evidence-based protocols, newer team member disciplines, such as community health workers, frequently lack standardized guidance for prioritizing interventions, instead relying on varied training approaches and personal experiences that may not consistently yield optimal outcomes [2].

This gap is particularly challenging when caring for patients with multiple chronic conditions, mental health disorders, substance use issues, and social needs. In time-constrained interactions, team members must make sequential decisions with long-term consequences, rapidly prioritizing among competing needs while recognizing that today's choices affect future patient states [3]. Current Medicaid care management programs typically rely on electronic health record documentation and clinical guidelines focused primarily on optimizing each individual's medical condition, with minimal decision support tools addressing social needs integration or optimal intervention sequencing.

The sequential nature of care management decisions, combined with the need to learn optimal intervention timing from longitudinal patient trajectories, suggests the potential utility of reinforcement learning approaches [4]. Unlike traditional supervised learning methods that treat each decision independently, reinforcement learning explicitly models how current actions influence future states and outcomes [5]. Traditional machine learning approaches cannot effectively capture these temporal dependencies and delayed rewards that characterize care management decisions. While large language models have shown promise in health care, they lack the ability to learn explicit action-value functions from sequential decision processes with delayed rewards [6].

Within reinforcement learning, the state-action-reward-state-action (SARSA) algorithm is particularly well-suited for clinical decision support due to its on-policy learning approach, which ensures that recommendations align with actual practice patterns while still optimizing for improved outcomes [7]. This on-policy characteristic provides crucial safety advantages over off-policy algorithms, such as Q-learning or deep Q-networks, which may recommend actions that deviate substantially from established clinical practice patterns and could potentially compromise patient safety. Unlike off-policy algorithms, SARSA's conservative on-policy approach provides an important safety constraint for health care applications where drastic deviations from established practice patterns may pose serious health risks.

Currently, care management teams typically rely on training that codifies expert knowledge into predefined curricula on how to address each patient's needs, often leaving the prioritization of multiple needs to team member experience [8]. This approach can fail to capture the value of experiences for newer team members early in their careers and address how simultaneous comorbid conditions and social-medical interactions can affect real-time decision-making in care management [9].

This Study

In this study, we report results obtained upon comparing SARSA-guided care management to the status quo approach of human experience–guided decision-making. Using real-world data from multidisciplinary care teams across 2 states, we performed counterfactual causal inference analyses and qualitative reviews to evaluate each approach's ability to recommend interventions that reduced subsequent acute care use while maintaining fairness across patient subgroups.

Methods

Study Design and Data Source

We conducted a comparative effectiveness study using longitudinal cohort data from Medicaid beneficiaries enrolled in care management programs in Virginia and Washington from 2023 to 2024. The programs involved multidisciplinary teams that engaged patients in community settings. Data were extracted from the programs' health record systems, capturing demographics, health conditions, social determinants, team interventions, and health care use outcomes. Complete code is available at the link included in Multimedia Appendix 1.

The cohort included Medicaid beneficiaries enrolled in care management between January 1, 2023, and December 31, 2024, with follow-up through February 28, 2025. Patient identification was done using a previously validated extreme gradient boosting algorithm considering chronic conditions, previous health care use, and social determinants to identify individuals at high risk for acute care use [10]. The primary outcome was a composite of emergency department visits and hospitalizations.

Reinforcement Learning Model Development

We estimated the impact of a SARSA reinforcement learning approach to optimize sequential intervention decisions. The SARSA model belongs to the temporal difference learning family and is well suited for health care applications due to its on-policy learning from multistep patient trajectories rather than optimizing for only the next immediate intervention [11].

The state representation comprised features across multiple domains, such as demographics, clinical metrics (chronic conditions and risk factors), social determinants of health, health care use history, and intervention history. The action space consisted of 9 mutually exclusive interventions derived through clinical expert consensus and existing care management protocols, such as substance use support, mental health support, chronic condition management support, food assistance, housing assistance, transportation assistance, utility assistance, childcare assistance, and watchful waiting. Actions are mutually exclusive at each decision point to prevent combinatorial complexity, with the model selecting the single most appropriate intervention based on the current patient state.

For function approximation, we developed a neural network architecture with an input layer accepting the multidimensional state vector, followed by 2 hidden layers with rectified linear unit activation functions and dropout regularization. The output layer contained 9 nodes corresponding to the Q-values for each intervention. Complete architectural specifications,

XSL•FO
RenderX

hyperparameter grids, and training procedures are detailed in Multimedia Appendix 1.

Reward Function Engineering

The reward function captured multiple aspects of clinical quality and safety. The primary component was a negative reward for acute care events, reflecting the main objective of reducing emergency department visits and hospitalizations. We incorporated a continuous reward signal proportional to the reduction in calculated risk score, allowing the model to learn the value of incremental risk reductions even when acute events did not occur.

Clinical appropriateness was encouraged through a structured reward bonus system, including a prevention bonus for avoiding acute care events (scaled based on preintervention risk level) and an intervention matching bonus when the selected intervention aligned with the patient's primary risk domain. Safety constraints were enforced through both a penalty system and an action masking mechanism that prevented the selection of interventions that violated clinical constraints or were deemed inappropriate based on the patient's current state.

Model Training and Evaluation

We divided our dataset into training (2222/3175, 70%), validation (635/3175, 20%), and testing (318/3175, 10%) sets, with stratification by outcome occurrence. All analyses used a fixed random seed (42) to ensure reproducibility. Software versions included Python (version 3.9.7; Python Software Foundation), TensorFlow (version 2.8.0; Google LLC), NumPy (version 1.21.0; NumFOCUS), Pandas (version 1.3.3; NumFOCUS), and Scikit-learn (version 1.0.2; NumFOCUS). The SARSA model was trained for 100 epochs, with early stopping based on validation set performance. Hyperparameters were tuned through grid search on the validation set, optimizing for reduction in acute care events. The code for reproducibility and extension is available at GitHub [12].

Counterfactual Evaluation

To estimate the clinical impact, we conducted counterfactual causal inference analysis using a held-out test set [13]. For each patient, we generated comprehensive paired trajectories under 2 distinct intervention policies: the status quo approach based on observed care management decisions and the SARSA-guided approach.

Our transition model captured the relationship between patient characteristics, interventions, and outcomes through a neural network architecture trained to predict state evolution conditioned on actions. This model was validated for calibration (expected calibration error of 0.08) and discrimination (area under the curve=0.78).

The transition model architecture comprised an input layer accepting 47 state features; 3 hidden layers with 128, 64, and 32 nodes, respectively; and an output layer predicting next-state probabilities. Additional validation metrics included Brier score (0.142), calibration slope (0.96), and Hosmer-Lemeshow test (P=.23), indicating good model fit. We conducted doubly robust sensitivity analysis using inverse probability weighting combined with outcome regression to assess robustness to unmeasured time-varying confounding.

We estimated CIs using bootstrapping with 1000 iterations, resampling at the patient level to account for within-patient correlation in outcomes. This methodology extends traditional causal inference approaches by modeling the complex, sequential nature of care management decisions [14].

We evaluated model performance using multiple metrics, including number needed to treat (NNT), absolute risk reduction (ARR), and relative risk reduction (RRR) with 95% CIs. We assessed fairness across demographic groups by calculating equalized odds discrepancy for self-reported gender, race, and ethnicity. Equalized odds discrepancy is defined as the maximum difference in true positive rates and false positive rates across demographic groups: max(|TPR_group1 – TPR_group2|, |FPR_group1 – FPR_group2|), with values less than or equal to 5% considered acceptable. We selected this metric over demographic parity or calibration measures because it directly assesses whether the model provides equitable benefit (true positive rate) and harm (false positive rate) across groups, which is most clinically relevant for care management decisions [15]. Disparities were assessed on observed outcomes rather than predicted risk scores. Analyses followed the Minimum Information About Clinical Artificial Intelligence Modeling checklist (MI-CLAIM) [16] and Developmental and Exploratory Clinical Investigations of Decision support systems driven by Artificial Intelligence (DECIDE-AI) guidelines [17].

Qualitative Analysis of Recommendation Differences

We conducted a qualitative analysis of cases where the status quo and SARSA models recommended different interventions, using a grounded theory approach [18]. We selected a purposive sample of 200 patient cases where intervention recommendations differed. To ensure diverse representation, we stratified this sample based on primary risk domain (medical, behavioral, and social) and the presence or absence of acute events following intervention.

Our qualitative analysis followed standard grounded theory methodology with 3 stages of coding [18,19]. Two independent coders with clinical (internal medicine) and social science (medical anthropology and social work) backgrounds conducted the analysis, with regular reflexivity sessions to examine potential bias in interpretation. First, in open coding, we independently reviewed each case, identifying key factors influencing divergent recommendations. Intercoder agreement was assessed using Cohen κ (κ=0.82; indicating substantial agreement). Second, during axial coding, through iterative comparison and refinement, we identified recurring patterns and developed provisional categories describing why and when the models diverged. Finally, in selective coding, we refined these categories into core conceptual themes that explained when the SARSA model's recommendations differed most substantially from the status quo approach. A complete audit trail documented all coding decisions and category development. We maintained detailed reflexivity notes throughout the process to acknowledge potential researcher bias and ensure analytic rigor.

Ethical Considerations

This study was approved by the Western Institutional Review Board–Copernicus Institutional Review Board (20243894). All data were deidentified using the safe harbor method to preserve patient privacy, and waiver of consent was obtained from the institutional review board; patients were not compensated for participation.

Results

Characteristics of the Study Population

Table 1 presents the demographic and clinical characteristics of the 3175 Medicaid beneficiaries enrolled in care management programs. The study population had a mean age of 34.5 (SD 18.5) years, with 2089 (65.8%) female participants. Most patients were categorized under other or multiple races (2181/3175, 68.7%), with smaller proportions identifying as White (423/3175, 13.3%), Black (376/3175, 11.8%), Hispanic (162/3175, 5.1%), or Asian (33/3175, 1%). The most common chronic conditions were hypertension (1371/3175, 43.2%), depression (1203/3175, 37.9%), and diabetes (939/3175, 29.6%). At baseline, 1642 (51.7%) participants had experienced at least 1 emergency department visit in the previous 6 months, and 738 (23.2%) had been hospitalized.

Table 1. Characteristics of the study population (N=3175).

Characteristic	Values
Age (y), mean (SD)	34.5 (18.5)
Female sex, n (%)	2089 (65.8)
Racial or ethnic group, n (%)	
Asian	33 (1)
Black	376 (11.8)
Hispanic	162 (5.1)
White	423 (13.3)
Other or multiple races	2181 (68.7)
Clinical conditions, n (%)	
Hypertension	1371 (43.2)
Depression	1203 (37.9)
Diabetes	939 (29.6)
Substance use disorder	635 (20)
Chronic obstructive pulmonary disease	476 (15)
Congestive heart failure	349 (11)
Social determinants, n (%)	
Housing instability	869 (27.4)
Food insecurity	730 (23)
Transportation barriers	571 (18)
Utility needs	428 (13.5)
Health care use, n (%)	
≥1 emergency department visit in the past 6 months	1642 (51.7)
≥1 hospitalization in the past 6 months	738 (23.2)

Comparative Effectiveness in Reducing Acute Care Events

In our counterfactual analysis comparing SARSA-guided care management to status quo practice, the SARSA approach achieved an acute event rate of 46% compared to 58% in the status quo condition, representing an absolute reduction of 12 percentage points (95% CI 2.2-21.8 percentage points; *P*=.02) and a relative reduction of 20.7% (Table 2). This translates to an NNT of 8.3 (95% CI 4.6-45.2), indicating that for approximately every 8 patients receiving SARSA-guided interventions instead of standard care, 1 acute care event would be prevented. The number needed to harm was infinite, indicating no cases of worsened outcomes because of following SARSA recommendations rather than the status quo approach.

XSL•FO
RenderX

Table 2. Effectiveness of the state-action-reward-state-action (SARSA)–guided care management compared to the status quo approach.

Outcome	SARSA, %	Status quo, %	Difference (95% CI)	*P* value
Primary outcome				
Acute care event rate	46	58	–12.0 (–21.8 to –2.2)	.02
Secondary outcomes				
Absolute risk reduction, percentage points	—[a]	—	12.0 (2.2 to 21.8)	.02
Relative risk reduction	—	—	20.7 (3.8 to 37.6)	—
Number needed to treat[b]	—	—	8.3 (4.6 to 45.2)	—
Number needed to harm	—	—	Not defined (infinite)	—
Risk-stratified analysis: number needed to treat [b]				
High-risk patients	—	—	5.2 (3.1 to 14.3)	.004
Medium-risk patients	—	—	8.9 (4.7 to 38.6)	.02
Low-risk patients	—	—	23.4 (11.2 to infinite)	.08
Fairness metrics: equalized odds discrepancy [c]				
Gender	3.8	5.3	–1.5% (0.3% to 2.7%)	.04
Race and ethnicity	5.6	8.9	–3.3% (1.1%-5.5%)	.008

[a]Not applicable.

[b]The number needed to treat is the number of patients who would need to receive SARSA-guided interventions instead of status quo care to prevent 1 acute care event.

[c]Lower equalized odds discrepancy values indicate more equitable performance across demographic groups. The improvement in fairness metrics for the SARSA model compared to the status quo approach represents a 28.3% reduction in gender-based disparities and a 37.1% reduction in race- and ethnicity-based disparities.

The effectiveness of the SARSA-guided interventions varied by patient risk level. We observed the greatest benefit among high-risk patients (top tertile of preintervention risk score), with an NNT of 5.2 (95% CI 3.1-14.3). Medium-risk patients (second tertile) showed moderate benefit with an NNT of 8.9 (95% CI 4.7-38.6), while low-risk patients (bottom tertile) demonstrated less substantial improvement with an NNT of 23.4 (95% CI 11.2-∞).

Sensitivity analysis using doubly robust estimation confirmed the robustness of our primary findings. The doubly robust estimator yielded an ARR of 11.2 percentage points (95% CI 1.8-20.6 percentage points), closely aligning with our primary counterfactual analysis. This consistency suggested that unmeasured time-varying confounding is unlikely to substantially bias our estimates.

Patterns of Intervention Recommendations

Analysis of the intervention patterns revealed substantial differences between the SARSA approach and status quo practice. The SARSA model recommended substantially more chronic condition management interventions (54% vs 36%, difference +18%) and substance use support (26% vs <0.1%, difference +26%). Conversely, status quo practice featured more mental health support interventions (34% vs 4%, difference –30%), housing assistance (10% vs 3%, difference –7%), and food assistance (9% vs 1%, difference –8%).

The differences in recommendations reflected the algorithm's learned patterns rather than a devaluation of mental health interventions. When examining cases where the status quo approach recommended mental health support but the SARSA model recommended substance use support, our qualitative analysis found that the SARSA model frequently identified underlying substance use issues contributing to mental health symptoms. The status quo approach often defaulted to treating mental health symptoms (anxiety and depression) without addressing potential substance use triggers.

Fairness Analysis Across Demographic Groups

The SARSA approach demonstrated improved equalized odds fairness metrics across demographic subgroups compared to status quo approaches (Table 2). For gender, the SARSA model showed a 3.8% disparity in outcomes versus 5.3% for the status quo approach, representing a 28.3% improvement in fairness. For race and ethnicity, the SARSA model demonstrated a 5.6% disparity compared to 8.9% for the status quo approach—a 37.1% improvement.

Qualitative Findings From Chart Reviews

The qualitative analysis revealed 7 key areas where the SARSA model's recommendations better recognized complex interactions among medical, behavioral, and social needs (Textbox 1).

XSL•FO
RenderX

Textbox 1. Seven key areas where recommendations by the state-action-reward-state-action (SARSA) model better recognized complex interactions among medical, behavioral, and social needs.

1. Housing quality and respiratory health interactions: the SARSA model identified cases where poor housing conditions exacerbated respiratory conditions and recommended housing and chronic condition interventions concurrently, whereas these interventions fell further down the list of priorities in the status quo.

2. Food security and chronic disease management: while the status quo approach often addressed either food insecurity or chronic disease separately, the SARSA model linked these needs, recommending food support and chronic condition interventions sequentially when people had these risk factors concurrently.

3. Substance use recognition: the SARSA model more frequently recognized underlying substance use issues in patients presenting with symptoms of anxiety or depression. Rather than solely recommending mental health support (as seen in the status quo approach), the SARSA model appropriately recommended substance use interventions when evidence suggested this was a primary driver of symptoms.

4. Housing stability and mental health: the SARSA model identified connections between housing instability and mental health deterioration, recommending coordinated interventions that addressed both needs, often addressing housing interventions before mental health or alternating between housing and mental health rather than focusing on mental health alone.

5. Transportation and health care access: the SARSA model recognized when transportation barriers directly affected health care access and treatment adherence, prioritizing transportation assistance at critical junctures in care, such as before or after outpatient visits; in the chart review of the status quo approach, transportation was usually addressed only after hospitalizations rather than proactively.

6. Utility access and health-dependent technologies: the SARSA model identified cases where utility issues (eg, electricity and water) affected health-critical technologies (eg, oxygen concentrators and medication refrigeration), whereas the status quo approach often missed these connections and did not offer utility support proactively when patients had durable medical equipment.

7. Social isolation and treatment adherence: the SARSA model recognized patterns where social isolation contributed to poor medication adherence or appointment attendance, recommending interventions that addressed underlying social needs, whereas the status quo approach often leaned toward “watchful waiting” for such patients.

Analysis of the relationship between emergent qualitative themes and quantitative outcomes revealed that cases involving medical-social interaction themes (theme 3: “integrated medical-social needs assessment” and theme 5: “housing-health interactions”) accounted for 65% of the observed ARR. Specifically, patients for whom the SARSA model identified housing and respiratory interactions or food insecurity and diabetes management needs showed the greatest benefit from SARSA-guided interventions compared to status quo care (NNT=4.2 vs overall NNT=8.3).

Discussion

Principal Findings

In this study, we examined whether reinforcement learning, specifically a SARSA approach, could effectively assist care management team members in prioritizing interventions for patients with complex medical and social needs. To the best of our knowledge, this is the first application of reinforcement learning beyond physician- or nurse-led medical decisions, entering into multidisciplinary care-team decision-making that now reaches more than 80 million Americans [1]. The SARSA-guided approach reduced acute care events by 12 percentage points compared to status quo practice, with improved fairness metrics across demographic groups. This ARR of 12% and RRR of 20.7% compares favorably to many established clinical interventions. For context, statins for patients with hypertension and cardiovascular risk factors show an ARR of 28% to 54% and RRR of 36% to 67% [20]. Our NNT of 8.3 indicates substantial clinical relevance, falling within the range considered highly effective for many pharmacological and behavioral interventions in chronic disease management [20].

In our qualitative assessment, the greater effectiveness of the SARSA model than the status quo approach appeared to derive from its ability to learn optimal intervention sequences from longitudinal patient trajectories [4,5] rather than relying on individual experience and judgment, which may vary among team members. The algorithm was particularly effective for high-risk patients (NNT=5.2), suggesting its utility in targeting intensive support to those most likely to benefit.

Our mixed methods approach [18] revealed several key features of the SARSA model’s differences from the status quo approach. The qualitative analysis identified 7 distinct patterns where the SARSA model recognized complex interactions between medical and social needs often missed in standard practice [9]. A particular strength of our study was the use of real-world care management data, capturing both medical and social care details often missing from conventional health records [1]. Previous work in health care artificial intelligence (AI) has largely relied on hospital or clinic-based data [21-23], limiting its applicability to community-based care settings where most of the care management occurs [1,8]. Our dataset uniquely captured the full scope of care manager activities, including home visits, social service visits, and “street medicine” interactions.

These findings compare favorably to other care management interventions reported in the literature. Kangovi et al [24] reported an NNT of 6 for preventing one 30-day readmission with community health worker interventions, while Krieger et al [25] found an NNT of 15 for increasing symptom-free days by 1 day per 2 weeks in children with asthma. Our observed NNT of 8.3 suggests that SARSA-guided care management provides efficient targeting of interventions within the range of established care management approaches.

Real-world deployment of SARSA-guided care management faces several implementation challenges beyond technical performance. Workflow integration requires careful consideration of existing care team processes, with

XSL•FO
RenderX

recommendations delivered through user interfaces that complement rather than disrupt established clinical workflows. Team training must address both technical literacy and trust building, as care team members need to understand when and why to follow or override algorithmic recommendations. Override mechanisms must be easily accessible and well documented to maintain clinical autonomy while capturing data on recommendation acceptance patterns. Continuous monitoring protocols are essential to detect model drift, reward hacking behaviors, and changes in patient population characteristics that might affect model performance.

The improved fairness metrics achieved by the SARSA model are particularly noteworthy given concerns about AI perpetuating health care disparities [15]. The reduction in outcome disparities across gender (3.8% vs 5.3%) and race and ethnicity (5.6% vs 8.9%) suggests that appropriately designed AI systems may help promote more equitable care delivery. We attribute this improvement to several factors, including the diverse training dataset, explicit consideration of social determinants in the state representation, and the action masking mechanism that prevented unsafe or inappropriate interventions.

While our fairness analysis demonstrates improved equity compared to status quo practice, the risk of unintended bias reinforcement through AI systems requires ongoing vigilance. We recommend implementing comprehensive bias mitigation strategies, including regular algorithmic auditing across demographic subgroups, continuous monitoring of recommendation patterns for evidence of discriminatory outcomes, and establishment of governance frameworks for detecting and addressing potential bias reinforcement. Future monitoring plans should include quarterly fairness assessments, annual model retraining with updated data, and systematic review of override patterns to identify the potential sources of algorithmic bias. In addition, diverse stakeholder engagement in model development and deployment can help identify blind spots that technical metrics alone might miss.

Limitations

Several limitations should be noted. First, while our counterfactual analyses showed promising results, prospective validation through a randomized trial would provide stronger evidence of effectiveness, particularly as our approach may not fully account for time-varying unmeasured confounders unaddressed by our individual-level causal inference methodology. Second, our training data came from Medicaid populations in 2 states, potentially limiting generalizability to populations with higher incomes and different health care insurance coverage or in regions with different care delivery systems or social service landscapes. Third, while we demonstrated improved fairness metrics [15-17], a longer-term study would be needed to confirm sustained reductions in health care disparities.

The generalizability of our findings is limited by the single-organization implementation across Virginia and Washington state Medicaid programs. Variations in state Medicaid waiver designs, social service infrastructure availability, and electronic health record integration capabilities may substantially affect both state vector quality and action feasibility in other contexts. For example, states with more robust housing assistance programs may see different patterns of housing-related intervention effectiveness, while states with limited mental health infrastructure may require modified action spaces. Successful adaptation to different health care contexts will likely require retraining models with local data, adjusting action spaces to reflect available services, and validating performance across diverse patient populations and care delivery systems.

Several additional limitations warrant consideration. The potential for gaming behaviors (influencing the model to achieve a desired recommendation) exists if care team members learn to manipulate model inputs to achieve preferred recommendations, which could undermine the integrity of the decision support system. We recommend implementing randomized auditing procedures and behavioral monitoring to detect and prevent such gaming. The single-vendor, 2-state implementation limits generalizability to other care management programs with different patient populations, service availability, or organizational structures. Future research should validate these findings across diverse health care contexts and patient populations.

The counterfactual evaluation approach, while methodologically rigorous, relies on assumptions about unmeasured confounding that cannot be fully validated without prospective implementation. Although our sensitivity analyses suggest robustness to unmeasured confounding, prospective randomized trials remain the gold standard for causal inference in clinical interventions. In addition, the 12-month follow-up period may not capture longer-term effects of intervention sequencing decisions, and the focus on acute care use may miss other important outcomes, such as patient satisfaction, quality of life, or care team efficiency.

Future Directions

Future research should explore several key directions. First, extending the SARSA approach to include more granular social determinants data and community resource availability could further improve intervention targeting. Second, investigating how to optimally integrate AI recommendations into care team workflows while preserving human judgment and relationship-based care delivery will be important. Third, examining how SARSA-guided care management performs across different health care contexts and patient populations could identify areas for refined algorithm development.

Successful integration of SARSA-guided recommendations into care team workflows requires careful attention to user interface design, governance structures, and quality assurance mechanisms. User interfaces should present recommendations with clear rationale, confidence indicators, and easy override options to maintain clinical decision-making autonomy. Governance frameworks must address algorithm change management, including procedures for model updates, performance monitoring, and stakeholder communication. Quality assurance protocols should include regular validation of model predictions against observed outcomes, monitoring for reward hacking behaviors where care teams might game the system, and assessment of recommendation acceptance rates

XSL•FO
RenderX

across different team members and patient populations. In addition, clear escalation procedures must be established for cases in which algorithmic recommendations conflict with clinical judgment or patient preferences.

Conclusions

Our findings suggest that reinforcement learning may effectively support complex care management decisions while promoting more equitable care delivery. As care management programs are mandated benefits for more than 80 million Americans and health care systems increasingly diversify the types of professionals working on these teams to address both medical and social needs, particularly through nonphysician team members for whom standardized guidelines are not universally available, AI approaches that can learn optimal intervention sequences while maintaining safety and fairness will become increasingly valuable. Further research should focus on prospective validation and optimal integration into care team workflows.

Abstract

Background: As physicians spend up to twice as much time on electronic health record tasks as on direct patient care, digital scribes have emerged as a promising solution to restore patient-clinician communication and reduce documentation burden—making it essential to study their real-world impact on clinical workflows, efficiency, and satisfaction.

Objective: This study aimed to synthesize evidence on clinician efficiency, user satisfaction, quality, and practical barriers associated with the use of digital scribes using ambient listening and generative artificial intelligence (AI) in real-world clinical settings.

Methods: A rapid review was conducted to evaluate the real-world evidence of digital scribes using ambient listening and generative AI in clinical practice from 2014 to 2024. Data were collected from Ovid MEDLINE, Embase, Web of Science–Core Collection, Cochrane CENTRAL and Reviews, and PubMed Central. Predefined eligibility criteria focused on studies addressing clinical implementation, excluding those centered solely on technical development or model validation. The findings of each study were synthesized and analyzed through the QUEST human evaluation framework for quality and safety and the Systems Engineering Initiative for Patient Safety (SEIPS) 3.0 model to assess integration into clinicians' workflows and experience.

Results: Of the 1450 studies identified, 6 met the inclusion criteria. These studies included an observational study, a case report, a peer-matched cohort study, and survey-based assessments conducted across academic health systems, community settings, and outpatient practices. The major themes noted were as follows: (1) they decreased self-reported documentation times, with associated increased length of notes; (2) physician burnout measured using standardized scales was unaffected, but physician engagement improved; (3) physician productivity, assessed via billing metrics, was unchanged; and (4) the studies fell short when compared to standardized frameworks.

Conclusions: Digital scribes show promise in reducing documentation burden and enhancing clinician satisfaction, thereby supporting workflow efficiency. However, the currently available evidence is sparse. Future real-world, multifaceted studies are needed before AI scribes can be recommended unequivocally.

Introduction

Health care has arguably failed to preserve one of the fundamental pillars of medicine: protecting time for meaningful patient-clinician communication. For each hour spent on direct patient care, physicians now spend up to 2 hours on the electronic health record (EHR), both during and outside clinic hours [1,2]. This shift toward increased documentation and EHR-driven tasks, driven by billing, medicolegal, and regulatory requirements, has led to more time in front of the computer and strained the patient-physician relationship [1,3,4]. The effects have been far-reaching, impacting patient care quality and contributing to physician burnout [3,5-8].

To address these challenges, health care has turned to digital tools promising to offload work burden, revive patient-clinician interactions, and reduce burnout [9]. In particular, digital scribe technology, spurred on by recent advancements in automated speech recognition, increased computational power, and breakthroughs in the development of large language models, which underlie services such as ChatGPT, has enabled rapid advancements in automated documentation [10-12]. These digital scribes, which use a listening device (such as smartphones) to ambiently record patient-clinician conversations and automate generation of a suitably formatted clinical note (eg, a structured progress note) on completion of the encounter, present a potentially promising solution to the pernicious problem of documentation burden. And, despite the relative novelty of digital scribe technology (Nuance DAX, 2020 being the first major tool in the market [13]), and perhaps because of the pressing issues it aims to address, numerous next-generation digital scribes have already entered the market and clinical practice.

Despite the rapid implementation of digital scribes, real-world research on their effectiveness in improving documentation quality, patient safety, outcomes, and physician well-being remains limited [14]. Medicine and health IT are replete with examples of prematurely adopted technologies that failed to meet expectations [15]. Robotic surgical systems, for instance, were widely embraced with promises of precision and faster recovery, but subsequent studies revealed mixed results, highlighting limited benefits over traditional surgery and raising concerns about high costs and steep learning curves [16]. Similarly, wearable health monitors such as fitness trackers and smartwatches, initially praised for enhancing patient engagement, often produce data that are not clinically actionable and can contribute to patient anxiety, without clear evidence of improved health outcomes [17,18].

Given the rapid adoption of these tools in clinical practice, there is a pressing need to evaluate their effectiveness in real-world settings [4,14,19]. While many studies have examined algorithmic performance, assessments of how these technologies influence routine care, including everyday clinical workflows, physician satisfaction, and patient care quality, are just emerging. This rapid review seeks to address this gap by synthesizing the current literature on the practical use of artificial intelligence (AI)–enabled digital scribes in clinical environments.

Methods

Study Design and Rationale

We applied a rapid review approach to assess the real-world impact of quickly evolving digital scribe technology [20]. Unlike systematic reviews, which are comprehensive but time intensive, a rapid review provides timely, relevant findings to support immediate decision-making [21]. Compared to scoping reviews, which broadly map research areas, our rapid review focuses on synthesizing actionable evidence on the effectiveness of digital scribes [22]. This approach balances rigor and timeliness, making it well-suited for evaluating evolving technologies.

Literature Search—Selection Criteria and Search Strategy

We searched Ovid MEDLINE, Embase, Web of Science–Core Collection, Cochrane CENTRAL & Reviews, and PubMed Central to discover relevant articles. The search strategy was developed in conjunction with a professional librarian to ensure comprehensive coverage of the topic. The strategy used a broad approach that included AI concepts implied in the metadata, thereby capturing articles that might otherwise be excluded by discrete AI-related terms.

We included papers that mentioned ambient listening technology within the health care domain within the last 10 years (2014 - 2024), particularly following the advent of AI and advanced transcription technologies, with a focus on practical impact on physicians and staff, rather than theoretical model development. We excluded studies focused solely on model development, nonclinician populations, and technologies other than ambient listening using generative AI. In addition, studies outside the specified time frame, theoretical papers, and those not in English were excluded. The full search strategy is available in Multimedia Appendix 1.

Data Extraction

To ensure uniformity and consistency in data extraction, a standardized data abstraction tool, subsequently referred to as the evidentiary table, was developed collaboratively and agreed upon by all authors. Articles that met the predefined inclusion criteria were assigned equally among team members for independent review. Each article was reviewed by at least 2 reviewers, with a third reviewer available to adjudicate any discrepancies. The review team included NSK, YVR, TB, ZD, IVF, and CS. Extracted data were systematically recorded using an Excel (Microsoft Corporation) spreadsheet to create an evidentiary table for synthesis.

The review process followed a systematic, multistage approach corresponding to the identification, screening, and inclusion stages specified in the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines. In the title and abstract screening phase, studies were screened for eligibility, with discrepancies among reviewers being documented, and interrater reliability measured using prevalence-adjusted bias-adjusted κ (PABAK) and AC1 statistics. Following this phase, selected articles proceeded to the full-text review, where they were further evaluated against predefined inclusion criteria. This stage also included interrater

XSL•FO
RenderX

reliability measures to assess reviewer agreement, ensuring consistency.

Data Synthesis and Organization

The data synthesis for this study was conducted using a structured thematic approach guided by the QUEST human evaluation framework [23], Systems Engineering Initiative for Patient Safety (SEIPS) 3.0 model [24,25], and a study by Abbasian et al [26]. These frameworks were used to ensure that the data extraction and organization comprehensively addressed all relevant aspects of digital scribe implementation, including clinician efficiency, satisfaction, safety, quality, and practical barriers in real-world clinical settings.

We used the QUEST Human Evaluation Framework to assess the quality and safety of information provided by digital scribes [23]. Specifically designed for evaluating LLMs in health care, QUEST comprises 3 phases: planning, implementation and adjudication, and scoring and review. It is guided by 5 key principles: quality of information, understanding and reasoning, expression style and persona, safety and harm, and trust and confidence. In this study, QUEST was used to evaluate generated clinical documentation for accuracy, bias, comprehensiveness, and safety issues, such as transcription errors and hallucinations.

The SEIPS 3.0 model was applied to evaluate the broader impact of digital scribes on patient safety and health care processes. SEIPS 3.0 focuses on the patient journey and how health care activities are distributed across different settings and times. This framework guided assessment on how digital scribes influenced patient outcomes (eg, engagement and satisfaction), clinician outcomes (eg, efficiency, workload, burnout), and organizational outcomes (eg, workflow and productivity). We used the study by Abbasian et al [26] as a basis to evaluate foundation metrics of user perspectives and real-world contexts. In their paper, they describe the health care metrics in 4 domains, namely accuracy, trustworthiness, empathy, and performance.

Reviewer Assessment

To maintain accuracy in the selection and abstraction process, both title and abstract screening and full-text review phases included measures of interrater reliability. We used 2 specific metrics: PABAK and Gwet AC1 [27]. These measures were selected due to their robustness in handling data with a high prevalence of rater bias, common in systematic reviews where agreement on inclusion criteria can be challenging. PABAK was chosen as it adjusts for both prevalence and bias, providing a more stable agreement measure when the likelihood of certain ratings is high, thus avoiding the common limitations of Cohen κ in such scenarios. Gwet AC1 was included because it similarly accounts for prevalence effects but is less sensitive to rater bias, making it an optimal complement to PABAK for accurately capturing agreement levels. Both metrics offer a reliable, comprehensive view of interrater reliability, aligning with our study's emphasis on precision and consistency in data extraction [28,29].

Results

We begin by outlining the key characteristics of the review process, followed by the main study results categorized by major findings; due to the diversity of study types and outcomes, the results were not combined. Table 1 summarizes each study's title, aim, and key outcomes.

XSL•FO
RenderX

Table . General characteristics of the studies included in this rapid review.

Study	Authors and year	Objective	Sample size	Study design	Setting	Tool/ vendor	Key findings
AI[a]-driven digital scribes in clinical documentation: pilot study assessing the impact on dermatologist workflow and patient encounters	Cao et al [30], 2024	Explore the use of DAX[b] as a digital scribe in an academic and community-based dermatology setting	12 dermatologists	Research letter	Not available	Nuance DAX	Digital scribes decrease average documentation time by 22% (90.1-70.3 min/d), ease administrative burdens, and improve both clinician and patient experience in dermatology clinics. A total of 83.3% would be "very disappointed" if the tool was taken away.
Impact of an AI-based solution on clinicians' clinical documentation experience: initial findings using ambient listening technology	Galloway et al [31], 2024	Report the impact of a pilot implementation of ambient listening on clinicians' documentation experience in the EHR[c] and on overall well-being	31 physicians	Survey	Academic Medical Center	Abridge	Positive responses on documentation meeting requirements rose from 41.9% to 71% post implementation, and ease of use improved from 32.3% to 48.4% post implementation. Negative impacts on well-being and patient experience dropped significantly, with 35.5% recommending the solution and 58.1% noting increased productivity. Using DAX over an in-person scribe could equate to US $13,400 to US $14,400 in cost-savings
The impact of nuance DAX ambient listening AI documentation: a cohort study	Haberle et al [32], 2024	To assess the impact of the use of DAX on caregiver engagement, time spent on EHR, productivity, attributed panel size for value-based care providers, documentation timeliness, and CPT[d] submissions	99 clinicians (DAX users)+76 matched controls	Peer-matched controlled cohort study	Medical Group 12 specialties	DAX	Nuance DAX appears to have no benefit in productivity for fee-for-service clinicians and no improvement in total panel size for value-based primary care. Positive trends in provider engagement were noted, while nonparticipants saw worsening engagement

XSL•FO
RenderX

Study	Authors and year	Objective	Sample size	Study design	Setting	Tool/ vendor	Key findings
Implementing digital scribes to reduce EHR documentation burden among cancer care clinicians: a mixed-methods pilot study	Nguyen et al [33], 2023	Assess digital scribe's feasibility, acceptability, appropriateness, usability, and its preliminary association on clinician well-being	21 clinicians, (paired survey responses from 9 clinicians only)	Mixed methods study	Live clinic settings at a National Cancer Institute	DAX	Among the 9 clinicians who completed the paired survey, perceived sufficiency of documentation time (on a 5-point Likert scale) significantly improved from 2.1 to 3.6 (P=.005), but no significant changes were seen in burnout score (3.6-3.9, P=.08).
The association between use of ambient voice technology documentation during primary care patient encounters, documentation burden, and clinician burnout	Owens et al [34], 2024	Evaluate the association between ambient voice technology, coupled with natural language processing and AI on primary care provider documentation burden and burnout	110 clinicians	Survey and observation	Not available	DAX	Among high DAX use providers, documentation times decreased by 28.8% per encounter translating to time savings of about 50 min daily. High DAX users showed significantly less burnout compared to the lower use physicians on the OLBI[e] disengagement subscore

XSL•FO

Study	Authors and year	Objective	Sample size	Study design	Setting	Tool/ vendor	Key findings
Ambient AI scribes to alleviate the burden of clinical documentation	Tierney et al [11], 2024	Understanding how ambient AI scribes reduce documentation burden, enhance physician-patient encounters, and augment clinicians' capabilities	3442 physicians, 303,266 patient encounters	Commentary	21 medical centers in primary care, pediatric, hospitalist, mental health, surgical, ED[f] clinicians	Not declared specifically	Compared to the clinicians not using AI scribe, statistically significant reduction in "pajama time" by 2.5 units and time spent in notes during appointments by 0.5 min. Patient feedback (from a survey of 21 patients) was also positive, with 71% noting increased time spent speaking with their physician and 81% observing their physicians spent less time looking at screens during consultations

[a]AI: artificial intelligence.

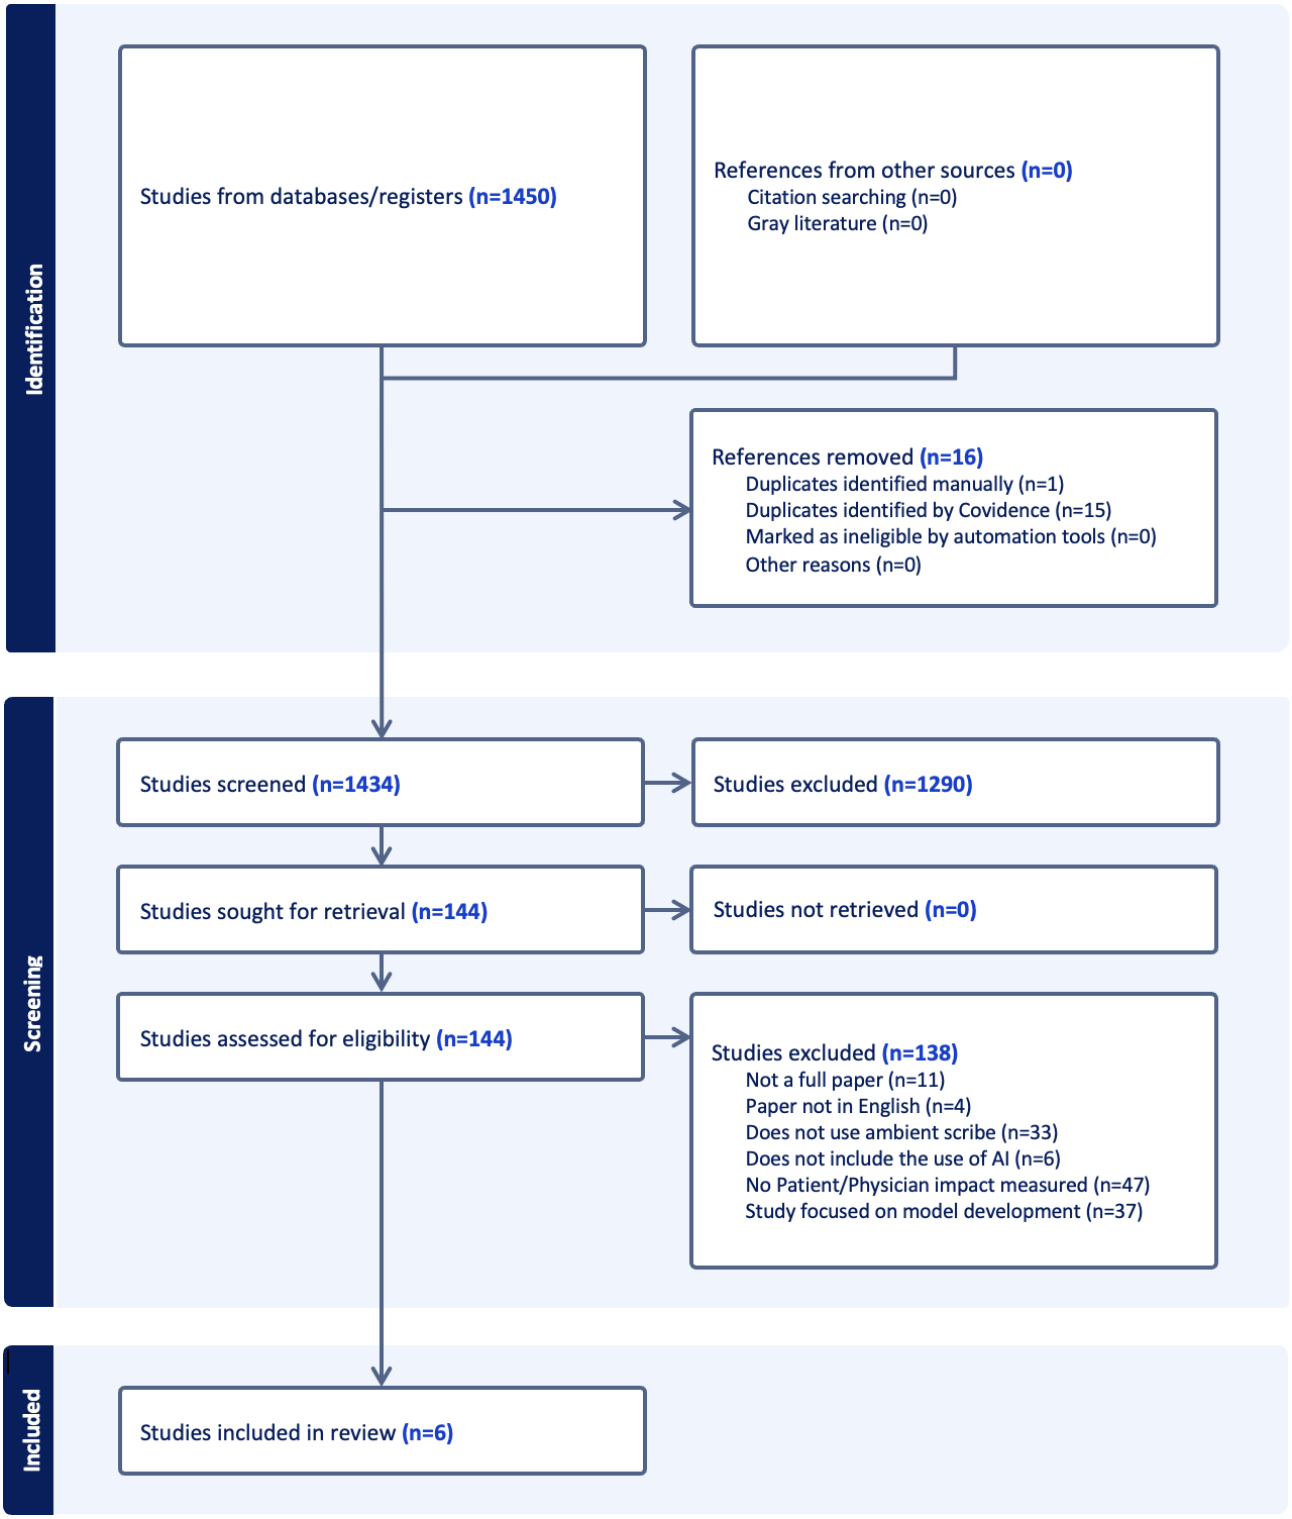
[b]DAX: Dragon Ambient Experience.

[c]EHR: electronic health record.

[d]CPT: Current Procedural Terminology.

[e]OLBI: Oldenburg Burnout Inventory.

[f]ED: emergency department.



Characteristics of the Review Process

Number of Papers Identified

Out of the 1450 studies identified through database searches, 16 references were removed for various reasons, including duplicate entries (Figure 1). This resulted in 1434 studies being screened. Of these, 1290 studies were excluded during the screening phase, primarily for not meeting the eligibility requirements. Subsequently, 144 studies were retrieved and assessed for eligibility, and 138 were excluded at this stage due to reasons such as the study not being a full paper (n=11), being published in a language other than English (n=4), not involving the use of ambient scribe technology (n=33), not including AI use (n=6), lacking measurements on patient or physician impact (n=47), or focusing solely on model development (n=37). Ultimately, only 6 studies satisfied all inclusion and exclusion criteria and were included in the review (Table 1).

XSL•FO
RenderX

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) diagram.

Studies That Fit Inclusion Criteria but Were Ultimately Excluded

Several studies initially appeared to meet the inclusion criteria; however, upon detailed review, they were excluded. For example, the paper "AutoScribe: extracting clinically pertinent information from patient-clinician dialogues" is about an ambient AI product, AutoScribe, which has been widely used in some health environments [35]. However, this paper only presents a proof of concept outside a hospital environment without real physicians. Similarly, the paper "A patient-centered digital scribe for automatic medical documentation" presents an ambient AI tool but was tested with medical students posing as patients and not in a real patient-doctor setting [36].

Interrater Reliability

In the title and abstract screening phase, 64 discrepancies were identified, with a PABAK of 0.9107 and AC1 of 0.9497, indicating high agreement among reviewers. During the full-text review phase, 13 discrepancies were identified, with PABAK

XSL•FO
RenderX

of 0.8194 and AC1 of 0.8927, also demonstrating substantial interrater reliability.

Key Findings

Study designs included an observational study, a research letter, a case report, a peer-matched cohort study, 2 survey-based studies, and 1 mixed methods longitudinal study. Sample sizes varied significantly: 3 of them below 30, 2 of them around 100, and one of them 3442 users. The settings were diverse, spanning academic and community health systems and an outpatient dermatology clinic (Table 1).

Documentation

Documentation Time

Of the 6 studies, 4 studies discussed documentation time. In a pre-post study, among the 19 clinicians who used Dragon Ambient Experience (DAX) in >60% of their visits ("high users"), there was a reported 28.8% lower documentation time per encounter, translating to an average of 1.8 minutes per visit [34]. In a group of 3442 physicians, they observed that time spent in notes decreased from a mean of 5.3 to 4.8 minutes per encounter for AI scribe users, comparable to a reduction from 5.0 to 4.7 minutes for nonusers in the same setting [11]. In addition, the use of ambient AI technology was associated with a 22% decrease in clinical documentation time (90.1-70.3 min/d) in a group of 12 dermatologists [30]. In the fourth study, a subjective ease of documentation process was measured, and 32.3% of the respondents had a positive experience compared to 48.4% postimplementation (P=.02) [31].

Documentation Length

Documentation length was reported in 2 studies. In a group of dermatologists, compared to manually written notes, the tool-assisted notes showed an increase in length, with word counts rising by 30 to 50 words per note in the machine-transcribed versions [30]. In the same study, the portion contributed by the user decreased by "nearly 50%." Similarly, in the group of 19 clinicians who used DAX in >60% of their visits (a high-use subgroup drawn from 110 surveyed primary care providers), they reported an increase in documentation length by 542 characters [34].

Documentation Accuracy

Among these 6 papers, only 1 study was an explicit attempt to assess the accuracy of notes. They modified the Physician Documentation Quality Instrument and added attributes to measure hallucinations, burden, and bias. In the transcribed notes, they reported an average accuracy score of 48 out of 50 [11]. Furthermore, they reviewed a random sample of 35 notes and noted "few" instances (not quantified) of hallucinations and gave some specific examples in the paper.

Physician Well-Being

All studies have examined the impact of AI scribes on physician burden in some form, each targeting different aspects of clinician experience.

Burnout

Two of the studies addressed burnout. Different standardized tools were implemented to study the burnout in physicians: Mini-Z was used in a group in the cancer center, and they noted nonsignificant changes in the composite scores (33.3 vs 35.9; P=.26) [33]. There was significant improvement in the perceived sufficiency of documentation time, which increased from 2.1 to 3.6 on a 5-point Likert scale (P=.005) [33]. In a primary care cohort using the Oldenburg Burnout Inventory (OLBI), no significant change was observed overall; however, a high-use subgroup (DAX in >60% of encounters) had a significantly lower OLBI disengagement subscore than lower-use clinicians (Δ=−2.1; 95% CI −3.8 to −0.4) [34].

Well-Being

In a study of a multispecialty group of 100 providers, they reported results from the Press Ganey Survey, which showed improvements in the engagement (3.62 vs 3.37), safety (4.16 vs 3.92), resilience/decompression (2.83 vs 2.81), and work-life balance (3.14 vs 2.90) [32]. In a survey-based study, respondents reported an improvement in well-being related to documentation, increasing from 38.7% to 71% (P=.01) [31].

Pajama Time

"Pajama time," wherein a physician works after scheduled hours to complete their clinical work, is a well-cited marker of physician burden [37]. This was reported in 2 studies; the mean percent time spent after hours decreased from 14.2% compared to the control group of 14.9% in 1 study [32], and the other reported a "large decrease" (without quantification) [11].

Patient Satisfaction

A Press Ganey Survey item, "Likelihood to Recommend," was used as a measure for patient satisfaction among 99 users by using this tool, but they did not find a statistical difference (86.3% in users to 86.1% in controls) [32]. In another survey-based study, respondents were less likely to report that their documentation process negatively affected the patient experience after implementation of an AI scribe than before the intervention (6.5% compared to 35.5%; P=.005) [31].

Anecdotes

Three papers reported anecdotes from the users. A mixed methods study reported comments from physicians such as "I can reconnect with the patient" and an overall positive perception and noted it was "acceptable, appropriate, and usable" [33]. The group of dermatologists felt that they would be "'very disappointed' if AI scribes were no longer available" [30], and similarly, in the study of 3442 physicians, there were quotes like "this technology was a game-changer" [11]. In the last study, the authors shared the sentiment of "we recognize that the underlying technology and concomitant workflow would continue to evolve rapidly" and "a major goal is to directly integrate artificial intelligence scribe tools into the electronic health record."

Barriers

In this commentary by Tierney et al [11], they described some barriers to implementation. One of the barriers mentioned was the reliance on English-only transcription. Although the tool had multilingual support, regulations about certified medical interpretation services in their institution limited its use. In the same paper, they also reported a lack of direct integration with

XSL•FO
RenderX

EMRs as a hindrance. In a mixed methods study, they discussed the need for editing, which ranged from minor to major, but reported that eventually, this workload improved as time progressed [33].

Productivity and Costs of Implementation

Three of the 6 studies discussed associated costs. When examining the effect of DAX in a peer-matched controlled cohort study of physicians across 12 specialties, there was no significant change in the projected work relative value units for the year (ranging from 90.6% to 91.6%) or in Current Procedural Terminology code submission rates (P=.57 and P=.51), showing no benefit in productivity for fee-for-service clinicians [32]. They corroborated these findings with an internal audit. However, in a convenience sample survey of 117 physicians who piloted an AI scribe at an academic medical center, 58.1% agreed that the tool increased their productivity [31].

The cost of implementation was reported in 1 study with initial setup costs, which ranged from US $1000 for clinician onboarding to US $1850 per month for software use, compared to US $3050 per month for human scribes [30].

Net Promoter Score

Galloway et al [31] in their survey-based study reported that 35.5% of participants responded that they would be highly likely to recommend this documentation solution to a colleague.

QUEST, SEIPS 3.0, and Extrinsic Evaluation Metrics

The QUEST human evaluation framework helps one evaluate on the basis of quality of information, bias, and any fabrication, and the SEIPS 3.0 model allows us to study the sociotechnical systems approaches, whereas the study by Abbasian et al [26] allows us to review the proposed intrinsic and extrinsic measures. Tables 2 and 3 describe the comparative analysis of the studies based on these tools [23,25,26].

XSL•FO
RenderX

Table . Evaluation of included studies using QUEST, Systems Engineering Initiative for Patient Safety (SEIPS) 3.0, and evaluation metrics proposed by Abbasian et al's [26] frameworks.

Discussion

Key Findings

Ambient scribe technology, a relatively recent advancement, is increasingly deployed to assist with clinical documentation, with the aim of reducing administrative burden on clinicians. In this rapid review, which screened 1450 studies, we identified 6 that assessed the real-world impact of AI-enabled scribes on documentation efficiency and related metrics. Findings showed consistent reductions in documentation time and modest reductions in "pajama time." Improvements in clinician engagement were noted, although burnout levels remained unchanged, and patient satisfaction metrics showed no significant difference. Other key areas, including patient perceptions, cost-effectiveness, care quality, and safety concerns such as transcription errors and fabricated content, were infrequently addressed.

Across varied study designs and clinical settings, a consistent finding was a reduction in documentation time, with time savings ranging from 5.3 to 4.8 minutes per encounter in 1 study [11], and a decrease from 90.1 to 70.3 minutes per day in another [30]. Some studies also reported a modest reduction in "pajama time," indicating a decline in after-hours documentation (from 14.9% to 14.2%) [32]. An increase in documentation length, with notes expanding by 30 to 50 words per entry or 542 characters in some cases [34], emerged as an unintended consequence. The effect of digital scribes on physician well-being was less consistent, with burnout scores (measured by Mini-Z or OLBI scales [34]) showing no improvement, although engagement scores, such as those measured by Press Ganey, were generally positive. Anecdotal feedback highlighted clinicians' satisfaction with enhanced patient connection, with some describing AI scribes as a "game changer" [11]. From a productivity standpoint, digital scribes demonstrated cost savings over human scribes [30], although productivity gains were minimal [32]. While patient satisfaction metrics did not show significant differences, 1 study reported an improvement in patients' perception of their experience [31]. A notable concern, albeit briefly discussed, was the potential for "hallucinations" [11]—where the AI may fabricate information, thereby altering the accuracy of medical documentation. Most studies fell short when compared to standardized frameworks (SEIPS 3.0, QUEST) in terms of completion.

These findings underscore the potential of AI-enabled scribes to reduce documentation burden and improve workflow efficiency, yet they raise important questions about the readiness of this technology for broad implementation. Although reduced documentation time is valuable in a health care landscape where documentation demands contribute significantly to clinician burnout, it remains uncertain whether these efficiency gains translate into more time for direct patient care or increased patient loads. This uncertainty highlights the need to evaluate how AI scribes influence patient-clinician interaction and, ultimately, patient care quality. Moreover, while shorter documentation times are beneficial, the increased note length may introduce redundancy, necessitating further study into the clinical relevance and user satisfaction with these longer, AI-generated notes. The perceived improvements in clinician engagement and work-life balance suggest that digital scribes may alleviate certain administrative burdens; however, they are unlikely to fully address the multifaceted issue of clinician burnout, which is influenced by factors such as workload, institutional culture, and support systems. Other key areas, including patient perceptions, cost-effectiveness, care quality, and safety concerns such as transcription errors and fabricated content, were infrequently addressed in the reviewed studies.

Future Directions

Despite a growing interest in the use of ambient AI in health care, there is a dearth of high-quality, real-world evidence of its utility. In spite of a large number of studies (n=144) describing the use of digital scribes, many using the same technology, we found only 6 studies that spoke about real-world effectiveness. Among those 6 studies, the sample sizes were small, most papers had fewer than 100 participants, 1 described 12 physicians, and the other cited only anecdotal evidence. Future research on digital scribes should focus on large-scale, longitudinal studies to assess their long-term effectiveness, safety, and impact on clinician and patient outcomes. Standardized evaluation frameworks, such as QUEST and SEIPS 3.0, should be consistently applied to ensure reliable assessment of documentation quality, clinician well-being, and workflow integration. Furthermore, standardized burnout scales, such as

XSL•FO
RenderX

the Maslach Burnout Inventory, could be considered while evaluating physician burnout [38]. In addition, patient-centered studies are needed to evaluate how these tools influence patient outcomes, satisfaction, and care quality. Economic analyses should be conducted to understand the cost-effectiveness of digital scribes, particularly in diverse health care settings. The financial implications of adopting digital scribes, including software costs, training, and potential productivity gains or losses, remain unclear. As health care systems increasingly invest in AI technologies, understanding their economic impact will be vital for informed decision-making. Data on the cost of implementation and current service pricing were opaque, both in the literature and in reviewing websites of individual vendors, with limited publicly facing pricing information making product comparison challenging. Finally, research should explore strategies to mitigate potential risks, such as transcription errors and "hallucinations," to enhance trust and reliability in these emerging technologies. Overall, the focus should be on addressing the clinical relevance and long-term impact of AI-assisted documentation on both clinicians and patients.

Limitations

This rapid review has several limitations. First, while the rapid review methodology enabled the timely synthesis of current evidence, it lacks the comprehensive rigor of a systematic review. This approach may have resulted in the omission of relevant studies, especially those in the gray literature or recently published works not yet indexed in major databases. Second, the small number of included studies and their heterogeneity in design, setting, and population limit the generalizability of the findings. Most studies were observational, with limited sample sizes and specific to certain clinical environments, such as dermatology and oncology. This variability restricts broader applicability across diverse health care settings. Third, the reliance on self-reported measures of documentation time and clinician well-being introduces potential biases, such as recall and social desirability bias. Objective metrics, such as direct observation or EHR log data, were rarely used, which could provide more reliable insights into the actual impact of digital scribes. Fourth, the included studies varied in their evaluation frameworks and outcome measures. There was a lack of consistent use of validated tools for assessing documentation quality, patient satisfaction, and clinician burnout, which hampers the ability to draw definitive conclusions about the effectiveness and safety of digital scribes. Finally, the rapidly evolving nature of digital scribe technology, driven by advancements in AI, means that the findings of this review may quickly become outdated. Several additional studies have been published since the completion of our review [38-45], further highlighting the importance of ongoing, rigorous evaluation of this rapidly evolving clinical technology. We recognize these contributions and note that our findings should be viewed as an early snapshot within a quickly expanding body of evidence. Continuous evaluation through robust, large-scale studies is essential to keep pace with technological developments and to provide more conclusive evidence on the long-term impact of digital scribes in clinical practice.

Conclusions

Digital scribe technologies are being well received in their initial rollout, but it is important to note that there is still a severe paucity of data in real-world settings. Before further expansion is considered, robust large-scale studies on usability, acceptance, effectiveness, patient feedback, accuracy, safety, and cost should be conducted. Although the studies we reviewed reveal a positive trend, we hope that future larger, well-designed studies will comprehensively evaluate these tools and demonstrate that they indeed live up to their claimed promise in alleviating documentation burdens and associated concerns.

Data Availability

This rapid review is based on publicly available data from previously published studies. All articles included in the review were retrieved from Ovid MEDLINE, Embase, Web of Science–Core Collection, Cochrane CENTRAL & Reviews, and PubMed Central following a systematic search strategy. The datasets analyzed during the study are accessible through the original sources cited in the manuscript. No new primary data were generated in this study. For further details, readers may refer to the references cited within the article.

Authors' Contributions

RAT and NSK conceived the study and designed the analyses. AB designed the search criteria and set up the review environment. NSK, YVR, TB, ZD, IVF, and CS participated in the review. NSK, YVR, and ZD prepared tables. NSK, YVR, MI, AL, DW, ERM, CS, and RAT drafted and edited the manuscript, and all authors contributed substantially to its revision and approved the final version submitted for publication. RAT takes responsibility for the paper as a whole.

Abstract

Background: Spinal cord injury (SCI) is complicated and varied conditions that receive a lot of attention. However, the prognosis of patients with SCI is increasingly being predicted using machine learning (ML) techniques.

Objective: This study aims to evaluate the efficacy and caliber of ML models in forecasting the consequences of SCI.

Methods: Literature searches were conducted in PubMed, Web of Science, Embase, PROSPERO, Scopus, Cochrane Library, China National Knowledge Infrastructure, China Biomedical Literature Service System, and Wanfang databases. Meta-analysis of the area under the receiver operating characteristic curve of ML models was performed to comprehensively evaluate their performance.

Results: A total of 1254 articles were retrieved, and 13 eligible studies were included. Predictive outcomes included spinal cord function prognosis, postoperative complications, independent living ability, and walking ability. For spinal cord function prognosis, the area under the curve (AUC) of the random forest algorithm was 0.832, the AUC of the logistic regression algorithm was 0.813 (95% CI 0.805-0.883), the AUC of the decision tree algorithm was 0.747 (95% CI 0.677-0.802), and the AUC of the XGBoost (extreme gradient boosting) algorithm was 0.867. For postoperative complications, the AUC of the random forest algorithm was 0.627 (95% CI 0.441-0.812), the AUC of the logistic regression algorithm was 0.747 (95% CI 0.597-0.896), and the AUC of the decision tree algorithm was 0.688. For independent living ability, the AUC of the classification and regression tree model was 0.813. For walking ability, the model based on the vector machine algorithm was the most effective, with an AUC of 0.780.

Conclusions: The ML models predict SCI outcomes with relative accuracy, particularly in spinal cord function prognosis. They are expected to become important tools for clinicians in assessing the prognosis of patients with SCI, with the XGBoost algorithm showing the best performance. Prediction models should continue to advance as large data are used and ML algorithms develop.

Introduction

Spinal cord injury (SCI) is one of the most devastating diseases. From 1990 to 2019, the global prevalence of SCI increased by 81.5% (74.2% - 87.1%) and the incidence increased by 52.7% (30.3% - 69.8%), with an annual rise [1]. The injury has severe impacts on patients, potentially leading to varying degrees of motor, sensory, and autonomic dysfunction [2]. Furthermore, SCI imposes a heavy burden on the health care system and socio-economics. Statistics show that the average lifetime rehabilitation cost for patients with SCI may exceed US $750,000, resulting in an estimated annual expenditure of US $6 billion for SCI in the United States [3]. Since there are still no effective treatments for SCI, the actual cost of treatment keeps going up every year. Due to the complexity of SCI, it has become a global public health issue, with significant public concern regarding its treatment, rehabilitation, and prognosis. The prognosis of SCI is especially important for clinical doctors. Early assessment of patients with SCI is crucial to prevent overtreatment and to provide early personalized treatment for those with favorable prognostic opportunities, thus improving patient outcomes and facilitating their return to home and society as much as possible. Prognosis assessment is a challenging undertaking for clinicians due to the complexity, diversity, and individuality of SCI.

Currently, clinical tools for SCI prognosis assessment largely rely on Abbreviated Injury Scale (AIS) scores [4] and Frankel grades [5], which involve evaluating the sensory and motor

XSL•FO
RenderX

functions of patients after injury to roughly determine the nature of SCI and the patient's prognosis. However, the assessment process requires high patient cooperation, and the results can be easily influenced by factors, such as the timing of neurological examinations (eg, spinal cord concussion period), the patient's condition (eg, intoxication, sedation, and accompanying brain injury), and the subjectivity of the evaluator [6]. Machine learning (ML) is a significant area of artificial intelligence that has seen extensive application in clinical care in recent years due to the field's rapid progress. Park et al [7] used ML combined with low-dose CT to predict prognostic biomarkers and molecular subtypes associated with invasive breast cancer. Gupta et al [8] used ML combined with magnetic resonance imaging to detect and classify brain tumors and their stages. Jumper et al [9] used ML to construct AlphaFold for predicting protein structures. ML has demonstrated high accuracy and predictive ability [10], establishing more reliable predictive models through continuous integration and analysis of large amounts of complex, nonlinear data to assist clinical decision-making.

ML has attracted considerable attention from researchers regarding SCI prognosis. Nevertheless, there is a dearth of solid data supporting the efficacy of ML models in the prognosis of SCI, and there are no systematic reviews contrasting the variations and importance of various models and prognostic markers. Therefore, this study aims to fill this gap. We conducted a systematic review and meta-analysis to evaluate the performance and quality of ML models in predicting SCI prognosis.

Methods

The systematic review was conducted following the Preferred Reporting Items for Systematic Reviews and Meta-Analyses for Diagnostic Test Accuracy (PRISMA-DTA) guidelines. The study protocol has been registered in the PROSPERO and was approved before the start of the study (ID: 42023481977).

Search Strategy

We conducted a literature search for studies on ML-based SCI prognosis prediction published up to February 20, 2024. A comprehensive search was performed across the following 9 electronic databases: PubMed, Web of Science, Embase, PROSPERO, Scopus, China National Knowledge Infrastructure, Cochrane Library, China Biomedical Literature Service System, and Wanfang Data.

Inclusion and Exclusion Criteria

Inclusion criteria were (1) study subjects are patients with SCI, regardless of the nature, degree, level, or time of SCI; (2) the research method involves ML, not limited to any specific algorithm or model; (3) the purpose of the study is to predict the prognosis of patients with SCI, including spinal cord function prognosis, complication occurrence, quality of life, etc; (4) the study provides performance metrics of the model, such as accuracy, sensitivity, specificity, area under the receiver operating characteristic curve, etc; and (5) published in Chinese or English. Exclusion criteria of the study were (1) concurrent cranial brain injury or injuries to other parts of the body outside the spinal column; (2) reviews, case reports, conference abstracts, expert opinions, or other non-original research; (3) studies that do not build ML models or do not provide relevant performance metrics for ML; and (4) articles for which full text or original data cannot be obtained, repeated publication, or data duplication.

Data Extraction and Analysis

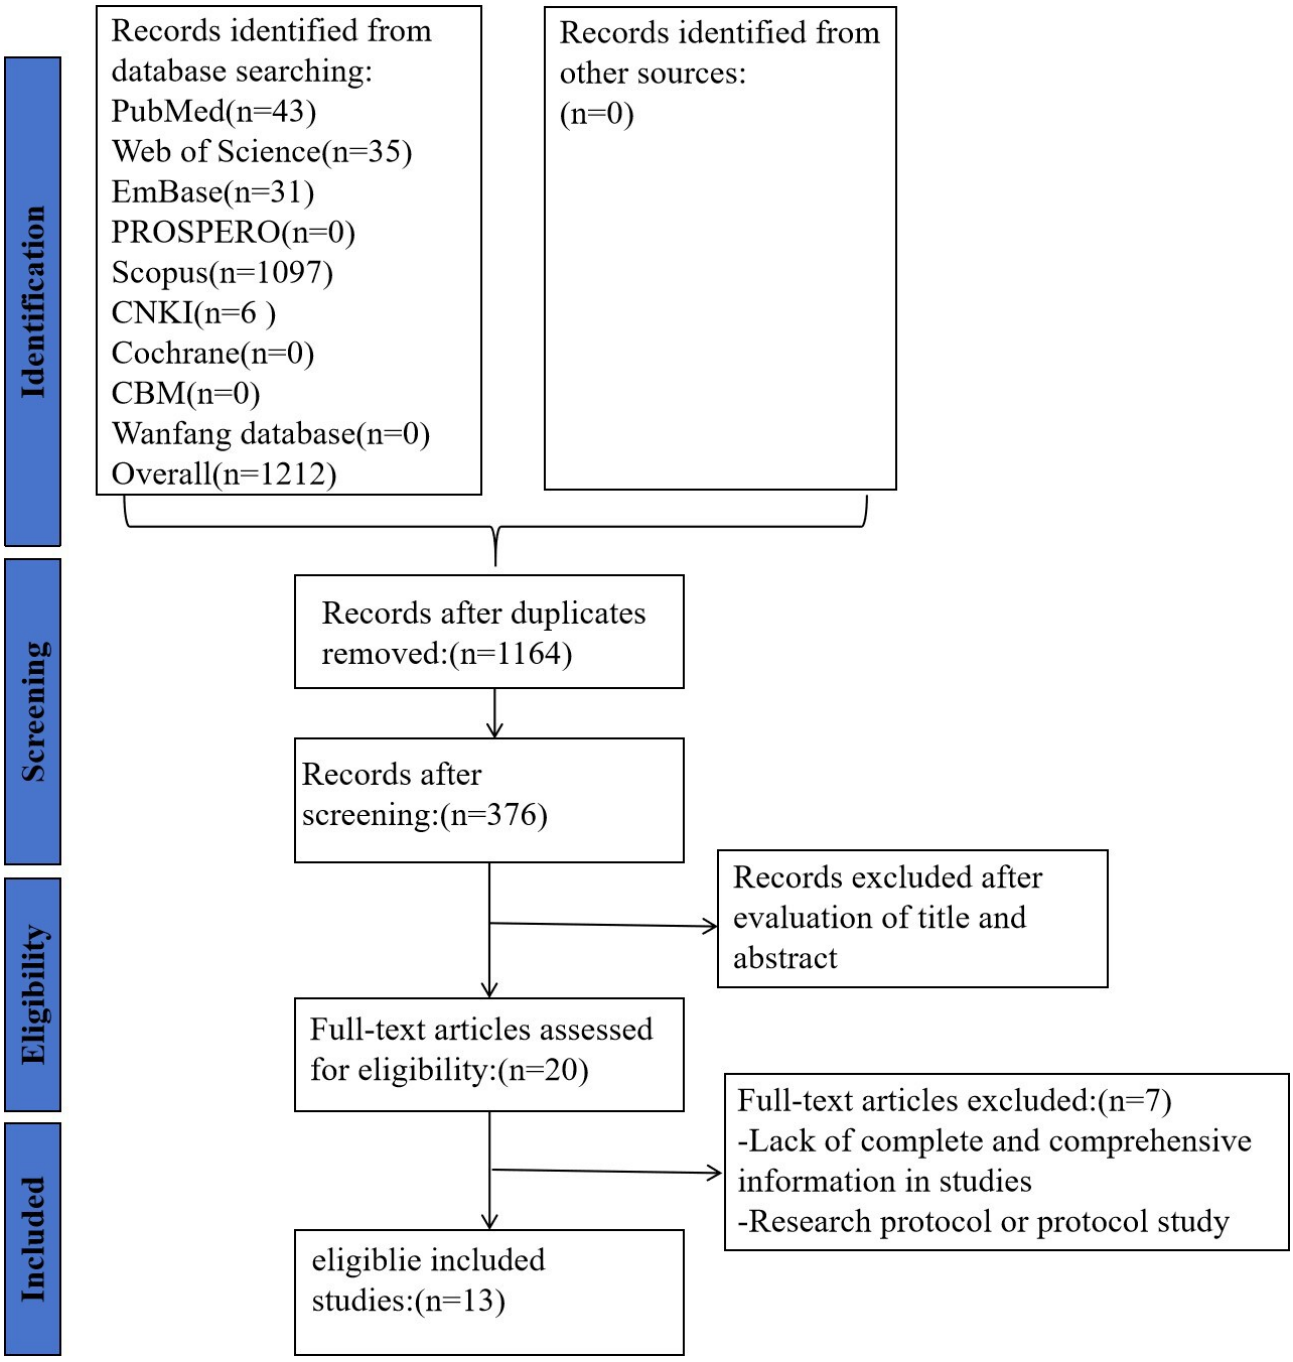
The literature retrieved from each database was imported into EndNote X9 (Clarivate) reference management software. Two researchers trained in the systematic review process performed the screening and data extraction, with cross-checking. Initially, articles were screened based on titles and abstracts, and then full texts were reviewed according to the inclusion and exclusion criteria. For information that was uncertain but crucial to the study, the original authors were contacted via email or phone. Following the Critical Appraisal and Data Extraction for Systematic Reviews of Prediction Modelling Studies (CHARMS) guidelines for extracting data from predictive model studies [11], the following data were independently extracted from each study: study design, characteristics of the SCI population, types of ML models used, study outcomes, and predictive performance of various models.

Risk of Bias Assessment

Two researchers used the risk of bias (ROB) assessment tool for predictive models (Prediction Model Risk of Bias Assessment Tool [PROBAST]) to evaluate the ROB of each model in every study and the applicability to the issues we reviewed [12]. Any disagreements were resolved by a third investigator. Each model was assessed in 4 domains (participants, predictors, outcomes, and analysis) as having "high-risk," "unclear," or "low-risk" based on a series of specific questions. The same scale was used to evaluate the applicability of each model to the issues we reviewed in 3 domains (participants, predictors, and outcomes).

Statistical Analysis

We used R software (version 4.2.3; R Core Team) to perform the meta-analysis. Based on the types and distributions of ML performance indicators, we selected appropriate effect metrics and models, such as 95% CI, and conducted a summary analysis using either a fixed-effects model or a random-effects model.



Results

Literature Selection Process

The research selection process was shown in Figure 1. A total of 1212 unique records were identified, and after excluding studies without full text, conference abstracts, registration protocols, studies that failed to provide accuracy metrics for ML, and those that did not develop new ML models, 13 studies [13-25] were finally included.

XSL•FO
RenderX

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram for the research search process.

Basic Characteristics of Included Studies

The 13 included studies were from Japan (6/13, 46.15%), the United States (2/13, 14.38%), India (1/13, 7.69%), Canada (2/13, 14.38%), South Korea (1/13, 7.69%), and China (1/13, 7.69%). The study types included retrospective cohort studies [13-15,17-24] (9/13) and prospective cohort studies (2/13) [15,25]. Most articles were published in 2023 (7/13) [13,15,16,18,21-23], followed by 2022 (2/13) [19,24], 2024 (1/13) [20], 2020 (1/13) [17], 2019 (1/13) [25], and 2016 (1/13) [14]. A total of 51 ML models were, with 31 models for predicting spinal cord function prognosis, 15 models for predicting postoperative complications, 1 model for predicting independent living ability, and 4 models for assessing walking ability. The study characteristics and performance metrics are presented in Table 1.

Evaluation Performance of Different Prediction Models

The area under the curve (AUC) has long been used to evaluate model performance and is therefore a primary performance indicator. The AUC range for ML prediction models is 0.532 - 0.904 (Figure 2). Additionally, other performance metrics of ML prediction models, such as specificity, sensitivity, accuracy, and F_1-score, were also extracted.

Results of Bias Risk Assessment

The ROB in ML prediction based on medical information was assessed using PROBAST (Table 2 and Figure 3). According to the PROBAST evaluation, only 2 studies [16,25] were designed as prospective cohort studies and were thus rated as low-ROB. In contrast, the majority of studies [13-15,17-24] were retrospective cohort studies and were consequently rated as high-risk. In the domains of predictors and outcomes, item 3.2 refers to whether the outcome was prespecified or defined using standard criteria. One study [15] lacked sufficient information on this item and was therefore rated as having an "unclear" ROB. Additionally, 2 studies [16,20] failed to appropriately evaluate model performance; specifically, item 4.7, which assesses whether performance measures were adequately reported and validated, was rated as "high-risk" for these studies. Given that most of the included studies were retrospective in nature, with only a few being prospective, the overall ROB in outcome assessment was considered to be high or unclear across the reviewed literature.

Meta-Analysis Results

We conducted separate meta-analyses on different prognostic indicators. Overall, ML applications in SCI prognosis showed a high AUC. Considering that many studies lacked assessments of accuracy, sensitivity, and specificity, and that there were certain differences between algorithms and models, this reflects the complexity and significance of SCI disease prognosis prediction. Therefore, we only focused on and explored the AUC. The specific analysis results are listed below.

Spinal Cord Functional Prognosis

We included a total of 8 studies [13-20] with 7326 patients, using 17 ML algorithms to predict functional recovery indicators, such as American Spinal Injury Association grading, motor scores, and sensory scores. Three studies [13,19,20] used the random forest (RF) algorithm, 4 studies [13-15,17] used the logistic regression (LR) algorithm, and 3 studies [13,15,17] used the decision tree (DT) algorithm. The sample size for studies using the RF algorithm was 3547, for the LR algorithm was 6594, and for the DT algorithm was 3452. The AUC for the RF algorithm was 0.832, for the LR algorithm was 0.813 (95% CI 0.805-0.883), for the DT algorithm was 0.747 (95% CI 0.677-0.802), and for the extreme gradient boosting (XGBoost) algorithm was 0.867 (Figure 4).

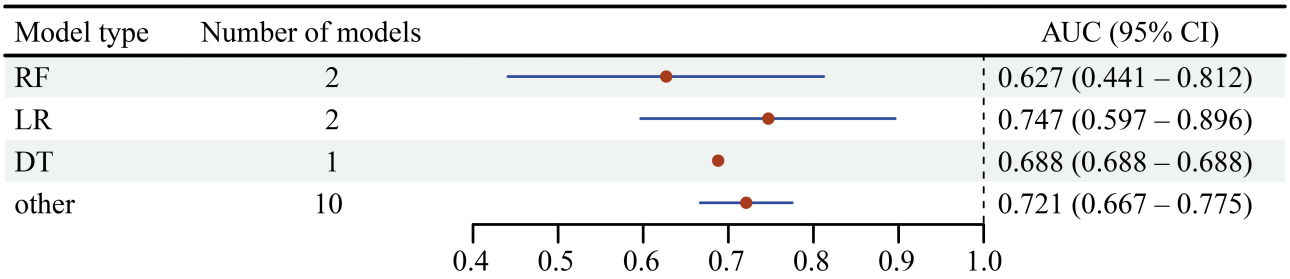

Figure 4. Forest plot of models related to spinal cord functional prognosis. DT: decision tree; LR: logistic regression; RF: random forest; XGBoost: extreme gradient boosting.

Postoperative Complications

We included 3 studies with a total of 6202 patients, using 12 ML algorithms. Two studies used RF and LR algorithms, with the RF algorithm having a sample size of 1493 and the LR algorithm having a sample size of 5332. The AUC for the RF algorithm was 0.627 (95% CI 0.441-0.812), for the LR algorithm was 0.747 (95% CI 0.597-0.896), and for the DT algorithm was 0.688 (Figure 5).

Figure 5. Forest plot of models related to postoperative complications. RF: random forest; LR: logistic regression; DT: decision tree.

Independent Living Ability

A study [24] was conducted to assess the ability of patients with SCI to live independently. A total of 1404 patients were included, and the classification and regression tree (CART) algorithm was used. The model's predictive variables included age, sex, Functional Independence Measure score, American Spinal Injury Association score, and the presence or absence of complications, such as diabetes and hypertension. The AUC of the CART model was 0.813.

Walking Ability

Currently, only 1 study [25] has been collected to evaluate the independent walking ability of patients with SCI at discharge or at a 1-year follow-up. This study included 862 patients and used LR, vector machine (VM), and Hicks algorithms for prediction, with AUCs of 0.720, 0.780, and 0.760, respectively. The model based on the VM algorithm showed the highest effectiveness.

Discussion

Principal Findings

SCI remains one of the leading causes of death and disability worldwide [26]. The heterogeneity factors, such as variable disease course, high inconsistency, and complex pathophysiological processes are major reasons for poor prognosis [27]. Clinically, a key concern for patients and their families is the prognosis, which is often assessed using imaging techniques, such as head computed tomography and magnetic resonance imaging, requiring considerable experience from clinicians. If clinicians had an objective assessment tool that could quickly and accurately predict prognosis based on the patient's condition, it would provide greater confidence in

XSL•FO
RenderX

prognosis judgments [28]. Therefore, the idea of using ML to facilitate objective and individualized prognosis predictions for patients with SCI has emerged. In recent years, the application of ML in SCI prognosis prediction has made continuous breakthroughs, and the number and quality of related articles have been increasing over time. To our knowledge, this is the first meta-analysis evaluating the performance of ML models in predicting SCI prognosis. We conducted a comprehensive literature search and systematically evaluated the performance of ML models in SCI prognosis. Ultimately, ML algorithms were used to predict SCI prognosis in 13 included studies [13-25]. Among various model algorithms, although LR is a traditional algorithm, it is still commonly used in SCI prognosis prediction [13-15,17,22,23,25]. Other major algorithms include RF, DT, XGBoost, ANN, etc. A total of 18 algorithms were used to predict functional recovery after SCI, 12 algorithms for predicting complications after SCI, 1 algorithm for predicting independent living ability after SCI, and 3 algorithms for predicting walking ability after SCI. These models demonstrated varying levels of AUC. AUC indicates the algorithm's ability to balance sensitivity and specificity to minimize false negatives and false positives [29]. Therefore, its evaluation is particularly important in SCI prognosis assessment models. For predicting functional recovery, the ANN algorithm showed the highest AUC of 0.902. For predicting complications, the support vector machine-linear algorithm showed the highest AUC of 0.904. For predicting post-injury walking ability, both LR and VM models demonstrated the highest AUC of 0.870. Our study also found that over 90% of the included studies were published in the past 3 years, indicating growing interest in using ML-related predictive models to guide clinical decision-making.

It is worth noting that although most of the data in this study come from hospitals, the participant populations are from different countries and ethnic groups, with a focus on Asian and European populations, and there is little research on African populations. Published studies have not yet used predictive models to examine different regional and ethnic groups. Therefore, further model construction and validation using data from different populations are needed to increase confidence. Research indicates that ML models are significantly superior to traditional statistical models in handling large sample data [30,31]. However, most of the 13 studies [13-25] included had sample sizes of fewer than 1000 cases, which suggests that future research should aim to collect sufficiently large and comprehensive sample sizes to reduce bias. Most studies opted to randomly split single-center data into training and testing sets or used different time periods for internal validation. However, the lack of external validation poses significant challenges to the model's applicability, potentially leading to overestimation of the model's effectiveness. Thus, SCI-related prognostic models require rigorous external validation to enhance their credibility.

Our study also indicates that most of the included studies use functional recovery as the outcome measure for SCI prognosis [13-20], and over time, research using ML has progressively reached higher quality standards. This has aroused considerable curiosity among SCI researchers and reflects the growing progress and recognition of ML applications in the field of SCI.

In clinical practice, the AIS score remains of significant importance for evaluating the prognosis of patients with SCI. The AIS score uses clear criteria to assess patients' neurological function, offering objectivity and reproducibility and is applicable to various types of SCI, including traumatic and nontraumatic [32]. Despite its practicality, the AIS score has limitations. First, it mainly focuses on physiological aspects, such as sensory and motor functions, while neglecting the impact of psychological and social factors, which may affect clinicians' prognosis assessments. Second, it may lack sensitivity and might not assess mild SCI, thereby affecting long-term prognosis. Additionally, the AIS score is not suitable for SCI in children younger than 4 years [33].

In contrast, ML continues to evolve, and the improvement of various SCI databases highlights the increasing potential of ML in predicting SCI prognosis. ML can handle large amounts of complex data and extract nonlinear relationships, offering promising solutions to unknown challenges [34]. Our study found that 5 studies [13-15,17,24] used public databases to build predictive models and achieved good results in model performance. Additionally, many studies not only used traditional models, such as RF and DT, but also used recently popular models such as XGBoost. For instance, the XGBoost model constructed by Inoue et al [17] achieved an AUC of 0.867, outperforming models, such as LR and RF, and holds promise for future clinical guidance. Traditional clinical prognostic tools often face subjective biases of researchers and limited variables, while ML incorporates as many variables as possible, including demographic data, imaging, and laboratory results. This broad coverage allows for accurate and detailed individualized predictions based on each patient's specific situation, greatly reducing ambiguity and generalization. Furthermore, ML models continuously learn and optimize to improve prediction accuracy and explore potential patterns in data, potentially matching or even exceeding human brain capabilities [35].

Limitations

This systematic review and meta-analysis have several limitations. First, the data quality from retrospective studies is lower compared to prospective studies. Among the 13 studies [13-25] included, only 2 were prospective, while the rest were retrospective, resulting in overall lower quality of the included literature. According to PROBAST guidelines, future research should aim to use prospective studies to obtain data, ensuring reliable model performance. Second, we focused solely on AUC to evaluate the performance of predictive models, without a comprehensive assessment using sensitivity, specificity, and F_1-score metrics. This is due to incomplete data in the selected literature, so the meta-analysis results may be somewhat one-sided. Moreover, because most studies did not consistently report key metrics, such as sensitivity and specificity, we did not perform a formal heterogeneity analysis. This limitation may affect the generalizability of the pooled AUC results across different study settings. Our study also did not focus much on the specific segments of the spinal cord damaged in patients with SCI or perform subgroup analysis based on different injury segments. Studies have shown that the mortality rate for patients with cervical SCI in the acute phase ranges from 11.2% to 25%

XSL•FO
RenderX

[36], with the risk of death being about 7 times higher in upper cervical SCI compared to lower cervical SCI [37]. This indicates that prognosis varies with different spinal cord segments, suggesting a need for future research to focus on this aspect.

We must also recognize that ML research is inherently susceptible to multiple sources of bias that extend beyond the scope of conventional study design. The included studies used a wide range of algorithms, from traditional LR models to more complex methods, such as XGBoost and neural networks, resulting in significant heterogeneity in both model development and performance evaluation. Moreover, bias may arise from imbalanced data distributions, insufficient feature representation, and lack of transparency in dataset construction. These issues are particularly concerning given that most studies did not undergo external validation, which further increases the risk of model overfitting and undermines the reliability of their clinical applicability. Additionally, model interpretability is an important factor to consider. To date, no ML model has been truly used for predicting SCI patient prognosis in clinical practice. Higher interpretability of a model allows clinicians to better understand its predictive value and make clinical decisions that benefit patients [38]. Lundberg et al [39] used the Shapley additive explanations algorithm to interpret any ML model's outputs and quantify each variable's contribution using Shapley additive explanations values, thereby promoting clinical application. Future research is expected to continue addressing this challenging issue of model interpretability [40].

Conclusions

Increasing research efforts are devoted to developing SCI prognosis prediction models, which can provide personalized prognosis assessments for patients and ultimately alleviate their burden. However, the application of ML in this field is still in its early stages. Existing studies lack some data and details on predictive model reporting, and the majority are retrospective, leading to limited practical application of these models. Although clinical translation of ML is still a long way off, this study demonstrates that ML under artificial intelligence is poised to bring about a significant revolution in the field of SCI.

Acknowledgments

The authors would like to thank all the researchers and participants involved for their contributions.

Funding

This work was partially funded by the Medical Key Specialty Project of PLA Joint Logistics Team (LQZD-SW), Fujian Provincial Science and Technology Innovation Joint Fund Project (2024Y9644), and the Science and Technology Innovation Platform Project of Fujian Province (2022Y2017).

Authors' Contributions

LZ, QH, HZ, and LW: concept and design.
LZ, QH, LX, YC, and JW: data collection, analysis, or interpretation.
LZ, QH, HZ, and LW: manuscript drafting.
LW: critical revision of the manuscript and technical or material support.
LZ: other protocol review.

Conflicts of Interest

None declared.

Abstract

Background: Artificial intelligence (AI) has the potential to transform global health care, with extensive application in Brazil, particularly for diagnosis and screening.

Objective: This study aimed to conduct a systematic review to understand AI applications in Brazilian health care, especially focusing on the resource-constrained environments.

Methods: A systematic review was performed. The search strategy included the following databases: PubMed, Cochrane Library, Embase, Web of Science, LILACS, and SciELO. The search covered papers from 1993 to November 2023, with an initial overview of 714 papers found, of which 25 papers were selected for the final sample. Meta-analysis data were evaluated based on three main metrics: area under the receiver operating characteristic curve, sensitivity, and specificity. A random effects model was applied for each metric to address study variability.

Results: Key specialties for AI tools include ophthalmology and infectious disease, with a significant concentration of studies conducted in São Paulo state (13/25, 52%). All papers included testing to evaluate and validate the tools; however, only two conducted secondary testing with a different population. In terms of risk of bias, 10 of 25 (40%) papers had medium risk, 8 of 25 (32%) had low risk, and 7 of 25 (28%) had high risk. Most studies were public initiatives, totaling 17 of 25 (68%), while 5 of 25 (20%) were private. In limited-income countries like Brazil, minimum technological requirements for implementing AI in health care must be carefully considered due to financial limitations and often insufficient technological infrastructure. Of the papers reviewed, 19 of 25 (76%) used computers, and 18 of 25 (72%) required the Windows operating system. The most used AI algorithm was machine learning (11/25, 44%). The combined sensitivity was 0.8113, the combined specificity was 0.7417, and the combined area under the receiver operating characteristic curve was 0.8308, all with $P<.001$.

Conclusions: There is a relative balance in the use of both diagnostic and screening tools, with widespread application across Brazil in varied contexts. The need for secondary testing highlights opportunities for future research.

KEYWORDS

artificial intelligence; Brazil; diagnosis; screening; PRISMA

Introduction

Artificial intelligence (AI) can be defined in various ways, often simplified as an "imitation" of the human mind. However, these programs go beyond this definition, as they operate with different datasets and levels of autonomy, refined according to the goals set by developers. Given these technologies' vast applications, a significant transformation is occurring in the global health landscape. AI demonstrates utility in several areas, with some of its main competencies being differential diagnoses, lesion identification in imaging exams, and mortality prediction in hospitals [1-3].

In this context, it is crucial to recognize that the AI model developed is a significant element in the process, but the application environment is equally important. Using these tools in different environments depends on the resources available in each. Thus, it is necessary to consider how inequality in device access and the particularities of each location may interfere with the results, accuracy, and safety of the technologies used [4].

Various models have been applied in Brazil, emphasizing diagnostic and screening areas. Screening is used to identify individuals at risk of a given condition, prioritizing sensitivity maximization. In contrast, diagnosis aims to confirm or rule out the presence of a condition in individuals already identified as at risk. In these cases, accuracy becomes crucial, requiring a more careful balance between sensitivity and specificity. Sensitivity refers to the percentage of positive results among

XSL•FO
RenderX

individuals with a given disease or clinical condition. At the same time, specificity denotes the test's ability to yield negative results in individuals who do not have the disease under investigation. These tools are developed by the public and private sectors, despite 70% of the Brazilian population relying on the Unified Health System (UHS), the public health care system used in the country. It spans the entire territory and all levels of health care, ensuring comprehensive, universal, and free access for the whole population. Understanding how these technologies are used in sectors with more abundant resources can serve as a foundation for future implementations in UHS [5].

Therefore, this study aims to conduct a systematic literature review on the application of AI in health in Brazil, focusing on addressing the following questions: Is the tool used in the research for diagnosis or screening? What is the context and location of the tool's application? Is the initiative public or private? Was the research funded? If so, by whom? What is the area or specialty of the tool? What type of AI app is used? What are the minimum requirements for using the tool? Was the tool tested? Was the tool tested on a population different from the one used to create the device? Was there evidence of health improvement?

These questions are fundamental for evaluating the effectiveness, accessibility, and safety of AI technologies in the Brazilian context, as detailed in Textbox 1. Thus, the review aims to understand the use of AI in the health area in Brazil, with emphasis on scenarios of limited resources, enabling the understanding of how these technologies are applied in the Brazilian reality, in order to visualize possible improvements to public health for a large part of this population.

Textbox 1. Research questions and motivation.

RQ1: Is the tool used for diagnosis or screening?

- This question helps clarify the primary objective of each intervention. This distinction is essential, as screening focuses on maximizing sensitivity to ensure few actual cases are missed, while diagnosis aims to confirm or rule out a condition in individuals already identified as at risk, requiring a balance between sensitivity and specificity.

RQ2: What is the context and location of the tool's application?

- The context of application is crucial to understanding the tool's target audience, as well as where and how it would be used. Additionally, the location indicates where these tools are more widely adopted and developed, highlighting the main centers advancing these technologies.

RQ3: Is the initiative public or private?

- This question helps indicate whether the tool's purpose leans more toward improving the public health sector in the case of public initiatives or if private initiatives might focus more on cutting-edge technological innovation, operational efficiency, and potentially commercializing tools.

RQ4: Was the research funded? If so, by whom?

- This question may influence the development, testing, implementation, and materials used for the tool.

RQ5: What is the field or specialty of the tool?

- The tool's field is essential to understand the specific needs of that specialty, ranging from data requirements to expected outcomes.

RQ6: What type of artificial intelligence (AI) application is it?

- This question clarifies the technological approach adopted and its implications for the tool's performance. Different types of AI have distinct capabilities and limitations that can directly impact the tool's accuracy, adaptability, and complexity. This choice affects model robustness, data types analyzed, and consequently, tool effectiveness.

RQ7: What are the minimum requirements for using the tool?

- This question is essential for assessing implementation feasibility in limited-income contexts like Brazil, as financial and technological constraints are crucial to ensuring effective and accessible tool use.

RQ8: Was the tool tested?

- This question is critical, as tool testing is necessary to validate its efficacy, accuracy, and safety before clinical implementation.

RQ9: Was the tool tested on a population different from the one used to create the device?

- This question assesses the tool's applicability across different contexts and populations, helping avoid sample bias and ensure functionality across diverse settings.

Methods

Search Strategy and Selection Process

The search strategy was conducted in the following databases: PubMed, Cochrane Library, Embase, Web of Science, LILACS, and SciELO. Multimedia Appendix 1 presents the search strategies adapted for each database. The Rayyan app was used for duplicate study removal, and 5 different authors independently used it with the blind mode enabled to assess study selection [6]. The first phase involved analyzing the title, abstract, and keywords; at the end of this phase, if there was a disagreement, the authors met to discuss the application of inclusion and exclusion criteria for each study. The second phase involved a full-text reading. The searches identified papers from 1993 to November 2023, leaving 25 papers for the final sample. This systematic review and meta-analysis followed the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines.

Inclusion and Exclusion Criteria

The inclusion criteria for this study consisted of papers in which AI is applied within the health sectors in Brazil as an aid for diagnosis and screening of pathologies, restricted to publications in English and Portuguese. Conversely, exclusion criteria were established to eliminate duplicate papers, literature reviews, animal studies, and studies where AI does not apply in the Brazilian context. Papers exclusively focused on robotic surgeries, AI using only within scientific methodology, hospital resource management, test reading, risk stratification and prognosis, risk factor assessment, epidemiological surveillance strategies, or any other topic unrelated to diagnosis and screening of pathologies were excluded.

Data Extraction

Data extracted from each study included: authors and publication date, location and application context, purpose (diagnosis or screening), type of initiative (public or private), study funding, benefiting specialty, type of AI application, whether tested in the population, tool functionality, and validation method. Additionally, values for accuracy, recall, precision, sensitivity, specificity, positive predictive value, and negative predictive value were obtained. Finally, the risk of bias was analyzed using the PROBAST (Prediction model Risk of Bias Assessment Tool; Table 1) to complete a risk assessment table based on the study data [7].

XSL•FO

Table . Risk of bias questions.

	Question	Possible answers
QV1	Were appropriate data sources used, for example, cohort, randomized controlled trial, or nested case-control study data?	Y/N ?
QV2	Were all the inclusions and exclusions of participants appropriate?	Y/N ?
QV3	Were predictors defined and assessed in a similar way for all participants?	Y/N ?
QV4	Were predictor assessments made without knowledge of outcome data?	Y/N ?
QV5	Were all predictors available at the time the model was intended to be used?	Y/N ?
QV6	Was the outcome determined appropriately?	Y N ?
QV7	Was a prespecified or standard outcome definition used?	Y/N ?
QV8	Were predictors excluded from the outcome definition?	Y/N ?
QV9	Was the outcome defined and determined in a similar way for all participants?	Y/N ?
QV10	Was the outcome determined without knowledge of predictor information?	Y/N ?
QV11	Was the time interval between predictor assessment and outcome determination?	Y/N ?
QV12	Were there a reasonable number of participants with the outcome?	Y/N ?
QV13	Were continuous and categorical predictors handled appropriately?	Y/N ?
QV14	Were all enrolled participants included in the analysis?	Y/N ?
QV15	Were participants with missing data handled appropriately?	Y/N ?
QV16	Was the selection of predictors based on univariable analysis avoided?	Y/N ?
QV17	Were complexities in the data (eg, censoring, competing risks, and sampling of control participants) accounted for appropriately?	Y/N ?
QV18	Were relevant model performance measures evaluated appropriately?	Y/N ?
QV19	Were model overfitting and optimism in model performance accounted for?	Y/N ?

Statistical Analysis

Quantitative methods were adopted to perform the statistical analysis of the studies included in this systematic review, aiming to synthesize and interpret the collected data. First, a descriptive analysis was conducted on study characteristics, such as type of initiative (public or private), application areas, and type of AI used (diagnosis or screening). These data were categorized and presented in absolute and relative frequencies.

Additionally, a quantitative analysis was conducted to assess the distribution of funding, classifying it as public, private, or mixed. The proportion of tested versus untested tools was evaluated to understand the robustness of the evidence presented by the studies. For issues related to application context and location, frequencies and percentages were calculated for different regions in Brazil. Finally, the analysis explored whether there was evidence of health improvement in studies that tested their tools.

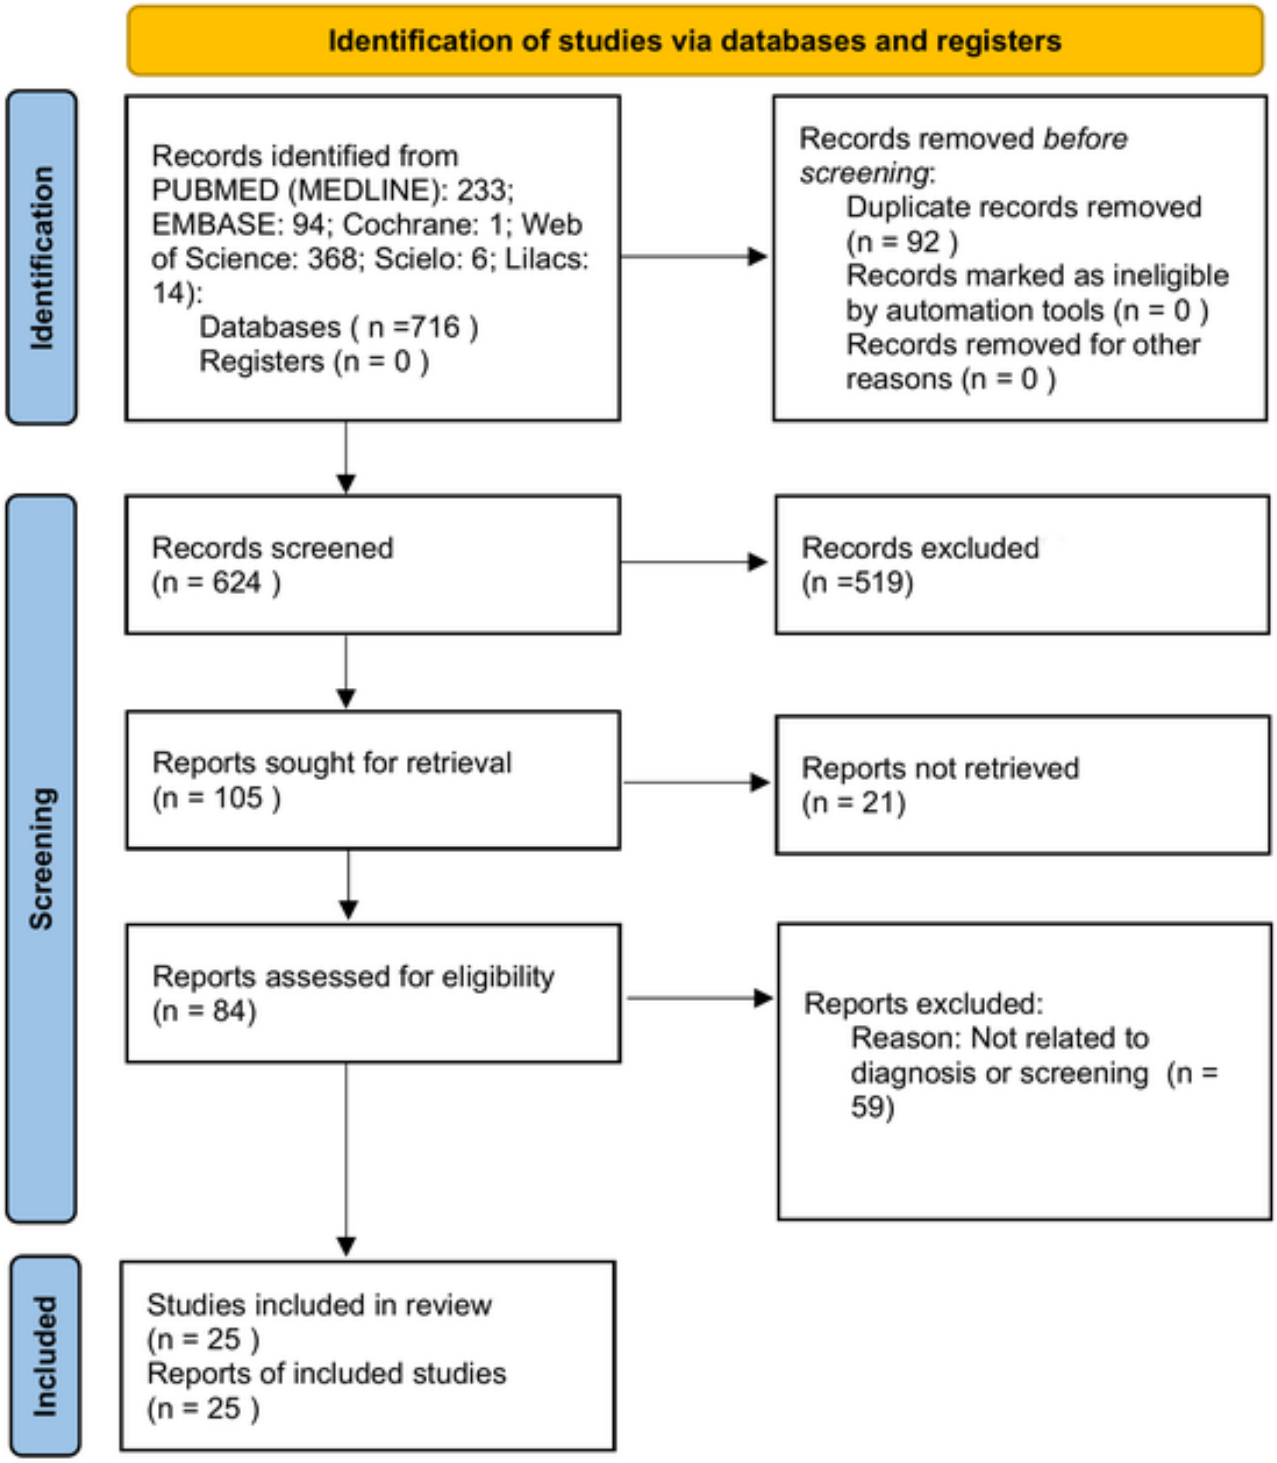
Meta-analysis data were evaluated based on three main metrics: area under the receiver operating characteristic curve (AUC), sensitivity, and specificity. A random effects model was used for each metric to address the variability among the included studies. The exclusion of missing data was essential to ensure the quality and integrity of the results obtained. The AUC is used to measure a diagnostic test's performance. The AUC

XSL•FO
RenderX

ranges from 0.5 to 1.0: an area of 0.5 suggests that the diagnostic test has no discriminatory ability, while an area of 1.0 is considered the ideal test with perfect diagnostic accuracy [8].

The primary analysis used a random-effects model to encompass heterogeneity across studies. Cochran Q statistic was used to evaluate overall heterogeneity, and the I^2 statistic was calculated to quantify the level of heterogeneity.

All statistical analyses were performed using R software(version 4.4.2, R Foundation for Statistical Computing) and RStudio (version 2024.09.1+394, RStudio, PBC), and the statistical significance level was set at α=0.05.



Results

Overview

The study was funded by the National Council for Scientific and Technological Development (CNPq), and the data analysis has already been completed, with a meta-analysis using a random effects model. After searching the databases, 714 papers were found, of which 233 were from the PubMed database, 94 from Embase, 1 from Cochrane, 368 from Web of Science, 6 from SciELO, and 14 from Lilacs. After removing duplicates, 624 studies remained. In the first selection phase, applying the inclusion and exclusion criteria by analyzing the title, abstract, and keywords, 105 papers were selected for full-text reading. However, after removing inaccessible, incomplete papers or those not meeting the previously defined exclusion criteria, 84 papers remained. Subsequently, papers that did not involve the diagnostic and screening process were removed, resulting in a final sample of 25 studies for this review, as illustrated in Figure 1. The papers are identified in Table 2.

Risk of Bias

Overview

The assessment of risk of bias in the papers revealed the following classifications (Multimedia Appendix 2 [8-32]): 7 of 25 (28%) papers presented medium risk, 5 of 25 (20%) presented low risk, and 13 of 25 (52%) presented high risk [8-32]. Among the papers with high risk, 6 of 25 (46%) showed high risk in data analysis [24-26,29,31,32]. Paper 25 stood out with a high risk of bias in analyses, predictors, and outcomes [25]. To perform the PROBAST classification, the studies were categorized by risk domains: participants, predictors, outcome, and analysis. In each category, if the study presented an equivalent number of “N” or “?” and “Y,” it was classified as having a medium risk of bias. If “N” or “?” exceeded “Y,” the study was classified as high risk, whereas if “N” or “?” were fewer than “Y,” it was classified as low risk. Based on these four classifications, the prevailing category determined the overall risk classification of the study.

Participants

The lowest risk of bias among papers was in participant selection. For participant selection, 14 of 25 (56%) presented low risk (9, 11, 12, 14, 15, 17, 18, 20, 22, 26, 27, 28, 31, and 32), 8 of 25 (32%) presented medium risk (8, 13, 16, 19, 24, 25, 29, and 30), and 3 of 25 (12%) presented high risk (10, 21, and 23) [8-32].

Outcomes

For outcomes, 13 of 25 (52%) presented low risk (9, 10, 12, 13, 15, 16, 18, 19, 21, 22, 23, 29, and 30), 10 of 25 (40%) presented medium risk (8, 11, 14, 17, 20, 26, 27, 28, 31, and 32), and 3 of 25 (12%) presented high risk (8, 24, and 25) [8-32].

Analysis

The criterion with the highest risk of bias was data analysis, with 13 of 25 (52%) papers showing high risk (8, 14, 20, 21, 22, 23, 24, 25, 26, 27, 28, 29, and 30), 8 of 25 (32%) presenting medium risk (8, 9, 10, 11, 12, and 14), and 5 of 25 (20%) presenting low risk (15, 16, 17, 18, and 19) [8-32].

Predictors

For predictors, 7 of 25 (28%) presented low risk (9, 16, 18, 21, 23, 24, 27), 12 of 25 (48%) presented medium risk (8, 11, 12, 13, 15, 17, 19, 20, 22, 28, 30), and 8 of 25 (32%) presented high risk (10, 14, 25, 26, 29, 31, 32) [8-32].

Study Objective

The studies’ objectives were classified as diagnosis or screening. Most (13/25, 52%) were focused on diagnosis, while 12 of 25 (48%) were focused on screening [8-32].

Specialty

The medical areas covered by the tools are varied, with ophthalmology predominating, being the subject of 5 of 25 (20%) papers, with an emphasis on diabetic retinopathy diagnosis [8,13,14,30,31]. Next is infectology, covered in 4 of 25 (16%) papers, focusing on COVID-19 diagnosis [9,23,24,27]. Additionally, specialties such as cardiology, internal medicine, dermatology, pulmonology, and mastology are each the subject of 2 of 25 (8%) papers, totaling 10 of 25 (40%) of the papers [11,12,14,17-21,29,32]. Other specialties, such as allergy and immunology, endocrinology and metabolism, gastroenterology, neonatology, oncology, and psychiatry, are each covered in 1 of 25 (4%) papers, totaling 6 (24%) of the papers [10,15,22,25,26,28].

Public or Private Initiative and Funding

The selected papers were characterized according to the nature of their initiative, being public or private. Most were part of a public initiative, totaling 17 of 25 (68%), while 7 of 25 (28%) were private initiatives, and 1 of 25 (4%) did not provide this information. Regarding funding, 7 of 25 (28%) papers did not provide information on this issue. In total, 2 of 25 (8%) papers were funded solely by the São Paulo Research Foundation (FAPESP), 2 of 25 (8%) by FAPESP in association with the National Council for Scientific and Technological Development (CNPQ), 1 of 25 (4%) by FAPESP in conjunction with various laboratories, 1 of 25 (4%) by FAPESP with the Technological Development Support Laboratory, 3 of 25 (12%) by the Minas Gerais State Research Support Foundation and CNPQ, and 1 of 25 (4%) by both and CAPES. Additionally, 1 of 25 (4%) was

XSL•FO
RenderX

funded by CNPQ and the National Institutes of Health, 1 of 25 (4%) by MIT libraries, 1 of 25 (4%) by the Pontifical Catholic University of Paraná, 1 of 25 (4%) by Funding Authority for Studies and Projects and CAPES, and 2 of 25 (8%) by FAPERJ, with 1 in conjunction with National Institutes of Science and Technology and CNPQ and the other with CAPES. Finally, 1 of 25 (4%) was funded by Program to Support the Institutional Development of the Brazilian Unified Health System, and 1 of 25 (4%) had no financial support. This information demonstrates a predominance of funding, respectively, from CNPQ and FAPESP [8-32].

Application Context or Location

Almost half of the papers were conducted in the state of São Paulo, totaling 12 of 25 (48%), of which 3 of 25 (25%) were conducted in collaboration with the states of Sergipe, Minas Gerais, and Amazonas [8,10,11,15,16,19-22,24,28,31]. Among these, 4 of 25 (33%) were associated with the Hospital das Clínicas of the University of São Paulo [10,21,24,28]. One of the studies also included the Hospital Estadual Sumaré, the Municipal Hospital of Paulínia, and the Delphina Rinaldi Abdel Aziz Hospital in Manaus [24]. The hospitals associated with Sergipe were unspecified, and the study in Minas Gerais was conducted at the Tropical Medicine Research Center in both states [11,16].

The other 4 of 25 (33%) studies conducted in the state of São Paulo took place at the São Camilo University Center, the Albert Einstein Israeli Hospital, the UNIFESP outpatient clinic, and an unspecified private health care institution [15,19,20,31].

In total, 2 of 25 (8%) tools from the papers were applied to populations during campaigns about diabetes mellitus, one in Santa Catarina and the other in Bahia [13,30]. A total of 3 of 25 (12%) studies were conducted in Rio de Janeiro, one at the Federal University of Rio de Janeiro (UFRJ) University Hospital, one at the Augusto Amaral Peixoto Polyclinic, and the other at Santa Casa de São Sebastião [12,25,32]. A total of 3 of 25 (12%) studies were conducted at the University Hospitals of UFRN (Rio Grande do Norte), UFPR (Paraná), and UFPE (Pernambuco) [9,14,26]. In total, 1 of 25 (4%) studies was conducted at the University Hospitals of Bahia, Paraíba, and Minas Gerais, associated with their respective federal universities [27]. Another 4 of 25 (16%) studies used data from the internet, with 1 of 4 (25%) associated with UFMG, 2 of 4 (50%) with UFRJ, and 1 of 4 (25%) with UFJF [17,18,23,29].

AI Algorithms

The analyzed papers used different AI algorithms, classified into five distinct groups, with some studies combining more than one type in their development (Table 3). A total of 11 of 25 (44%) studies used machine learning, 9 of 25 (36%) used deep learning, 1 applied fuzzy Logic, 3 of 25 (12%) adopted ensemble methods, and 3 of 25 (12%) used expert systems [8-32].

[f]ECG: electrocardiogram.

[g]FL: Fuzzy logic.

Minimum Requirements

Given the context of limited-income countries, such as Brazil, and their financial limitations, the minimum technological requirements necessary for the functionality of the tools were observed. The primary requirement is a computer, required by 19 of 25 (76%) of the papers, with 16 of 19 (84%) needing memory and compatibility for the machine learning models in these studies, 2 of 19 (10%) requiring specific software, and 1 of 19 (5%) with an electrocardiogram device connected to the computer, all compatible with Windows [8,10-12,14,15,17,18,20-27,30-32].

Additionally, 3 of 25 (12%) required specific cell phone models: a phone with sufficient memory and Android software version 4.0 (Ice Cream Sandwich; paper 8) and Samsung Galaxy S10 (Android 11; papers 13 and 14) [9,13,14]. A total of 2 (8%) were applicable on Android and iOS platforms, with no specific device model requirements (papers 19 and 29) [19,29]. Another 1 of 25 (4%) papers did not specify the necessary technology [28].

Test or External Application or Evidence of Health Improvement

All the papers conducted some form of testing to evaluate and validate the tools. However, only two of them performed a second evaluation with application to a different population. Additionally, all studies presented some evidence of health improvement, but the risks of bias associated with these evidences will be explored [8-32].

Results of Statistical Analyses

The sensitivity meta-analysis, using a random-effects model, resulted in a combined estimate of 0.8113 (95% CI 0.7856 - 0.8369), with a *z* score value of 62.0035 (P<.001). The analysis revealed high heterogeneity among the studies (I^2=88%), suggesting significant variability in the results of the included studies. The forest plot in Figure 2 visualizes each study's sensitivity estimate and the combined estimate, highlighting the dispersion of the results.

The combined specificity estimate was 0.7417 (95% CI 0.7113 - 0.7722), with a *z* score value of 47.7605 (P<.001). The analysis indicated high heterogeneity (I^2=88%), as shown in Figure 3, reflecting substantial differences in the study results. The corresponding forest plot illustrates these individual estimates and the combined estimate from the meta-analysis.

The AUC meta-analysis presented a combined estimate of 0.8308 (95% CI 0.8124 - 0.8492), with a *z* score value of 88.4640 (P<.001). The heterogeneity was moderate to high (I^2=76%), as visualized in the forest plot in Figure 4, suggesting variations in methods or populations among the studies.

The forest plots (Figures 3 and 4) provide a visual representation of the individual and combined estimates for sensitivity, specificity, and AUC. Each graph highlights the variability among the studies and the combined estimate obtained through the meta-analysis. The dashed vertical line in the graphs represents the combined estimate, while the CIs are indicated by horizontal bars for each study. Multimedia Appendix 3 presents the compilation of sensitivities, specificities, and the AUC.

Discussion

Principal Results

This study demonstrates that AI tools in Brazilian health are widely used for diagnosis and screening, with emphasis on ophthalmology and infectious diseases, and the public initiative is preponderant in the development of these technologies. In this context, the application of AI in health care has advanced significantly in Brazil, with various tools being developed for screening and diagnosis purposes. This distinction between screening and diagnosis is essential, as it directly influences the implementation and impact of technologies in different health care contexts. The primary goal of screening tools is to identify individuals at risk of a given condition, prioritizing sensitivity maximization. This means these tools are designed to ensure that few actual cases go unnoticed, even if it increases false positives. This approach is fundamental in scenarios where early detection can save lives or prevent disease progression [33].

On the other hand, diagnosis tools aim to confirm or rule out the presence of a condition in individuals already identified as at risk. In these cases, accuracy becomes crucial, with a more careful balance between sensitivity and specificity. Often, there is a focus on maximizing specificity to reduce false positives, thus avoiding unnecessary treatments. These accuracy requirements reflect the distinct needs of screening and diagnosis tools, with screening being more permissive regarding false positives to ensure no actual case is overlooked, while diagnosis seeks high accuracy to prevent clinical errors [33].

The implementation of these tools also varies depending on the context of use. Screening tools are often used in resource-limited settings, where there is a need to process large volumes of data quickly. Thus, they are used in community screening campaigns or public health programs, where the focus is on quickly identifying cases that need more thorough evaluation, as shown in papers 12, 13, 16, 22, 30, and 32 [12,13,16,22,23,32]. Diabetic retinopathy screening is prominent in this context, covered in papers 13, 16, and 30, as well as tuberculosis in papers 12 and 32, conditions highlighted in the Brazilian context [12,13,16,30,32]. Rare syndromes that require early intervention, such as inborn immunity errors in paper 22, were also explored [22].

Highlighted specialties for AI tools include ophthalmology and infectious disease. The former benefits from AI's image analysis capabilities, revisiting the topic discussed earlier: diabetic retinopathy research (13, 16, 30), allergic conjunctivitis screening (31), and glaucoma diagnosis (9) [8,13,16,30,31]. Meanwhile, infectious diseases, critically important in Brazil, stood out in COVID diagnosis—a crucial aspect, given the global impact of the pandemic. In this case, tools were used for clinical diagnosis (23,24), with one using imaging diagnostics through computed tomography (27) [23,24,27]. Another area worth noting, not due to the number of tools produced but because of its clinical importance in Brazil, also within infectious disease, is pulmonology, which includes tuberculosis screening, with both papers covering testing and clinical symptoms (12 and 32) [12,32].

The predominance of public initiatives and funding from scientific development programs—particularly National Council for Scientific and Technological Development (CNPQ) and São Paulo Research Foundation (FAPESP)—highlights the importance of state support for research. This support is crucial for advancing tools and studies in health care, significantly benefiting the country. Furthermore, the presence of private initiatives reflects the ongoing need for health care technology advancement in Brazil. Public-private partnerships, exemplified by Program to Support the Institutional Development of the Brazilian Unified Health System, are essential for improving practices and innovations in the sector, fostering a constantly evolving environment [8-32].

Brazil's vast and diverse territory shows varying trends in areas such as infrastructure, access to technology, and development in health care and educational institutions [34]. This review revealed a significant concentration of studies conducted in São Paulo state (12/25, 48%), with the Hospital das Clínicas at the University of São Paulo being involved in 33% (4/25) of these studies [8,10,11,15,16,19-22,24,28,31]. This event highlights the tendency for AI use to be concentrated in the country's wealthiest state: São Paulo. Additionally, a notable collaboration between São Paulo and other states, such as Sergipe, Minas Gerais, and Amazonas, highlights joint efforts to develop technology across regional boundaries within the country [11,16,24].

This is essential as it allows adaptation to different realities, with broader applications and more effective tools (tested in various populations).

Other states, such as Rio Grande do Norte, Bahia, Santa Catarina, and Pernambuco, also produced AI tools, demonstrating broad participation across Brazilian states [9,13,14,30]. Finally, prominent institutions, including Federal University of Minas Gerais (UFMG), UFRJ, and Federal University of Juiz de Fora (UFJF), used internet data to develop their technologies, showcasing the importance of digital resources for health research, expanding the reach and diversity of studied populations [17,18,23,29].

The most commonly used AI algorithm was machine learning (11/25, 44%), which uses models attempting to predict future outcomes based on a dataset and is helpful in automated diagnostics and decision-support systems, as seen in papers 7 and 25 [10,14,35]. Deep learning, a subcategory of machine learning, appeared in 36% (9/25) of the studies, allowing more complex data analysis involving larger volumes and image recognition, a critical feature in papers 18 and 22, for example, for image evaluation [13,23,36]. Additionally, paper 15 used ensemble methods, which combine multiple machine learning models to improve decision accuracy [27,37].

Another important algorithm is expert systems, which operate based on a predefined set of rules and knowledge, used for decision support, as in paper 26, or diagnosis, as in paper 8 [9,26]. Finally, fuzzy logic is valuable for decision-making in less precise cases requiring flexible interpretation, such as breast cancer characterization in paper 21 [21].

XSL•FO
RenderX

In limited-income countries like Brazil, minimum technological requirements for implementing AI tools in health care should be carefully assessed due to financial constraints and frequently inadequate technological infrastructure. The analysis of minimum requirements, as presented, reveals a predominant reliance on computers as a fundamental platform, with 76% (19/25) of papers indicating their necessity, underscoring the importance of computing in executing machine learning models [8,10-12,14,15,17,18,20-27,30-32].

The need for computers compatible with Windows operating systems was observed in 18 of 25 (72%) papers, revealing this operating system's prevalence in health care environments in Brazil. The use of specific software for running AI models was also noted, though at a lower rate (2/19, 10%). The compatibility with Windows may be attributed to its wide adoption and familiarity in the Brazilian market, potentially reducing barriers to adopting new technologies [8,10,11,14,17,20,22-27,30-32].

Besides computers, one paper mentioned using electrocardiogram devices linked to computers, indicating additional hardware integration for data monitoring and collection [14]. The need for specific mobile devices was identified in 3 of 25 (12%) papers, focusing on phones with minimum specifications, such as sufficient memory and specific Android OS versions. This requirement for compatibility with particular versions may limit the applicability of tools on older or less common mobile devices, potentially restricting technology access and dissemination, a negative point.

The diverse application of tools across Android and iOS platforms, without strict device model specifications, reflects an attempt at greater flexibility and accessibility [19,29].

Regarding ethics, AI models must be prepared to withstand cyberattacks to ensure the security and protection of patient data, with tools similar to those used by the pharmaceutical industry being a possible alternative. Furthermore, although much of the data are already stored for program reporting, policy development, strategic planning, and advocacy purposes, it often remains inaccessible to research areas. In this context, improving access to these data requires, first and foremost, maintaining clear communication with the population to ensure a proper understanding of how their data will be used, the potential benefits, and the measures in place to protect their privacy. Transparent dialog, community engagement, and the development of context-sensitive consent processes are essential to building public trust and fostering an ethical data-sharing environment [1].

The meta-analysis on AI model performance in medical diagnostics and screening revealed important clinical insights. The combined sensitivity was 0.8113, indicating that, on average, AI models correctly identify approximately 81% of true positives. This high sensitivity is crucial in clinical settings, particularly in initial screening, as it helps ensure that most patients with a medical condition are identified and treated, minimizing the risk of false negatives.

The combined specificity was 0.7417, suggesting that AI models correctly identify around 74% of true negatives. Although this specificity is considered good, it is lower than sensitivity, which may indicate a tendency for false positives in some scenarios. This is relevant, as false positives can lead to unnecessary treatments or additional tests for patients who do not have the condition in question. Due to existing financial constraints, these potential unnecessary costs are harmful, especially in low-resource settings.

The combined area under the AUC was 0.8308, pointing to AI models' excellent discriminatory ability between positive and negative cases. The AUC reflects overall model performance, demonstrating a satisfactory balance between sensitivity and specificity, which is essential for accurate diagnostics and screening.

Limitations

All papers presented evidence of health improvement, suggesting that AI tools have the potential to positively impact clinical outcomes. However, testing is crucial to ensure the effectiveness and safety of AI tools in health care. All papers reviewed reported some form of testing to validate their tools, indicating a commitment to performance evaluation of the proposed solutions.

The papers' main limitation was data analysis, with criteria Q15, Q16, and Q17 being absent in almost all studies. This lack of information regarding how the analysis was conducted suggests a significant bias, with potential participants being excluded without justification and unmentioned complexities, which could lead to biased estimates. Therefore, for future research, methodological transparency must be prioritized.

Among the outcomes, most presented a medium risk of bias, mainly due to missing data in criteria Q10 and Q11, which assess whether the evaluator was aware of the predictors when determining the outcome, potentially inflating the reported accuracy measures, or whether there was a time interval between predictor assessment and outcome determination.

In the predictors, a crucial issue not reported in most papers was Q4: Were predictor assessments made without knowledge of outcome data? Since this information was missing, it is possible that predictor collection was biased, influencing the actual effectiveness of the tools, compromising reproducibility, and the critical evaluation of the results presented.

Few studies had an inadequate participant selection process and sample representativeness, limiting generalizability to distinct populations, especially in a country as diverse as Brazil.

For future studies, the key is greater transparency with the data to increase trust in the tools.

Nevertheless, a major limitation of the studies is that only 3 papers conducted a second evaluation by applying the tool to a different population, limiting the generalizability of the results and increasing the possibility of statistical errors in real-world population outcomes. This practice raises the risk of overfitting, where the model performs excellently on the original sample but fails when applied to new contexts. One possibility for future studies is to conduct the test in different centers, with partnerships between universities, to increase the sample size and the tool's potential.

XSL•FO
RenderX

Another relevant factor is the high heterogeneity observed in all analyses, with I^2 values ranging from 76% to 88%. This variability suggests that the effectiveness of AI models may vary significantly between different studies and contexts. Differences in algorithms used, study populations, and implementation methods may contribute to this variation, further reinforcing the concern about retesting these tools in other contexts.

Conclusions

This review demonstrates a broad application of AI technologies in diagnostic and treatment areas, with relative equality in the use of both types of tools and broad use across Brazil in varied contexts. The predominance of public funding indicates the potential for tools for use in the Brazilian UHS, which is significant due to the widespread reliance on the Brazilian public health care system. The variety of specialties highlights the diversity of AI applications and their importance in the health sector. Finally, the need for secondary testing points to future research opportunities.

Acknowledgments

This research was funded by the National Council for Scientific and Technological Development (CNPq). The authors gratefully acknowledge the support provided, which made this study possible.

Abstract

Background: Artificial intelligence (AI) is a rapidly evolving technology with the potential to revolutionize the health care industry. In Saudi Arabia, the health care sector has adopted AI technologies over the past decade to enhance service efficiency and quality, aligning with the country's technological thrust under the Saudi Vision 2030 program.

Objective: This review aims to systematically examine the impact of AI on health care quality in Saudi Arabian hospitals.

Methods: A meticulous and comprehensive systematic literature review was undertaken to identify studies investigating AI's impact on health care in Saudi Arabia. We collected several studies from selected databases, including PubMed, Google Scholar, and Saudi Digital Library. The search terms used were "Artificial Intelligence," "health care," "health care quality," "AI in Saudi Arabia," "AI in health care," and "health care providers." The review focused on studies published in the past 10 years, ensuring the inclusion of the most recent and relevant research on the effects of AI on Saudi Arabian health care organizations. The review included quantitative and qualitative analyses, providing a robust and comprehensive understanding of the topic.

Results: A systematic review of 12 studies explored AI's influence on health care services in Saudi Arabia, highlighting notable advancements in diagnostic accuracy, patient management, and operational efficiency. AI-driven models demonstrate high precision in disease prediction and early diagnosis, while machine learning optimizes telehealth, electronic health record compliance, and workflow efficiency, despite adoption challenges like connectivity limitations. Additionally, AI strengthens data security, reduces costs, and facilitates personalized treatment, ultimately enhancing health care delivery.

Conclusions: The review underscores that AI technologies have significantly improved diagnostic accuracy, patient management, and operational efficiency in Saudi Arabia's health care system. However, challenges such as data privacy, algorithmic bias, and robust regulations require attention to ensure successful AI integration in health care.

(JMIR AI 2025;4:e69209) doi:10.2196/69209

KEYWORDS

artificial intelligence; AI; health care quality; Saudi Arabia; technology

Introduction

The health care industry is on the cusp of a significant transformation driven by the integration of artificial intelligence (AI). The fusion of big data, cloud computing, artificial neural networks, and machine learning has led to the development of machines that mimic human intelligence [1]. This study focuses on these machines referred to as AI, which can perceive, recognize, learn, react, and problem-solve, and explores their potential to revolutionize health care. The introduction of these innovative technologies is a possibility and a reality in health care, promising a bright future. In Saudi Arabia, the integration of AI in the health care industry has become increasingly prevalent over the last decade. For example, a study by Al Kuwaiti et al [1] states that AI applications have revolutionized health care, mainly since the advent of COVID-19, and presents a promising solution to future health care needs. Further, the Ministry of Health uses eHealth as a transformative tool to improve health care delivery through digital and information technology, aligning with the Saudi Vision 2030 implementation [2] and underscoring the significant and essential benefits of technology, particularly AI, in health care, wherein technology is transforming the diagnostic process into a more collaborative and efficient one [3]. This benefits health care organizations, professionals, patients, their families, researchers, and decision makers. The potential of AI in health care is not just promising but also instilling a strong sense of confidence in its capabilities.

Deep learning models have emerged as a game-changer in the health care industry, especially in the use of the Internet of Things (IoT) in health care. Shah and Chircu [4] highlighted that these models are being used with remarkable accuracy to monitor patients' heart failure, leveraging the power of intelligent IoT-based frameworks. This approach has proven highly effective in preventing heart failure–related complications

XSL•FO
RenderX

and reducing the burden on health care providers, as well as in enhancing patient outcomes, decreasing hospital readmissions, and lowering health care costs [4]. Integrating deep learning models in the IoT in health care framework has revolutionized the health care industry and potentially transformed health care services, with the ability to classify patients as alive or deceased and share health records with medical professionals for emergency assistance [5].

Furthermore, the AI is revolutionizing early diagnoses and predictions of dental implant cases, thereby significantly enhancing health care services in dentistry [6]. AI algorithms can also analyze medical images such as X-rays and magnetic resonance imaging, thereby aiding radiologists in detecting and diagnosing medical conditions, which leads to earlier detection and better patient treatment outcomes [7].

Almalawi et al [7] predicted that AI was expected to be indispensable in supporting clinical and supplementary applications that lead to more intelligent and efficient operations and care in the future. By using secure and interoperable data, health care organizations, health systems, and health plan companies can leverage the power of AI to gain valuable insights and drive informed decision-making. Businesses embracing AI will likely experience significant benefits, including short-term cost savings and long-term competitive advantages. Also, by adopting AI-powered solutions, these organizations can enhance their services, improve customer engagement, and stay ahead of the curve in a constantly evolving industry [7]. With AI technology at their fingertips, health care organizations can unlock new opportunities for growth and success while providing their customers with the best possible experience [7].

Indeed, as noted in the study by Almalawi et al [7], AI has the potential to transform the health care industry, but there are also potential pitfalls to consider. First, with the advancements in AI technology, there are legitimate concerns about its impact on society, particularly privacy, security, and employment. Privacy concerns are valid as AI systems can collect and use personal information, such as medical records, financial data, and location information. Establishing robust data protection protocols is imperative to prevent data breaches and the misuse of personal information. Additionally, AI systems can perpetuate biases and discrimination if the data they were trained on are biased or reflect existing inequalities. Therefore, unbiased data are necessary for training AI systems; addressing these concerns can ensure a more informed and prepared approach to integrating AI in health care [7]. Second, AI can pose a security risk if not designed and implemented securely. Malicious actors can exploit AI systems, leading to unauthorized data access or other harmful consequences. Health care privacy laws, such as those in Saudi Arabia, can also present challenges for legal regulations, allowing physicians to disclose patient information for educational purposes [7]. Finally, there are concerns about AI's impact on employment, with predictions suggesting that it may displace workers in industries like manufacturing and transportation. However, AI primarily uses supervised machine learning, and its role in Saudi Arabia's health care policy needs further clarification. To integrate AI effectively in health care, it is crucial to set clear goals and define specific objectives for AI integration, such as improving diagnostic accuracy, optimizing resource allocation, and enhancing patient management. Develop comprehensive policies and create guidelines that address ethical considerations, data privacy, and security measures to ensure responsible AI use.

Effective AI integration in health care requires a structured approach encompassing stakeholder engagement, pilot program implementation, and professional training. Engaging health care providers, policymakers, and patients ensures that AI policies align with practical and ethical considerations [8]. Implementing pilot programs facilitates real-world testing, allowing for evidence-based refinements and the expansion of successful initiatives [9,10]. Additionally, comprehensive training programs equip health care professionals with the necessary skills to seamlessly integrate AI into clinical practice, thereby enhancing patient care and operational efficiency [11,12]. Collectively, these measures support responsible AI adoption in health care, contributing to improved diagnostic accuracy, operational efficiency, and patient outcomes [7,12]. These actions will maximize AI's potential in health care [7]. Additionally, it is essential to note that AI could create new job categories and enhance human abilities, potentially leading to a more diverse and dynamic workforce [7].

Integrating AI technology in health care has become increasingly important for improving the quality and efficiency of health care services, especially in Saudi Arabian hospitals [7,8]. However, there is a lack of information available in the existing literature regarding the impact of AI on health care implementation in Saudi Arabia. Previous research has mainly focused on clinical outcomes, with less emphasis on the impact of AI on health care providers and the efficiency of adapting to AI in health care settings [3,5,6]. To address this gap, this study aims to examine how AI affects the quality of health care services in Saudi Arabia. By consolidating existing evidence, this study aims to provide valuable insights for policymakers and inform health care professionals and administrators about the most effective ways to optimize AI applications to improve efficiency and enhance the quality of patient care. The study reviewed the accuracy and reliability of AI systems compared to human doctors and the potential cost savings and increased efficiency resulting from their use. Ultimately, this research might support Saudi Arabia in making informed decisions about leveraging AI to improve health care services while prioritizing health care providers' and patients' welfare and privacy.

This study focuses exclusively on Saudi Arabia to provide a contextually relevant analysis of AI integration within its health care sector. Given the nation's digital transformation under the Saudi Vision 2030 program, the centralized nature of Saudi Arabia's health care system allows for a targeted evaluation that accounts for unique regulatory frameworks, cultural perceptions, and health care challenges, distinguishing it from other countries. By synthesizing evidence on AI's role in diagnostic accuracy, patient management, and operational efficiency, the study supports evidence-based decision-making and offers insights for policymakers and health care professionals seeking to optimize AI-driven health care solutions. The aim of this study is to systematically review the available evidence to answer the following research question:

XSL•FO
RenderX

What is the impact of AI on the quality of health care services in Saudi Arabia?

The significance of this review lies in its focus on a rapidly expanding area of health care transformation. AI adoption has the potential to elevate care quality, improve patient outcomes, reduce costs, and enhance efficiency. By consolidating the available evidence within the Saudi Arabian context, this study provides a timely and contextually relevant understanding of AI's contributions and challenges. The findings aim to guide health care leaders in selecting appropriate AI applications, shaping workforce training, and designing governance frameworks that ensure responsible and sustainable integration of AI in clinical practice.

Methods

Study Design and Search Strategy

We conducted a systematic search of the literature in accordance with the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 guidelines (Checklist 1). Five electronic databases—PubMed or MEDLINE, Web of Science, Scopus, Google Scholar, and the Saudi Digital Library—were searched to identify studies evaluating the impact of AI on health care services in Saudi Arabia. The search combined controlled vocabulary terms (eg, Medical Subject Headings) and free-text keywords related to AI and health care. The following concepts were applied: "artificial intelligence" OR "machine learning" OR "deep learning" AND "healthcare" OR "health services" OR "healthcare quality" OR "diagnostic accuracy" AND "Saudi Arabia" OR "Saudi healthcare." Additional terms were included to capture provider-level perspectives, such as "healthcare providers" OR "clinical decision support."

The search covered the period from January 2014 to April 2024 to ensure contemporary relevance, reflecting the accelerated adoption of AI in Saudi health care during the past decade. No language restrictions were applied at the search stage; however, only English language full texts were included at the screening stage. Boolean operators (AND and OR) and database-specific filters were used to refine results. The reference lists of all included studies were also hand-searched to identify additional relevant publications.

Criteria

Inclusion Criteria

Studies were included if they were original empirical investigations—such as observational studies (cross-sectional, cohort, or case control), quasiexperimental studies, case series, or surveys—conducted in Saudi Arabia between January 2014 and April 2024. Eligible studies needed to explicitly evaluate the use of AI in health care delivery, with a focus on diagnostic accuracy, patient management, or operational efficiency. Both quantitative and qualitative designs were considered, and studies were required to involve health care providers (eg, physicians, nurses, pharmacists, and allied health professionals) and patients receiving health care services in Saudi Arabian hospitals or clinics, whether governmental or private. Only studies published in English were included.

Exclusion Criteria

The exclusion criteria were applied to remove studies that did not meet the scope of this review. These included reviews (systematic, narrative, or scoping); editorials; conference abstracts without full data; and opinion pieces. Studies were also excluded if they were conducted outside Saudi Arabia; if the study population did not include health care providers or patients (eg, students, policymakers, or the general public); or if the focus was not directly related to AI in health care. Studies published before 2014 were excluded to ensure that the review reflects contemporary developments in AI adoption under the Saudi Vision 2030 program.

Data Extraction and Quality Assessment

This study is based on original research and academic papers from journals. The Mendeley References Manager software (Elsevier) identified all the records from the database to display the collected data [13]. The data were then entered into a Microsoft Excel worksheet to locate all the studies. After that, all titles were screened on the basis of the inclusion and exclusion criteria. Abstracts of the articles were analyzed in depth to ensure the quality and relevance of the academic literature included in the review process. Full-text screening was then done, and all these steps were presented on the PRISMA flow diagram. The systematic review followed the widely accepted PRISMA 2020 guidelines, which serve as a comprehensive flow diagram to ensure transparency and reproducibility [14]. The PRISMA flow diagram visually represents the study selection process from initial identification to the final inclusion of studies in the review.

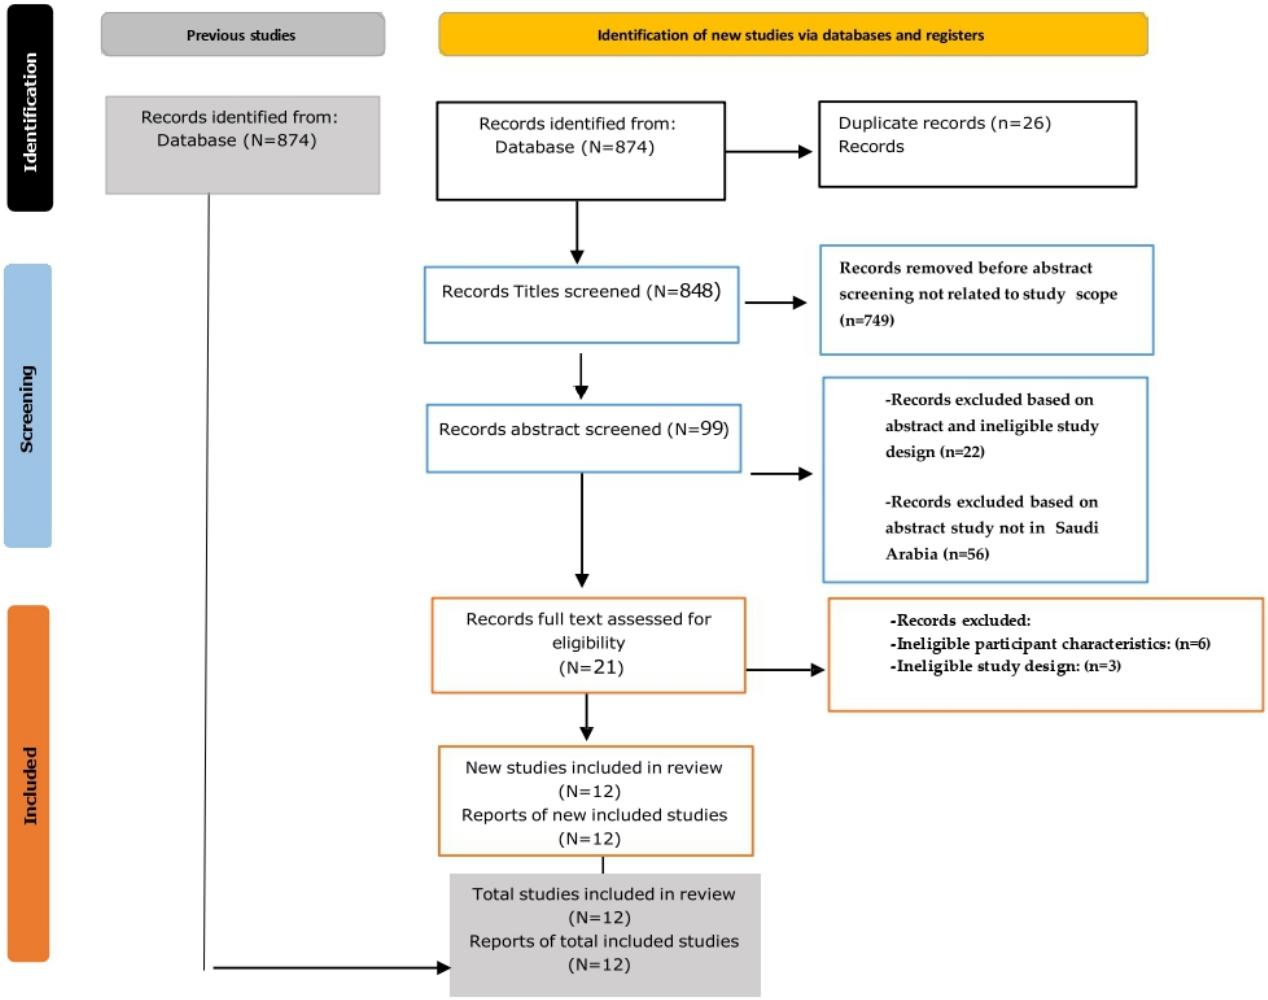
To ensure the quality of the review, each included research paper was evaluated carefully at a later stage through the Joanna Briggs Institute (JBI) critical appraisal checklist [15]. The JBI critical appraisal checklist enhances systematic reviews by ensuring methodological rigor, assessing bias, and improving the reliability of included studies. It supports transparent and reproducible research, strengthening evidence-based health care decisions. The methodological quality was assessed in the studies chosen using the JBI methodology's tailored criteria for different kinds of research. We performed the critical appraisal of eligible analytical cross-sectional studies for 8 studies, the critical appraisal of eligible cohort study research for 3 studies, and the critical appraisal of quasiexperimental studies for 1 study.

Results

Study Selection

At the beginning of the review process, 874 records were identified across 3 databases: 295 from Google Scholar, 293 from PubMed, and 286 from the Saudi Digital Library (Table 1). Of the total, 26 duplicates were removed, leaving 848 unique records. Following title screening, 748 records were excluded for irrelevance and 99 abstracts were reviewed. Of these, 22 were excluded due to ineligible study design and 56 because they were not conducted in Saudi Arabia; 22 full texts were

XSL•FO
RenderX



assessed, of which 9 were excluded (6 for ineligible populations and 3 for design). A final total of 12 studies were included. The PRISMA flow diagram is provided in Figure 1.

Table . Database sources: Boolean operators[a] were used to run the searches between March 2024 and April 2024.

Database sources	Records, n
Google Scholar	295
PubMed	293
Saudi Digital Library databases	286

[a]The study aimed to investigate the impact of artificial intelligence on health care organizations in Saudi Arabia, drawing from existing literature. The search strategy involved the use of specific search phrases such as “Artificial Intelligence,” “healthcare,” “health quality,” “(AI) in Saudi Arabia,” and “(AI) in healthcare.” Boolean operators, including AND and OR, were strategically used to combine and exclude these search phrases, thereby refining the search results to be more precise.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram.

Study Themes and Distribution

The included studies addressed 4 major themes: diagnostic accuracy (n=3), patient management (n=3), operational efficiency (n=3), and quantified impact (n=3; Table 2). These themes capture the breadth of AI applications in Saudi health care and highlight the diverse ways AI has been studied, from early diagnostic models to workforce efficiency and provider perceptions (Multimedia Appendices 1 and 2).

XSL•FO
RenderX

Table . Study themes and distribution.

Theme	Studies, n	Study examples
Diagnostic accuracy	3	Aljameel et al [16], Ibrahim et al [17], Olatunji et al [18]
Patient management	3	Alghamdi et al [11], Al Yousef et al [12], Olatunji et al [18]
Operational efficiency	3	Alharbi and Almutiq [6], Al Habib and Alharthi [9], Seliaman et al [19]
Quantified impact	3	Almalawi et al [7], Serbaya et al [20], Aldossari [21]

Diagnostic Accuracy

Three studies demonstrated that AI can improve diagnostic precision in Saudi health care contexts by leveraging clinical, imaging, and laboratory data. In the context of the COVID-19 pandemic, Aljameel et al [16] applied a random forest classifier to records from King Fahad University Hospital and achieved 95% accuracy and an area under the curve (AUC) of 0.99, suggesting that AI could serve as an effective early-warning tool for predicting disease severity and outcomes. This has direct implications for triaging patients in high-demand hospital settings. In oncology, Ibrahim et al [17] developed the AMAN detection system for interpreting equivocal mammograms, reporting 87% image classification accuracy, a 95% AUC, and 92% balanced accuracy, thereby confirming the feasibility of cost-effective deep learning–based systems to support breast cancer screening. In neurological care, a study tested 4 machine learning algorithms on hospital-based clinical and laboratory records, with support vector machines achieving 95.6% accuracy and an area under the receiver operating characteristic curve of 0.97 [22]. These results highlight the potential of AI to detect Alzheimer disease at earlier stages, where interventions may have a greater impact. Collectively, these studies show how AI can be integrated across diverse diagnostic pathways in Saudi Arabia, from infectious disease to oncology and neurology.

Patient Management

Three studies assessed how AI supports personalized care and treatment planning. Olatunji et al analyzed data from 569 patients with multiple sclerosis using explainable AI, a method that not only produced robust predictions but also provided insight into the decision-making process of the algorithms. This interpretability allowed clinicians to better understand the rationale for predictions, strengthening trust and adoption in clinical settings. Alahmadi et al [23] developed a gradient boosting model using records of 622 patients with COVID-19, achieving 96.3% accuracy and identifying 23 predictive features, including comorbidities and beta-blocker use, which may reduce disease severity. This work underscores the value of AI for risk stratification and treatment prioritization during public health emergencies. Al Yousef et al [12] applied data mining techniques to electronic health records from 5 National Guard Health Affairs hospitals to predict diabetes onset. While the models performed acceptably, missing data limited accuracy; however, the study demonstrated the feasibility of using routinely collected hospital data for early disease prediction in Saudi Arabia. These examples illustrate the expanding role of AI in chronic disease management and highlight its potential for precision medicine approaches.

Operational Efficiency

Three studies investigated AI applications for workflow optimization and organizational performance. Al Habib and Alharthi [9] used machine learning to predict physician noncompliance with electronic health record documentation. The random forest model achieved an AUC of 0.891, an F_1-score of 0.831, and a recall of 0.831, demonstrating strong predictive performance and offering a practical solution for hospitals to proactively address compliance issues. Seliaman evaluated physician and pharmacist perceptions of clinical decision support systems (BESTCare 2.0), which are widely implemented in the National Guard hospitals. Findings indicated that usability, availability of patient information, and accessibility were critical factors influencing acceptance, highlighting both the potential of clinical decision support systems and the challenges in integrating them seamlessly into clinical workflows. In dentistry, Alharbi and Almutiq [6] explored AI models for predicting dental implant cases, showing that AI could improve treatment planning and reduce complications, thereby streamlining dental services. Together, these studies suggest that AI has important applications not only in clinical care but also in enhancing hospital efficiency and administrative oversight.

Quantified Impact and Adoption

Three studies measured the broader impact of AI adoption in health care delivery. Alghamdi et al [11] reported that 47% of health care providers surveyed had used telehealth applications, but barriers such as poor internet connectivity, lack of time, and insufficient training limited widespread use. Serbaya et al [20] conducted a survey of health care workers in Jeddah and found that while 75% understood AI principles, only 50% were willing to use AI in medical decision-making. This gap highlights cultural and trust challenges that could slow AI adoption, even in settings where technical capability exists. Aldossari [21] showed that younger physicians, particularly those aged <30 years, expressed higher satisfaction with telehealth and demonstrated greater openness to expanded AI use in their practice. These findings emphasize the need for targeted strategies to improve provider engagement, training, and trust in AI tools.

XSL•FO
RenderX

Critical Appraisal

Critical appraisal indicated moderate to high quality across most included studies. Cross-sectional studies scored between 50% and 100% across appraisal items, while cohort and quasiexperimental designs achieved scores ranging from 27% to 72%. Habib and Alharthi [9] achieved the highest appraisal score (100%), reflecting rigorous methodology, comprehensive outcome measures, and strong predictive performance. Although variability in quality was observed, particularly among quasiexperimental studies, the majority demonstrated methodological soundness and provided valuable insights into the role of AI in Saudi health care (Tables 3 and 4). Only one quasiexperimental study (Ibrahim et al [17]) met the inclusion criteria. The study satisfied 4 of 9 quality appraisal items (44%), with clear reporting for participant selection and outcome measurement but limited information regarding confounding control and intervention description.

Table . Critical appraisal of an eligible analytical cross-sectional study.

Discussion

Principal Findings

This systematic review identified 12 eligible studies that examined the impact of AI on health care services in Saudi Arabia. The main findings show that AI applications have primarily focused on 4 domains: diagnostic accuracy, patient management, operational efficiency, and quantified impact. Across these studies, AI consistently demonstrated potential to improve diagnostic precision, support clinical decision-making, streamline health care workflows, and enhance cost-effectiveness. The integration of AI into health care represents a transformative development with profound implications worldwide, including in Saudi Arabia. The establishment of the Saudi Data and Artificial Intelligence Authority in August 2019 by royal decree marked a significant milestone in advancing the nation's digital transformation under [2,8]. AI's capacity to enhance diagnostic accuracy, streamline health care processes, and reduce operational costs is well

XSL•FO
RenderX

documented. Johnson et al [10] examined the impact of AI on the health care sector in the United States, highlighting several advantages that align with findings observed in Saudi Arabia.

Diagnostic Accuracy

AI-driven models have demonstrated significant advancements in medical diagnostics, enabling more precise disease identification and improving patient outcomes. For instance, Aljameel et al [16] developed a machine learning model for predicting COVID-19 outcomes, achieving 95% accuracy with an AUC of 0.99, thereby demonstrating AI's potential in pandemic response. Similarly, Ibrahim et al [17] introduced the AMAN system for breast cancer detection, reporting an 87% accuracy in mammography and a 95% AUC, reinforcing AI's role in oncological diagnostics. These findings align with global efforts to enhance diagnostic precision through AI-driven methodologies.

Patient Management

AI has been instrumental in advancing patient management by facilitating early disease detection and optimizing treatment strategies. Olatunji et al [18] developed a machine learning model for early multiple sclerosis diagnosis, allowing for timely intervention and personalized treatment, which is critical for managing chronic conditions. Alghamdi et al [11] examined telehealth adoption among health care providers, revealing that 47% of surveyed professionals used telehealth, although barriers such as limited time availability and limited connectivity impeded broader implementation [26-28]. These insights underscore AI's role in enhancing health care accessibility and personalized care delivery.

Operational Efficiency

Beyond clinical applications, AI improves operational workflows and compliance monitoring. Al Habib and Alharthi [9] applied machine learning techniques to predict electronic health record documentation compliance, achieving an AUC score of 0.891, thereby assisting in identifying noncompliant physicians and supporting regulatory adherence. Furthermore, Alharbi and Almutiq explored AI applications in predicting dental implant cases, demonstrating AI's ability to enhance patient outcomes and reduce complications associated with dental procedures [3]. These advancements underscore AI's role in improving the efficiency of health care systems.

Quantified Impact

AI integration extends to health care data security, cost reduction, and competitive advantages. Almalawi et al [7] emphasized the importance of secure health care data management, highlighting AI's potential in mitigating cybersecurity risks while improving efficiency in health care administration. Similarly, Al Yousef et al [12] developed predictive models for early diabetes diagnosis, aiding in proactive disease prevention and effective health monitoring despite persistent technical challenges. AI-driven predictive analytics can significantly reduce health care costs and contribute to data-driven decision-making models.

Regulatory and Cultural Considerations

Despite these advancements, notable differences exist between Saudi Arabia and the United States regarding data privacy and security concerns. While both countries acknowledge the importance of data protection, their regulatory frameworks diverge significantly. Saudi Arabia aligns AI integration with National Data Governance Regulations, fostering a centralized approach to data protection. In contrast, the United States operates within a multifaceted regulatory landscape that includes the Health Insurance Portability and Accountability Act (HIPAA) alongside various federal and state privacy laws, resulting in a more fragmented approach to data governance [29].

Resistance to AI adoption among health care providers has also been observed across both regions. In Saudi Arabia, skepticism is often linked to concerns about the potential erosion of the human element in patient care and the technological adaptations required for AI integration [8]. Conversely, in the United States, reluctance is more commonly associated with apprehensions regarding job displacement and challenges in integrating AI with existing health care IT infrastructure [10].

Trust and Adoption Among Health Care Professionals

Several factors, including professional roles and cultural attitudes, influence AI adoption. A study by Serbaya et al [20] found that pharmacists exhibited a higher level of trust in AI compared to physicians and nurses, a trend also observed in European health care settings. Pharmacists' familiarity with medication management technologies and their perception of AI-assisted decision-making as objective may contribute to this pattern. Additionally, gender disparities in AI confidence levels have been documented, with male health care professionals displaying greater confidence in AI applications than their female counterparts. Findings from previous studies attribute this discrepancy to greater exposure to technology among male professionals, job roles requiring technological engagement, and societal norms influencing interactions with emerging technologies [13,30,31]. Addressing these disparities through targeted educational programs and inclusive AI development strategies is crucial for equitable technology adoption.

Recommendations

The following are actionable recommendations for stakeholders:

1. Enhancing data privacy and security
2. Implement robust data protection protocols
3. Develop clear data governance policies to safeguard patient information [2]
4. Address algorithmic bias
5. Ensure the availability of diverse and representative data
6. Conduct regular bias audits to maintain fairness in AI algorithms [3]

The following are recommendations to improve infrastructure and training:

1. Invest in technological infrastructure
2. Provide continuous training for health care professionals to use AI technologies effectively [2]

XSL•FO
RenderX

The following are recommendations to foster collaboration and innovation:

1. Encourage public-private partnerships
2. Create innovation hubs to drive advancements in AI solutions for health care [1]

The following are regulatory suggestions for AI implementation:

- Establishing regulatory frameworks
  1. Develop comprehensive AI regulations
  2. Implement regulatory sandboxes to safely deploy AI technologies [1]
- Ensuring transparency and accountability
  1. Mandate transparency in AI systems
  2. Establish accountability mechanisms to foster trust and address adverse outcomes [2]

Challenges in AI Adoption in Saudi Health Care

The following are challenges with regard to data quality and availability:

1. Ensure high-quality data are available for AI training
2. Establish standards for data collection, storage, and processing that align with global best practices, as delineated by Health Level Seven International [32] and the Global Alliance for Genomics and Health [33]

The following are challenges with regard to regulations and ethical guidelines:

1. Formulate comprehensive regulations for ethical AI use in health care
2. Integrate ethical principles (fairness, transparency, and accountability) into AI system development. The Saudi government may consider frameworks such as the European Union's guidelines on AI ethics, which emphasize respect for human autonomy, harm prevention, promotion of fairness, and the need for explicability [32].
3. Impose strict penalties for patient privacy or data security violations, including unauthorized data transmissions and data mining activities conducted without explicit patient consent
4. Secure informed consent from patients before using their data. Align data protection policies with the principles of the General Data Protection Regulation [8].

The following are challenges faced in providing training for medical personnel:

1. Provide adequate training for health care professionals to use AI tools effectively
2. Emphasize continuous education in AI to enhance the understanding of AI technologies, data privacy, and bias mitigation. A study conducted by the American Medical Association highlighted the need for ongoing education and training for health care professionals in AI to ensure they are adequately equipped to care for patients and enhance patient care [8].

Conclusions

Integrating AI into health care policy and enhancing the continuous use of AI health devices requires a multifaceted approach. By defining clear objectives, involving stakeholders, and focusing on user-friendly design and constant monitoring, we can ensure that AI technologies are effectively used to improve health care outcomes. Addressing challenges such as data privacy, infrastructure investments, and bias mitigation will be crucial for successful implementation.

AI can potentially revolutionize health care in Saudi Arabia by predicting patient outcomes; personalizing medicine; streamlining administrative tasks; and improving accuracy, efficiency, and cost-effectiveness. However, it is critical to also focus on proper training for medical personnel while maintaining data privacy and addressing biases in AI algorithms. The Saudi Arabian health care sector can benefit from AI in many ways, including predicting disease outbreaks, enhancing patient admissions processes, and supporting ongoing education for medical professionals. Furthermore, deploying telehealth services and other digital health strategies highlights AI's vital role in the region's health care future. To fully realize AI's potential in health care, it is essential to tackle the associated challenges and risks. With careful implementation and training, AI can lead to more accurate and efficient health care services, improving patient outcomes and reducing costs.

Abstract

Background: Conversational agents (CAs) are finding increasing application in health and social care, not least due to their growing use in the home. Recent developments in artificial intelligence, machine learning, and natural language processing have enabled a variety of new uses for CAs. One type of CA that has received increasing attention recently is smart speakers.

Objective: The aim of our study was to identify the use cases, user groups, and settings of smart speakers in health and social care. We also wanted to identify the key motivations for developers and designers to use this particular type of technology.

Methods: We conducted a scoping review to provide an overview of the literature on smart speakers in health and social care. The literature search was conducted between February 2023 and March 2023 and included 3 databases (PubMed, Scopus, and Sociological Abstracts), supplemented by Google Scholar. Several keywords were used, including technology (eg, voice assistant), product name (eg, Amazon Alexa), and setting (health care or social care). Publications were included if they met the predefined inclusion criteria: (1) published after 2015 and (2) used a smart speaker in a health care or social care setting. Publications were excluded if they met one of the following criteria: (1) did not report on the specific devices used, (2) did not focus specifically on smart speakers, (3) were systematic reviews and other forms of literature-based publications, and (4) were not published in English. Two reviewers collected, reviewed, abstracted, and analyzed the data using qualitative content analysis.

Results: A total of 27 articles were included in the final review. These articles covered a wide range of use cases in different settings, such as private homes, hospitals, long-term care facilities, and outpatient services. The main target group was patients, especially older users, followed by doctors and other medical staff members.

Conclusions: The results show that smart speakers have diverse applications in health and social care, addressing different contexts and audiences. Their affordability and easy-to-use interfaces make them attractive to various stakeholders. It seems likely that, due to technical advances in artificial intelligence and the market power of the companies behind the devices, there will be more use cases for smart speakers in the near future.

Introduction

Background

In the context of ongoing public debates on artificial intelligence (AI), dialogue systems or conversational agents (CAs) are receiving increasing attention. Their potential applications are being discussed in various fields, including health care [1,2] and social care [3]. CAs have been used in both fields for several years, but recent developments in AI have fueled the scientific discourse [4,5]. The developments in the field of machine learning and natural language processing (NLP), as well as the success of commercially available CAs, such as Amazon's Alexa or Apple's Siri, have been particularly decisive in this regard.

The use of CAs is not limited to a single context; rather, they are used in a variety of settings, including those pertaining to the acquisition of information related to health [6]. CAs using NLP offer a number of features that can be implemented in a variety of health care and social care settings. The field of AI has witnessed considerable progress in recent years, with speech recognition (SR) and NLP advancing significantly. This has enabled the processing of medical terminology in various settings [7]. Although SR in health care has a long tradition dating back to the 1980s, when initial attempts were made to dictate doctor's letters [8], CAs offer multiple additional features. In the context of hands-free interaction, CAs have been used for the purposes of medication reminders [9], symptom management [10], documentation [11], or communication between patients and nurses or doctors, covering multiple medical fields. These include diabetes care [12], monitoring of pregnant women [13], children with special health care needs [11], hearing tests [14], cardiovascular disease [15], and the support of persons with dementia, to name a few [16].

The Rise of Smart Speakers

The term "CA" is not clearly defined, and within the literature, multiple synonyms are used interchangeably. These include "virtual assistants," "AI-driven digital assistants," "voice-based assistants," "voice-controlled intelligent personal assistants," and others. In the study by Laranjo et al [1], the term "CA" is defined as encompassing a range of technologies, including chatbots, embodied CA, which involves a computer-generated character such as an avatar, and smart conversational interfaces, such as Apple's Siri or Amazon's Alexa. In order to characterize CAs, the authors propose that it is necessary to differentiate between the type of technology in question (eg, if the software application is delivered through a mobile device or the telephone), the type of dialogue management (finite-state, frame-based, or agent-based), the actors with control over the dialogue initiative (the user, the system, or a combination of both), the input or output modality (spoken or written, or visual in the case of the output), and whether the system is task-oriented or not [1].

This paper is particularly interested in the use of CAs that are embodied in a physical stationary artifact, which is referred to as a smart speaker. Examples of such devices include Amazon's Echo and Apple's HomePod. Smart speakers are typically confined to a specific location and serve as a platform for a smart conversational interface or AI-driven digital assistant that can be operated through voice input. In the case of the Echo, this is "Alexa", while in the HomePod, it is "Siri". Such assistants are capable of fulfilling a range of tasks, including answering simple questions, switching on lights in conjunction with a smart home system, and playing music. The devices are equipped with one or multiple microphones and software that is capable of analyzing and generating spoken language. In order to operate the devices, the user must utter a designated wake word, such as "Alexa" or "Computer" in the case of Amazon's Echo [17].

The diffusion of smart speakers has been observed to be high in private households in Europe and North America. Amazon launched the first smart speaker in the United States in 2015. As of 2022, approximately 35% of the total US population had used smart speakers [18]. In comparison to the figures from 2019, this represents an increase of 11.1% [19]. A number of studies conducted by market research companies in other countries have reached similar conclusions. For instance, these studies have found that 33% of internet households in the United States, 34% in the United Kingdom [20], and approximately 12%-33% of all households in Germany own at least one smart speaker [21,22].

A recent study by Gaspar and Neus [23] of smart speaker users in the United States, United Kingdom, and Germany shows that Amazon is still the current market leader (United States: 58%; United Kingdom: 71%; and Germany: 68%) followed by Google (United States: 34%; United Kingdom: 22%; and Germany: 25%) and other brands (United States, United Kingdom, and Germany: 7%). It was also found that in all countries, at least 40% (United States: 46%; United Kingdom: 40%; and Germany: 44%) of respondents use smart speakers several times a day. Participants were also asked about the attractiveness of certain application scenarios, including medical diagnosis. Here, participants gave high ratings: United States (19% very attractive and 36% attractive), United Kingdom (12% very attractive and 34% attractive), and Germany (13% very attractive and 35% attractive).

In light of the commercial success of smart speakers and the aforementioned technological advantages in SR and NLP, there has been a growing body of literature on smart speakers in different health care and social care settings [1,24-27]. Commercial devices, such as Amazon's Echo, offer a multitude of features. These devices can be used without any direct contact, are relatively inexpensive and easy to operate, and can be customized and personalized by installing new applications and features [28]. These factors have played a pivotal role in the dissemination of the technology. Finally, the widespread adoption of the technology was driven by the pandemic and the subsequent shift in clinical practices toward greater reliance on digital technologies [29]. Nevertheless, the pervasive use of these devices has also given rise to a multitude of issues and concerns, most notably data collection, storage, and protection [8].

Hence, the devices have attracted increasing attention, with several reviews on CAs in health care settings having been published recently. Each of these reviews has a specific focus:

XSL•FO
RenderX

these include, for instance, design and evaluation challenges [30], effectiveness and usability [31], or chronic conditions [32,33]. To the best of our knowledge, no review has been conducted to date that specifically examines the use of smart speakers within health care and social care settings.

As evidenced by the current state of research, smart speakers are becoming increasingly prevalent in the field of health care and social care. However, there is currently no systematic review available that specifically investigates use cases, settings in which the devices are used, or target groups. To address this gap, our main research question is as follows: What are the scenarios of the use of smart speakers in health care and social care? To address this research question, the main aim of this paper is to present a review of the current research on the use of smart speakers in health care and social care.

Methods

Overview

In order to provide an overview of the existing literature on smart speakers in health care and social care, we conducted a scoping review. The main aim of this approach is to observe, synthesize, and understand current trends [34]. In contrast to a systematic review, which is more suitable for the presentation of a specific clinical question or the presentation of evidence for practice, a scoping review is particularly suitable for identifying features and concepts. Furthermore, it does not aim to provide a synthesizing result for a specific question but rather to provide an overview of a specific topic [34,35]. Thus, the scoping review is a particularly suitable instrument for analyzing the research interest. This encompasses the identification of the nature of the literature, the collation of information on key topics, and the identification of knowledge gaps [35]. Its methodological framework was first published by Arksey and O'Malley [36] and later adapted by Levac, Colquhoun, and O'Brien [37]. Contrary to a systematic review, search terms can be adjusted along the process of a scoping review [36,38]. For the conduction of the present review, the guidelines of Peters et al [39], the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) [40] and its extension for Scoping Reviews (PRISMA-ScR) [41] were followed. The results were presented according to the PRISMA checklist (Multimedia Appendix 1).

Search Strategy and Selection Criteria

The literature search was conducted between February 2023 and March 2023. This included a systematic literature search of 3 databases (PubMed, Scopus, and Sociological Abstracts) and a cross-search of the first 20 pages of Google Scholar. This was supplemented by tracing reference lists for further relevant studies. We used the program Citavi 6 for literature management. The review protocol is available on request from the authors. The following keywords were applied in varying combinations and spellings for the systematic search (Table 1):

1. Technology: Here, several terms described above that are found in the literature on CA were used. As the focus of this review is on smart speakers, the search was restricted to this specific type of CA.
2. Product name: As smart speakers were introduced to the market by major American information technology companies, which often use the product names as synonyms for the product, we also included the product or brand names in our search. Globally, Amazon, Google, and Apple are the 3 leading manufacturers; therefore, we included the names of their brands in our search [42].
3. Setting: In order to ensure the most comprehensive search results, we elected to limit our search to the 2 domains of health care and social care without imposing any further restrictions.

Table 1. Keywords used in the literature review.

Technology	Vendor, brand, and product	Setting
Smart speaker	Amazon Alexa	Health care
Voice assistant	Amazon Echo	Social care
Voice-based assistant	Apple HomePod	Care
Voice-controlled assistant	Apple Siri	Nursing
Artificial intelligence–driven digital assistant	Google Home	—[a]
Conversational agent	Google Nest	—
Virtual assistant	—	—

[a]Not applicable.

The terms were linked using Boolean operators. Multiple combinations of the search terms were used using different operators (Multimedia Appendix 2).

To select studies relevant to our research interest, we defined the following inclusion criteria for the full-text screening: (1) publications that were released after 2015, as this was the year in which the first commercial smart speaker was introduced to the market, and (2) the use of a smart speaker in health care and social care settings. No restrictions were placed on the specific setting, including hospitals or long-term care facilities. Furthermore, articles were included in which the devices were not implemented in real settings but were developed for specific settings. Studies were excluded if they met one of the following exclusion criteria: (1) papers that do not report on the specific devices that were used (for instance, in some cases, the authors described the use of a personal assistant without explicitly indicating the specific device on which the assistant was

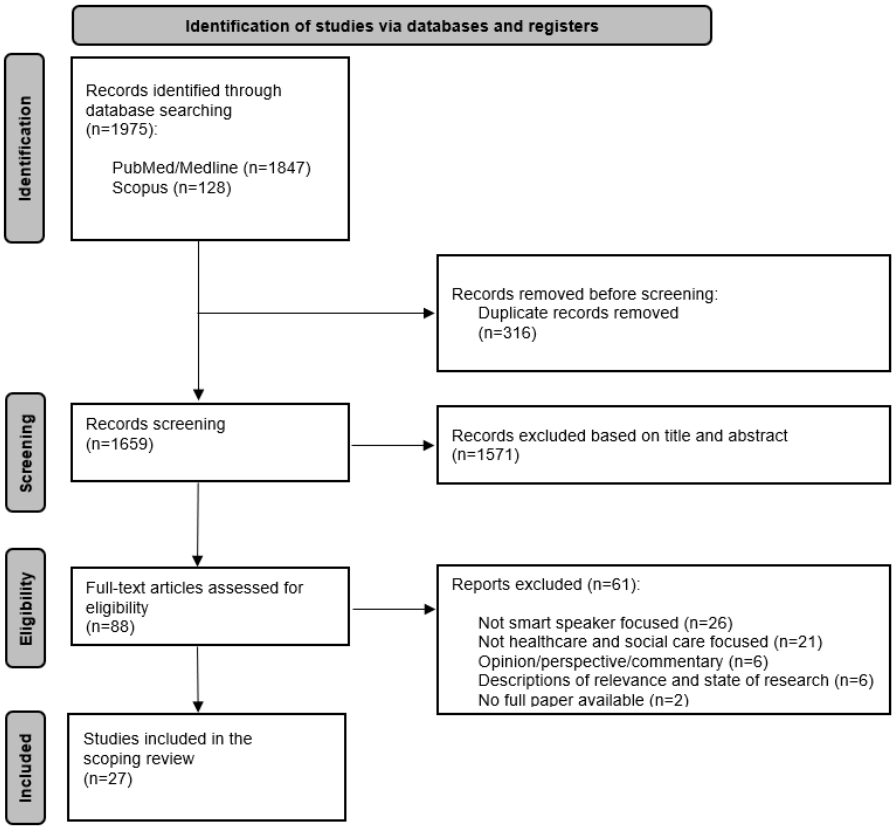
XSL•FO
RenderX

operational), (2) studies that did not specifically focus on smart speakers (this encompasses the development of voice-operated applications for use on smartphones or tablets), (3) systematic reviews and other forms of literature-based publications, and (4) articles not published in the English language.

Process of Study Selection and Data Extraction

We first screened the titles and abstracts for relevance by both authors. No exclusion criteria were applied to the type of publication during the title and abstract search. Should the title or abstract screening indicate the use of a smart speaker in a health care or social care context, the articles were deemed eligible for full-text screening. For the title and abstract screening, as well as the full-text screening, the same 2 authors reviewed each article independently in order to decide on its inclusion or exclusion. In the event of conflicting decisions regarding inclusion or exclusion, the authors attempted to reach a consensus through discussion. As there was no disagreement, there was no need to involve a third party. The data extraction table contains the following information about each article: (1) authors, (2) year of publication, and (3) country of publication. Furthermore, data were collected on the product and the use case. Furthermore, the following aspects were considered: the settings, the target groups, the motivation for using smart speakers, and the limitations of using such a device. As the primary focus was not on methodological aspects, and due to the heterogeneity of the included literature (some described only technical development while others also included user testing and the often-limited reporting of methods), no such information was collected. The articles included were subjected to qualitative thematic analysis in accordance with the methodology outlined in [43]. Using Kuckartz's [43] approach to qualitative thematic text analysis, researchers identify codes through analysis based on the data gathered. During the process, these codes are then refined. Researchers then identify themes or categories that represent the main findings of the analysis. Identifying themes is a process of examining patterns and similarities between codes and then relating the themes to each other. Consequently, all papers included were read and re-read by both authors, with initial codes being identified. The codes were then compared by the authors, discussed, and grouped into themes. In particular, this included an analysis of the motivation for using the devices and the limitations encountered during the research and development process.

Ethical Considerations



Given the nature of the study, there were no direct interactions with human participants, and thus, no participants to recruit or consent, and no institutional ethical approval was required.

Results

Overview

In total, our search yielded 1975 articles. After removing 316 duplicates, 1659 titles and abstracts were screened by the 2 reviewers. The screening of titles and abstracts resulted in the exclusion of 1571 records, leaving 88 full texts to be assessed for eligibility. Of these, 61 articles were excluded, resulting in a final pool of 27 articles for analysis (Figure 1). The data extraction table for the articles included can be found in Multimedia Appendix 3 [3,9,13-15,44-65].

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart of the search process.

XSL•FO
RenderX

Year and Country of Publication

The majority of articles included in the analysis were published in the United States (n=15 [9, 15, 39, 45, 46, 49, 51, 53-57, 61, 63, 65]), followed by the United Kingdom (n=4 [3,13,43,62]), North Macedonia (n=2 [58,59]), and Australia (n=2 [52,64]). All articles were published between 2018 and 2022, with 2021 being the year with the highest number of publications, with 11 articles.

Technology

There was a clear preference for the devices used: Amazon products were used in 23 of the articles, followed by Google (5). A total of 3 papers used a prototype. It should be noted that some articles used devices from several companies. We found 2 types of articles: Those that use the devices, including the infrastructure (eg, frameworks) provided by the developers, and those that mainly use the hardware (eg, for heart rhythm monitoring; Multimedia Appendix 3 [3,9,13-15,44-65]).

The devices were found to be used In 3 main ways: (1) as standard smart speakers without any further modification, for example, to communicate with patients or to support people living alone (for instance, [44,47]); (2) to develop a skill for a specific use case or multiple use cases (for instance, [48]); and (3) to use the smart speaker and, in some cases, the skill to feed information into another system or as a communication device for other systems (for instance, [15]).

Settings and Target Groups

Given the diverse range of health care and social care settings, we have defined the following categories (Textbox 1). It should be noted that not all articles reported the testing of smart speakers in real health care and social care settings. In some cases, applications were tested in laboratory environments. In the event that this was the case, the intended setting was coded.

Textbox 1. We used the following settings within the domains of health care and special care.

Private homes

- The private living environment includes a person's own home.

Hospitals

- This setting covers acute care hospitals as well as urgent care centers.

Long-term care facilities

- This category includes all settings in which long-term care is provided, for example, nursing homes or rehabilitation centers.

Outpatient services

- This category covers specialized outpatient services, for example, dental or pain management clinics.

Other

- In case the device was tested in a setting not matching the definition of the ones listed above, we categorized it as "other." For instance, this could be in a car.

Furthermore, 4 target groups were identified. It should be noted that an article can have several target groups, including (1) patients, (2) medical staff members such as physicians, (3) nurses and professional caregivers, and (4) informal caregivers who provide unpaid help to a friend or family member. Moreover, category (5), "other," was defined for all target groups not matching any of the aforementioned. It should be noted that multiple target groups were covered in one article. Only those who directly interact with the device were included. For instance, Domínguez et al [50] developed a system to support assisted reproduction treatment. Although physicians are involved, only the patients interact with a smart speaker and hence were included.

The most prevalent setting mentioned in the studies included was home care (n=20), followed by hospitals (n=6). Outpatient care (n=3) was less frequently observed (Multimedia Appendix 3 [3,9,13-15,44-65]). In one instance, the setting was not specified [14]. However, it is best classified under home care.

Among the target groups, patients are the most frequent users mentioned in 23 of the articles (Multimedia Appendix 3 [3,9,13-15,44-65]). Older adults, in particular, were often seen as a promising target group, and we found that 11 of the included publications focus on this target group [66] (Multimedia Appendix 3 [3,9,13-15,44-65]). While some articles included descriptions of the development and testing of skills specifically designed for older adults [51,52], others explored the general acceptance and potential of the technology for older adults. For instance, Lee et al [51] developed multiple skills aimed at older persons, including a reminder to take medication, a diet tracking system, and a skill alerting caregivers in case of a fall. Nallam et al [49] simulated a CA to answer health-related questions asked by older persons. O'Brien et al [47] used off-the-shelf devices without any form of modification to investigate the effects on home-bound older adults with social isolation. The participants used the devices for a variety of purposes, including monitoring their health and well-being, as well as for emergency communication. Some authors report that older adults constitute the largest group of first adopters of smart speakers. In addition, smart speakers allow easy contact with caregivers [12] or low-threshold access to health information [13]. Older adults as potential users of CA have been the focus before [39,67,68].

XSL•FO
RenderX

The second most frequent target group was physicians (n=11), followed by other health professionals (eg, nurses; n=9) and informal caregivers (n=1; Multimedia Appendix 3 [3,9,13-15,44-65]). These results demonstrate that the majority of articles focus on supporting nonresidential care.

Table 2 provides an overview of all settings and target groups. It is important to note that a single paper can include multiple settings and target groups.

While previous statements covered the number of papers included in the review, Table 2 combines user groups and settings across the studies covered. It shows that patients are the most common target group, while home care is the most common setting.

Table 2. Settings and user groups.

	Patients	Physicians	Older adults	Nurses and so on	Informal caregivers	Other	Total
Home care	19	5	11	7	1	1	44
Hospitals	4	5	0	2	0	0	11
Outpatient care	2	2	1	1	0	0	6
Total	25	12	12	10	1	1	

Use Cases

We found several use cases covering, among others, hearing tests [14], cardiovascular diseases [15,46], pregnancy companion [13], cancer management [eg, 58,59], or medication reminders [69]. It must be noted that several articles reported that smart speakers were used in multiple use cases. For example, Wright [70] describes that a local authority was involved in developing applications, including “a Skill that prompted users to take their medicine; a Skill that helped to record and manage care tasks; a Skill to facilitate communication with caregivers by recording messages; and a Skill to connect users to a trusted LA directory of services” [44]. Jadczyk et al [71], who developed a voice-enabled automated platform for the collection of medical data from patients with cardiovascular disease, describe 5 use cases within their study: (1) education, (2) process optimization, (3) patient support, and (4) data collection, and (5) medical device grade solutions (eg, diagnose and treatment). The devices were used to open patient files and images, initiate conference calls, or record images and videos [4].

While most of the identified use cases were found in the domain of health care, social care played a subordinate role. Still, we found several articles reporting on the use of smart speakers in this domain. Within this field, elderly care was the most relevant area. For instance, O’Brien et al [47] use a smart speaker to reduce loneliness and social isolation among older adults living at home. Palumbo et al [72] developed personalized coaching for older individuals to increase their well-being by aiming at the areas of physical activity, nutrition, cognition, and social relationships. In the domain of social care, older adults living at home or care home residents were the main user group (eg, [3]).

Motivation for Use

The reasons for using smart speakers in health care are framed with various arguments. Besides their low acquisition costs [51], this also includes aspects applying to digital technologies in health care and social care in general, such as the possibility to deliver care remotely without restrictions in time and space (eg, Sadavarte et al [13]). Another motivation is the fact that smart speakers are already widely accepted as a consumer technology [45,52]. Hence, users already know how to operate the devices and are also familiar with their limitations. Other aspects cover potentially increased productivity across the use cases that we identified. For instance, Bhatt et al [45] used a voice-based assistant to access and update an electronic health record. They see advantages in terms of efficiency (less time spent on data input) and accuracy, as speech-to-text might result in fewer errors. Ultimately, this might also benefit patients as waiting time is reduced [45]. Jadczyk et al [71] highlighted the main potential in the possibility of automating traditional telehealth services: “Voice chatbots can support routine care through automatic at-home monitoring, triaging, screening, providing medical recommendations and guidelines, and improving operational workflow” [15,71].

Another advantage is the user interface, which is easy to navigate [11]. Cheng et al [55] argue that the main advantage of the technology is that it: “eliminate[s] the struggles that are associated with strictly tactile screens.” (2018); or that human-like verbal communication that feels more natural and intuitive and particularly that the devices can be used hands-free [55]. Jansons et al [52] drive on the research of Foehr and Germelmann [73] and argue that the devices “may enhance adherence to remotely-delivered exercise interventions […], because the human-like attributes associated with these technologies may elicit a sense of familiarity, social presence, and human engagement” [52]. Moreover, the authors see this as an advantage for older users [53] who support this viewpoint and argue that “digital non-natives” might be especially benefitting from this technology. For instance, Kim [4] tested the experiences of older adults who used the devices for the first time and found that due to the simple interaction, health-related questions were a typical use case.

The form of smart speakers and their design were mentioned in some publications. Gouda et al [74] saw the fact that smart speakers are “non-invasive” technology as a main advantage. As the devices can be placed nearly anywhere in the room and can be operated without the need to see them, it allows for new ways of interaction. Luo et al [56] also see a benefit in the fact that the immobility of the devices is as helpful as this helps, in contrast to mobile phones, in establishing habits and routines.

XSL•FO
RenderX

Wright [44] describes the use of smart speakers in trials run by local authorities in England. Drawing on interviews with managers from 8 English local authorities, benefits are seen in the low-cost supplement or alternative to telecare. Or, as one of his interview partners put it: “have the advantages of being sophisticated and powerful, relatively cheap, already widely used and familiar, designed with a degree of accessibility and intuitive use in mind, and a growing level of interoperability with other networked digital devices aided by an open development framework” [44]. One of the results of the study is that local authorities chose Amazon’s Echo because of “councils facing depleted funds, a lack of expert guidance on care technologies, and an increasingly complex and fragmented care technology marketplace” [44].

Limitations of Smart Speakers

In addition, various limitations of the technology were addressed in the included articles. Here, most technical limitations were named (1) insufficient hearing comprehension [57], speech recognition [51], or emotion recognition [54]; (2) that there is no interruption of the recording during slow speeches allowed [14]; (3) difficult functioning in the natural living environments due to interfering noises [3]; (4) that the correctness of the answer is not always accurate [51]; and (5) that the devices allow longer conversations [49]. Internet access must also be provided [48,75]. Besides these technical aspects, there were also social aspects mentioned. This covered the (lack of) user acceptance, particularly among older users and professional caregivers [45,76], but also their lack of basic digital skills [75]. These supposedly low digital skills might lead to challenges in interacting with the devices. Users might forget the wake word, there may be timing issues when communicating with the devices, or they might have difficulties in setting up the devices [47,53]. Another issue that was mentioned regularly was data protection. Here, the misuse of sensitive data is particularly pointed out. For example, if security measures are inadequate, it would be possible to manipulate the medication and thus actively harm the patient [12]. Cheng et al [55] also argue for multimodal solutions as people might feel uncomfortable talking to devices in front of other people.

Discussion

Principal Findings

Our aim was to identify use cases and scenarios in which smart speakers can be used within health care and social care. The results show that smart speakers are used in various contexts and for multiple reasons. The main features used are NLP and hands-free interaction. Moreover, the fact that the technology is widely used in private homes and hence many persons are used to interact with the devices are important aspects. In addition to offering relatively inexpensive hardware, smart speakers and the companies behind them provide software frameworks and infrastructure, such as Amazon’s skill, which assists developers in the design and marketing of their products.

It is important to note that there is no clear definition of smart speakers. One challenge of this study was the varying definitions of the technology, with the term often being used interchangeably with personal assistants such as Siri or Cortana. These assistants play an important role in the use of smart speakers, which arguably only serve as a shell equipped with microphones and loudspeakers for them. However, we argue that smart speakers should be considered a distinct technology. Based on this review, we understand smart speakers as a type of CA bound to a fixed location. Within the field of health care and social care, the technology can be used in various settings and use cases such as communication, documentation, or diagnosis and therapy of diseases hands-free. Smart speakers are equipped with microphones and loudspeakers and connected to the internet. They usually come with an integrated digital assistant, but even without such an assistant, they offer multiple features that can be used across various settings. Smart speakers can be customized using either skills or apps that can be installed on the devices.

The results show that all publications were published between 2018 and 2021. Furthermore, the majority were published in the United States. The following explanations can be given for these 2 results. Alexa was the first voice assistant that was compliant with the Health Insurance Portability and Accountability Act (HIPAA), allowing it to be the access example of clinical records. In England, the National Health Service contracted with Amazon to enable Alexa in 2019 to answer health-related questions, raising questions about privacy and how health care data would be used [44,45]. The HIPAA compliance and the fact that the National Health Service contracted with Amazon explains why most studies have been carried out in the United States and the United Kingdom. Arguably, European countries are not as present due to more strict data protection regulations. Moreover, the use of smart speakers is significantly higher in the United States than in other countries, which in turn could also be related to data protection regulations [77]. Interestingly, Asian countries have, with few exceptions, also not been represented in the included articles. This seems counterintuitive as, in terms of market sales, smart speaker technology by Asian technology companies is more and more successful [42].

It also became clear that the devices were clearly dominant in the publications. This should be criticized from a scientific point of view. We were able to identify the following explanations for this result.

Since Amazon entered the market in 2015 and continuously updates its product line, off-the-shelf devices have recently increased in terms of market penetration, making them more popular for research and development. That Amazon’s Echo was used in the vast majority of articles included comes as no surprise, and Amazon’s market dominance is based on several factors. First, the company was the first to release a smart speaker to consumers. Second, Amazon’s voice assistant, Alexa, has been embedded in a broad range of devices, including wall clocks, by third-party manufacturers. Third, Amazon sells products of the Echo family at comparably low prices, starting at around US $20. Fourth, Amazon offers an infrastructure through its Skill Store and several frameworks for developers. Fifth, in the United States, the Echo is HIPAA-compliant.

The dominance of Amazon’s smart speaker in the included papers poses several risks depending on the use case, some of

XSL•FO
RenderX

which are discussed in the papers themselves. In terms of the devices themselves in their off-the-shelf version, the interaction is limited. For example, Nallam et al [49] used a smart speaker prototype as they argue that developed solutions often do not support conversational interactions and explore scenarios that are not yet supported.

The articles included in this publication address a diverse range of use cases across various settings, thereby demonstrating the versatility of smart speakers and the technology of NLP and AI incorporated in them. This technology can be used in a multitude of contexts within the domains of health care and social care. Overall, 2 general use cases can be distinguished: (1) supporting patients and their relatives in their private living environments and (2) supporting professional health care workers in clinical settings. As the devices were originally developed for private home environments and primarily for entertainment and e-commerce applications, it is unsurprising that this setting was the dominant one across the papers included in this review. This could be seen as an indicator of the restructuring of health care services, with an increased focus on the private living environment. Several clinical use cases supported by smart speakers could be automated and not be restricted to clinical settings (eg, [14,48]). Only in a few cases does the paper focus on clinical use cases and professional personnel (eg, [4,45,71]).

That patients, and particularly older adults, were the main target group supports this conclusion. Moreover, this also underlines that the role of patients and practices of health and care change against the background of digitalization and the use of AI [78]. While some of the use cases identified were exclusively designed for clinical settings, the majority can, in theory, be implemented in multiple settings. This could support patient empowerment, as smart speakers can be used to support the household as a central place of health care. An argument supporting the fit of the devices for older adults is that smart speakers do not require "reasonable levels of vision and manual dexterity" [79,80].

A key rationale for using the devices is not only their competitive pricing but also the potential to reduce expenditure by enhancing the efficiency of staff members and care processes, for instance, through enhanced documentation or facilitating straightforward communication with patients, colleagues, or clients. Although the majority of the papers reviewed argue that smart speakers could provide such benefits, these potential benefits depend on several circumstances. The first is whether the devices can be installed as they are or whether new skills or, more complexly, additional hardware or modifications are required. This depends on the use case and also the target group. Although many people are used to interacting with the devices, older adults might not have any experience and could need training.

The majority of the papers in our sample can be classified as exploratory in nature. The research designs used are predominantly qualitative, with sample sizes that are relatively small and no long-term studies conducted in real-world scenarios. This underscores the fact that the technology itself is still relatively new, particularly within the context of health care and social care. In addition, researchers and developers are still exploring the technology's potential applications in health care and social care, which may have become more apparent in the context of the pandemic. Both sectors are currently experiencing financial strain due to rising expenditure and a shortage of qualified personnel [81]. New technologies are frequently viewed as a potential solution to these challenges [70].

Smart speakers and digital voice assistants like Alexa are quite limited in terms of their initial dialogue management, which can be seen as an important motivator to using the systems as they are easier to develop and control. This finding is in line with a systematic review of CA in health care carried out by Laranjo et al [1]. The authors could identify 17 articles using 14 different CA. Most papers covered by the review evaluated task-oriented CA that aims at supporting patients and clinicians. Systems allowing the management of complex dialogues were only identified in 1 case. Even though conversational systems have proven to be beneficial for health-related purposes, most assistants allow only constrained user input (eg, multiple-choice answers) [1,82]. Clark et al [83] argue that users interact in "clearly delineated task-based conversations" and "fall short of reflexive and adaptive interactivity." According to the authors, the term conversation is "a poor description of the current interaction experience" with an AI using common smart speakers [83]. Hence, they suggest testing "human-agent interaction as a new genre of conversation, with its own rules, norms and expectations" [83]. The devices have only a limited capability to actually be able to engage in a conversational dialogue. Conversations are task-oriented instead of offering interactions initiated by the user and not by the device. While this might be true, it seems to be only a matter of time before future updates might be used to allow more natural dialogues, as is already the case with generative AI such as ChatGPT.

The analysis showed that change in existing practices and routines is an important aspect. Drawing on Sezgin et al [84], Capasso and Umbrello [85] argue that the novelty of CAs is that they act as "intermediaries between the health care system as a whole and the public," changing practices in health care and social care. Here, several studies follow the normative aim to implement innovative technologies in order to improve processes and outcomes. The use of smart speakers—or CAs in general—follows a technology-driven approach. Already existing technologies are transferred to the domains of health and social care. Due to the exploratory design of most studies, the emphasis is put on the technology and not on the context, like organizational or social factors. The logic of a "fitting" technology seems to be a main driver of many studies, neglecting the analysis of potentially changing social practices.

The dominance of Amazon in our sample has to be seen from a critical perspective. The company itself began offering the service Alexa Together and was able to emulate existing approaches and leverage its financial and market clout to challenge competitors. Moreover, developers depend on the technology, that is, the hardware and also the software frameworks of one company. As a consequence, the dominant position of Amazon might increase due to research using the company's products. If only one product from a particular company is examined, the capabilities of other products are not

XSL•FO
RenderX

taken into account, as they may perform better, for example, and might be used to copy promising applications.

Limitations

This paper has several limitations. First, the number of databases searched. To address this limitation, a cross-search was performed in Google Scholar to rule out the possibility that important articles were not found. In addition, to broaden the search strategy, other forms of literature, such as trial reports, could be included in future studies. For instance, a few trials using smart speakers are registered on clinicaltrials.gov. However, we decided not to include these as they did not provide all the information we wanted to obtain (eg, motivations for using the devices). Second, we restricted our search to the English language only. Few papers were found from the Asian region, probably due to the language limitation of the search. This limitation was mitigated by using brand names as search terms focusing on the brands with the highest market share. However, as recent market research shows, there is a shift toward products developed in Asian countries, and future studies should include a wider range of brands and products. Another limitation is that we only looked at smart speakers, which excludes other voice assistants that use essentially the same technology (such as digital assistants on smartphones and tablets). We deliberately excluded these as this review focused specifically on smart speakers as a form of CA, and we argue that the technology of smart speakers needs to be seen as a technology in its own right.

Conclusion

In this paper, a scoping review was conducted on the use of smart speakers in health care and social care settings. The analysis showed that—due to the widespread use of devices like Amazon's Echo—smart speaker technology has been tested and implemented in various settings and use cases in the health and social care sectors. The main setting was the private home environment, and the main user group was patients. There are, however, also approaches to making use of the technology in other settings, such as hospitals. It seems likely that due to technical progress in the field of AI and the market power of the companies behind the devices, there will be more use cases of smart speakers in the (near) future.

Abstract

Background: Pain, a leading reason people seek medical care, has become a social issue. Automated pain assessment has seen notable advancements over recent decades, addressing a critical need in both clinical and everyday settings.

Objective: The objective of this survey was to provide a comprehensive overview of pain and its mechanisms, to explore existing research on automated pain recognition modalities, and to identify key challenges and future directions in this field.

Methods: A literature review was conducted, analyzing studies focused on various modalities for automated pain recognition. The modalities reviewed include facial expressions, physiological signals, audio cues, and pupil dilation, with a focus on their efficacy and application in pain assessment.

Results: The survey found that each modality offers unique contributions to automated pain recognition, with facial expressions and physiological signals showing particular promise. However, the reliability and accuracy of these modalities vary, often depending on factors such as individual variability and environmental conditions.

Conclusions: While automated pain recognition has progressed considerably, challenges remain in achieving consistent accuracy across diverse populations and contexts. Future research directions are suggested to address these challenges, enhancing the reliability and applicability of automated pain assessment in clinical practice.

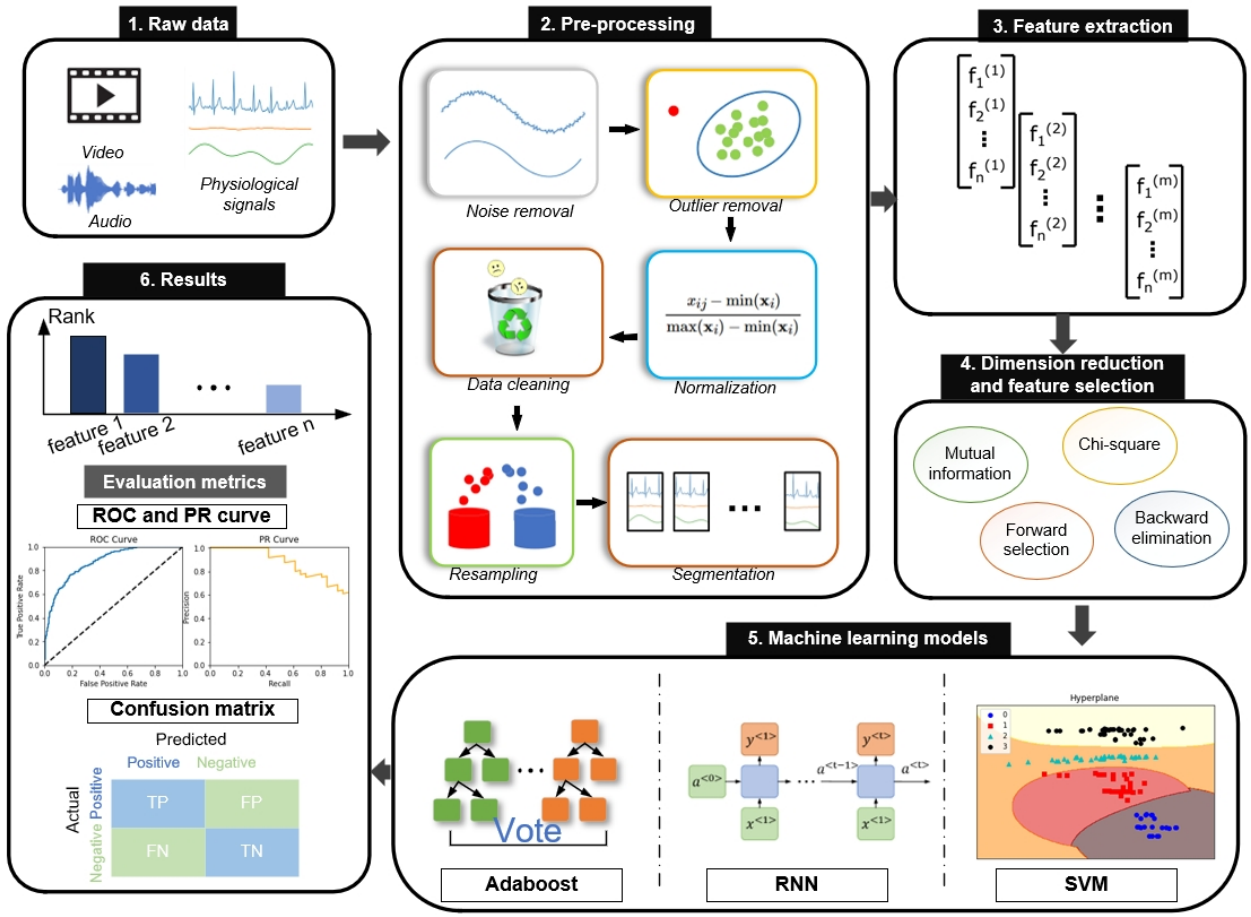
Introduction

Pain is “an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage,” according to the International Association for the Study of Pain [1]. However, the discussion on the most precise definition of pain is still ongoing, and the advances in the understanding of pain instantiate the biopsychosocial perspective on pain to capture evidence-based understanding and the evolution of pain [2]. On the basis of the pain origin, it is categorized as nociceptive (due to stimulation of sensory nerve fibers), neuropathic (due to impaired somatosensory nervous system), or psychogenic pain (caused, increased, or prolonged by mental, emotional, or behavioral factors). On the basis of the time duration of the pain, it may be categorized as acute (short duration) or chronic (long duration, may last >3 months).

Approximately 20% of adults have chronic pain in the United States, and chronic pain is the most common reason adults seek medical care. For society, chronic pain contributes to an estimated US $560 million each year in medical expenses, lost productivity, and disability caused by types of pain such as low back pain, arthritis, and joint pain [3,4]. These negative impacts make chronic pain a persistent public health concern.

XSL•FO
RenderX



Inappropriate pain management can lead to very deleterious physical, psychological, social, and financial consequences for patients. Untreated pain can lead to chronic pain syndrome, which is often accompanied by decreased mobility, impaired immunity, decreased concentration, anorexia, and sleep disturbances. More importantly, the use of prescription opioids for the treatment of chronic noncancer pain is associated with a substantial risk for abuse, dependence, and overdose [5].

As the first step of pain management, pain assessment holds an essential role [6]. Unprecise pain assessment can lead to severe consequences. Undertreatment of pain not only causes psychological consequences but also physiological consequences, for example, increased blood pressure and heart rate. By contrast, overtreatment of pain may result in nausea, vomiting, or constipation immediately and drug addiction in the long term. Traditionally, pain assessment is conducted through self-reports or observational scales. Self-report refers to the conscious communication of pain-related information by the person in pain, typically using spoken or written language or gestures. Various pain rating scales have been developed to capture patients' self-report of pain intensity. Traditional approaches used to play an important role in pain assessment, including the Verbal Rating Scale [7], the Visual Analog Scale [8], the Numerical Rating Scale [9], and the Wong-Baker FACES Scale [10].

However, such scoring methods are not feasible for certain patients, such as such as those who are unconscious. For this, different observational pain scales, such as the Behavioral Pain Scale [11], Pain Assessment in Advanced Dementia [12], or Neonatal Infant Pain Scale [13], are used in clinical settings. Most scales consider facial expressions, vocalizations, and body language, while some include vital parameters. It is difficult to assess and compare the validity of the various scales because studies differ a lot in design, methodology, participants, and conceptualization of the pain phenomenon. Pain assessment through observation is very challenging and is affected by the subjective biases and errors in beliefs of the observer [14].

To solve these challenges, it is necessary to develop an objective, accurate, continuous pain assessment method, as shown in Figure 1. In the last decades, multiple studies have been conducted to evaluate the feasibility of automated pain assessment using multimodality and machine learning (ML) techniques. This paper surveys and reviews the recent advances in the field in terms of datasets, modalities, and ML models. Finally, we present the challenges remaining in the field and propose future directions.

Pain Mechanism

The pain mechanism is not completely understood because of its complexity and diversity [15]. Pain, created by the brain, is a psychological state rather than a physical one [16]. Unlike pain, nociception refers to the response of the peripheral and central nervous systems to internal or external stimuli, triggered by the activation of nociceptors [17]. The noxious stimulus damages the tissue or potentially activates the nociceptors in the peripheral structure. Then, the information is transmitted to the spinal cord dorsal horn or the nucleus caudalis. From there, the information continues to the cerebral cortex via the brainstem in the brain, and the perception of pain is generated. Thus, no brain, no pain [18]. Figure 2 presents the mechanism of pain.

Figure 2. Pain mechanism.

Usually, pain is regarded as chronic or acute according to its duration. Acute pain is a type of sudden pain. The mechanism of momentary pain is well understood [19]. The nociceptors generate the nociception, and the information is transmitted to the brain, where the perception of pain is caused. There are 2 major types of nociceptors responding to different stimuli: C-fibers, associated with unmyelinated axons, and A-delta fibers, associated with thinly myelinated axons [20]. C-fibers generate slow, diffuse pain, while A-delta fibers are related to sharp, pricking pain. Silent nociceptors typically respond to endogenous chemical mediators related to tissue injury [19].

Chronic pain, lasting >3 months, does not have a useful biological function and is challenging to treat due to its varied etiologies [21-23]. According to the *International Classification of Diseases, Eleventh Revision*, chronic pain can be categorized into musculoskeletal, neuropathic, visceral, and cancer pain [21].

Psychological distress refers to a diffuse subjective experience as an internal response to noxious stimuli. Many patients argue that psychological pain is more severe than intense physical pain [24]. Chronic pain can lead to psychological pain and depression, while depression can exacerbate chronic pain [25,26]. Psychogenic pain is physical pain caused or increased by mental and emotional factors [27]. Treatments such as transcutaneous electrical nerve stimulation or psychotherapy are often more effective for reducing psychogenic pain compared to traditional painkillers [28,29].

The body responds to pain via multiple physiological processes: the sympathetic nervous system (SNS), neuroendocrine system, immune system, as well as emotions [30]. The SNS, known for the fight or flight response, increases heart rate and blood pressure via hormones such as catecholamines, epinephrine, and norepinephrine when activated [31]. The SNS also activates sweat glands via acetylcholine, reflecting the active level of SNS through the volume of secreted sweat within a time range [32].

Pain Datasets

Data that are representative are crucial in the creation of a pain recognition system and the demonstration of its efficacy. Crucially, the system should perform optimally within the intended medical context, a fact that must be validated through clinical studies involving patients. In the early stages of development, experimental pain research with healthy volunteers could be useful. This approach allows for strictly controlled conditions, larger participant pools, and the repeated application of pain stimuli. These data are foundational to the development of ML models for automated pain detection.

For studying pain in healthy adults, an external stimulus is needed. Common methods include heat applied via contact (eg, heated objects and electrical heaters) or radiant sources (eg, infrared light). Table 1 summarizes the publicly available datasets that were used for pain recognition research. The UNBC-McMaster Shoulder Pain Expression Archive Database [33] includes 200 video sequences that capture the facial expressions of 25 participants experiencing shoulder pain. Each video sequence includes individuals performing a series of active and passive range-of-motion tests to provoke visible responses to pain, providing a unique dataset rich in both the variety and volume of pain expressions. The dataset includes self-reported and observer assessments of pain intensity at the video level, along with Facial Action Coding System (FACS) coding at the frame level. The BioVid Heat Pain Database [34] is a collection of physiological data and videos from 90 healthy adults subjected to controlled heat stimuli. BioVid consists of several sections: A, B, and C, which focus on pain stimulation, along with sections D and E, which are dedicated to posed expressions and emotion elicitation, respectively. The MIntPAIN

XSL•FO
RenderX

database [35] collected color, depth, and thermal videos from 20 healthy adults who were subjected to approximately 1600 instances of electrical pain stimuli at 4 different intensity levels. EmoPain [36], SenseEmotion [37], X-ITE Pain [38], BP4D-Spontaneous [39], and BP4D+ [40] datasets are substantially resources for pain and emotion studies. EmoPain contains video, audio, motion, and a surface electromyogram (sEMG) for lower back pain. SenseEmotion and X-ITE Pain include audio and physiological data from healthy adults subjected to experimental pain stimuli, while X-ITE provides thermal videos, body movement data, and electromyography measurements. BP4D-Spontaneous and BP4D+ offer facial video recordings from individuals undergoing the cold presser task, with BP4D+ further providing 3D and thermal videos, along with physiological signals.

Table 1. Pain databases.

Database	Participants	Modalities	Annotation
Database with adults			
UNBC-McMaster [33]	25 adults with shoulder pain	Video of the face (RGB[a])	FACS[b], VAS[c], and OPI[d]
BioVid [34]	87 healthy adults	Video of face (RGB), EDA[e], electrocardiogram, and electromyography	Stimulus (calibrated per person)
MIntPAIN [35]	20 healthy adults	Video of face (RGB, depth, and thermal)	Stimulus (calibrated per person)
EmoPain [36]	22 adults with chronic back pain	Video, audio, electromyography, and motion capture	Self-report and naive OPI
SenseEmotion [37]	45 healthy adults	Video of face, audio, EDA, electrocardiogram, and electromyography	Stimulus (calibrated per person)
X-ITE [38]	134 healthy adults	Video of face, video of body, audio, EDA, electrocardiogram, and electromyography	Stimulus (calibrated per person)
BP4D-spontaneous [39]	41 healthy adults	Video of face (RGB and 3D)	Stimulus and FACS
BP4D+ [40]	140 healthy adults	Video of face (RGB, 3D, and thermal), heart rate, respiration rate, blood pressure, and EDA	Stimulus and FACS
Database with neonates			
iCOPE [41]	26 healthy neonates	204 RGB photographs of face	Category (pain, rest, cry, air puff, and friction)
YouTube [42]	142 infants	Video and audio	FLACC[f]
APN-db [43]	112 healthy neonates	Video of face (RGB)	NFLAPS[g], NIPS[h], and NFCS[i]
NPAD-ID [44]	36 healthy neonates and 9 neonates who underwent surgery	Video of face and body (RGB)	NIPS and N-PASS
iCOPEvid [45]	49 neonates	Video of face (grayscale)	Category (pain and no pain)
USF-MNPAD-I [46]	36 neonates	Video of face (RGB), audio, heart rate, blood pressure, SpO_2[j], deoxyhemoglobin (HbH), oxyhemoglobin (HbO_2)	NIPS and N-PASS[k]

In the field of infant pain research, the iCOPE [41], YouTube [42], APN-db [43], iCOPEvid [45], and USF-MNPAD-I [46] databases are the publicly available datasets. The iCOPE consists of 204 static photographs that capture 26 neonates during various

XSL•FO
RenderX

procedures. The images provide valuable insights into the facial expressions associated with infant pain experiences. The YouTube dataset offers 142 videos accompanied by audio, showcasing the reactions of different infants undergoing immunizations. The APN-db is a dataset that includes >200 videos of infants undergoing various procedures, and it features unique annotations, such as Neonatal Face and Limb Acute Pain intensity. The USF-MNPAD-I dataset collects video, audio, and physiological data from 58 neonates during their hospitalization in the neonatal intensive care unit (ICU) and is annotated using the Neonatal Infant Pain Scale and N-PASS scales.

Postoperative Pain

Although automated pain assessment in controlled settings is well studied, postoperative pain has not been extensively researched due to the difficulty of data collection. Postoperative pain results from tissue injury following surgery and is critical to manage, as inadequate treatment can lead to serious physiological and psychological outcomes. Postoperative pain datasets often exhibit imbalanced distributions and may contain missing labels due to variability in patient experiences and clinical settings, further complicating accurate and comprehensive pain assessment. The NPAD-IA database [44] captures video, audio, and physiological data from 40 infants undergoing procedural (heel lancing and immunization) and postoperative (gastrostomy tube) pain. Notably, it includes postoperative pain data, addressing the complexity and variability of pain levels in real-world clinical settings, thereby enhancing the ecological validity of the assessment. Salekin et al [47] present a novel fully automated deep learning framework to assess neonatal postoperative pain. It uses a bilinear convolutional neural network (B-CNN) to extract facial features and a recurrent neural network (RNN) to model the temporal patterns of postoperative pain. The study uses a dataset of >600 minutes of visual, vocal, and physiological data from neonates, demonstrating the feasibility and efficiency of combining B-CNN and RNN for continuous and accurate assessment of postoperative pain intensity in clinical settings. Salekin et al [46] introduce an automated system for assessing neonatal postoperative pain by integrating visual, vocal, and physiological data. The study also uses a B-CNN for spatial feature extraction but uses a long short-term memory (LSTM) network for capturing temporal patterns, demonstrating that the multimodal spatial-temporal approach significantly outperforms unimodal methods, achieving an area under the curve (AUC) of 0.87 and accuracy of 79%. Automated postoperative pain assessment is still in its nascent stages, primarily hindered by a lack of comprehensive datasets and consistent research efforts. The current methods, often unimodal and focused on short-term procedural pain, fail to capture the complex and prolonged nature of postoperative pain. There is a pressing need for more extensive and diverse datasets to improve the accuracy and reliability of these systems. Despite these challenges, the potential benefits of automated pain assessment are immense, offering more consistent and objective pain management that can significantly enhance patient outcomes and reduce the burden on health care providers.

Automatic Pain Assessment

Overview

Automated tools for pain assessment have great promise. Because pain results in different physiological and behavioral responses, signals that capture these may be used to detect the presence of pain. However, prior research work has been limited, and automated approaches have not yet become widely used in clinical practice. In this section, we briefly outline the different approaches relevant to the development of automated pain assessment methods described in the research literature. Specifically, we review their system architecture (inputs and outputs) and describe the data sources available for the research and development of ML-based automated pain assessment tools, together with an overview of system validation challenges. This section summarizes the results of the survey of automatic pain detection approaches.

The Use of Modalities

The selection of sensors is a critical aspect of automated pain assessment, as different sensors can convey varying levels of information and have different discriminative abilities. Modalities commonly used in this field can be broadly classified into 3 categories: video, audio, and physiological signals, as shown in Table 2. Functional magnetic resonance imaging (fMRI) was found to be the most prevalent sensor in pain studies, with a prevalence score of 95.9. Electroencephalogram and electrocardiogram were also frequently used, with prevalence scores of 69.6 and 39.1, respectively. In contrast, functional near-infrared spectroscopy (fNIRS) and photoplethysmography had much lower prevalence scores of <10. Moreover, Multimedia Appendix 1 also includes information on modalities used in studies (including brain activity, cardiovascular activity, electrodermal activity (EDA), respiration activity, and pupil size). In terms of physiological signals, brain activity can be measured using electroencephalograms, fMRI, and fNIRS. Cardiovascular activity can be measured using an electrocardiogram or photoplethysmography, while EDA is often measured by skin conductance level or sEMG. To gain insight into the prevalence of each modality, we conducted a search for “Modality AND Pain AND Machine learning” (eg, “EEG AND Pain AND Machine learning”) on PubMed and Scopus, limiting the search to the period from January 1, 2010, to August 1, 2023. We then recorded the number of results and normalized them to the range of (0-100) for each database. The prevalence scores were then calculated as the average of the normalized results from PubMed and Scopus.

XSL•FO
RenderX

Table 2. Summary of the commonly used modalities.

Category and name	Description	Prevalence[a]	References
Video			
Video analysis	Analyzes facial expressions and body movements to assess pain levels [48].	100	[33,35]
Audio			
Audio analysis	Analyzes vocal characteristics and speech patterns to assess pain [49].	48.2	[49]
Pupil size			
Pupil size measurement	Measures changes in pupil diameter as an indicator of pain [50].	12.7	[51,52]
Brain activity			
Electroencephalogram	It is a test that detects tiny electrical charges that result from the activity of brain cells [53].	69.6	[54-56]
Functional magnetic resonance imaging	It uses magnetic resonance imaging to measure the changes in hemodynamics caused by neuronal activity [57].	95.9	[58-60]
Functional near-infrared spectroscopy	It uses scattering arising from the main components of blood upon exposure to near-infrared light (600 nm to 900 nm) to measure changes in oxyhemoglobin and deoxyhemoglobin during brain activity [50].	7.9	[61,62]
Cardiovascular activity			
Electrocardiogram	It is a test that measures the electrical activity of the heartbeat [63].	39.1	[64-66]
Photoplethysmograph	It is an optical technique that can be used to detect blood volume changes in the microvascular bed of tissue [58].	9.4	[65,67]
Electrodermal activity			
Skin conductance level	It is the measurement of the electrical conductivity of the skin [60].	25.9	[65,66,68]
Surface electromyogram	It is a technique to measure muscle activity noninvasively using surface electrodes placed on the skin overlying the muscle [61].	25.6	[66,69,70]
Respiration			
Respiration	Respiration refers to a person's breathing and the movement of air into and out of the lungs [66].	17.5	[69,71]

[a]Prevalence is measured by the weighted search results from Scopus and PubMed, covering the period from 2010 to 2023, using the keywords "Name" AND "Pain" AND "Machine learning" as of August 1, 2023; the results are standardized on a scale of 0 to 100.

As shown in Table 2, video was found to be the most prevalent sensor in pain studies, with a prevalence score of 100. fMRI, electroencephalogram, and electrocardiogram were also frequently used, with prevalence scores of 95.9, 69.6, and 39.1, respectively. In contrast, fNIRS and photoplethysmography had much lower prevalence scores of <10.

Convenience and feasibility should also be considered when selecting sensors. For example, some sensors such as electroencephalograms and fMRI are nonwearable and can be invasive, which may limit their utility in certain settings. Moreover, complex signals require more sophisticated processing techniques and computing resources, which may not be practical in some situations, such as those involving microprocessors.

Facial Expression

Overview

Facial expression during the experience of pain is not unspecific grimacing but conveys pain-specific information. Studies investigating facial expressions of pain have most often used FACS [48], the gold standard for facial expression research. FACS is a fine-grained, objective, and anatomically based coding system that differentiates between 44 facial movements known as action units (AUs). Coders are trained to apply specific operational criteria to determine the onset and offset as well as the intensity of the AUs. Using FACS, it was shown that facial expressions of pain are composed of a small subset of facial activities, namely, lowering the brows (AU4), cheek raise or lid tightening (AUs 6 and 7), nose wrinkling or raising the upper lip (AUs 9 and 10), and eye closure for >0.5 seconds (AU 43). Prkachin and Solomon [72] developed the Prkachin and Solomon Pain Intensity metric based on this observation, which is a 16-level scale based on the contribution of the individual intensity of pain-related AUs and is defined as follows:

$$Pain = AU4 + (AU6, AU7) + (AU9 + AU10) + AU43$$

Figure 3 shows samples of different PSPI levels from UNBC-McMaster pain dataset. The list of pain-related AUs has been further expanded in more extensive research [73] to include lip corner puller (AU12), lip stretch (AU20), lips part (AU25), jaw drop (AU26), and mouth stretch (AU27).

XSL•FO
RenderX

Figure 3. Image frame samples of the UNBC-McMaster shoulder pain database. PSPI: Prkachin and Solomon Pain Intensity.

Facial activities during experimental and clinical pain are largely inborn but not uniform across individuals. People display different parts or combinations of facial activities. Cluster analyses identified four distinct facial activity patterns: (1) narrowed eyes with raised upper lip or nose wrinkling and furrowed brows, (2) narrowed eyes with furrowed brows, (3) narrowed eyes with mouth opening, and (4) raised eyebrows, which are less frequent and stable, often indicating novelty or surprise in response to pain. Recognizing these patterns improves pain detection more than focusing on a single expression. Thus, acknowledging variability in facial expressions can enhance pain communication.

Facial expression analysis uses spatial and spatiotemporal features. Spatial features capture static details of the face, such as the geometric and textural characteristics of the eyes, eyebrows, nose, lips, and facial contours, using techniques such as facial landmark detection, geometric feature extraction, Gabor filters, local binary patterns (LBPs), and histogram of oriented gradients (HOG). Spatiotemporal features capture dynamic changes in expressions over time using techniques such as optical flow or differences between consecutive frames. Advanced methods may involve 3D facial modeling or LSTM networks to identify temporal dependencies. Combining spatial and spatiotemporal features provides a comprehensive analysis of facial expressions.

Vision-Based Spatial Features

In the research conducted by Ashraf et al [74] and Lucey et al [75], features derived from the Active Appearance Model were input into support vector machine (SVM) classifiers for the purpose of frame-level pain recognition. In addition, they implemented pain detection at the sequence level by averaging the frame-level predictions. Gholami et al [76] used a Bayesian extension of SVM, known as the relevance vector machine, to differentiate between instances of pain and no pain in neonates. They also used this methodology to assess varying pain intensity levels. Meanwhile, Hammal et al [77] identified 4 levels of pain intensity through the use of log-normal filter-based features and an SVM classifier. Kaltwang et al [78] conducted a comparative study involving 3 separate methodologies. They used facial landmarks, discrete cosine transform, and LBP features to train 3 distinct relevance vector regression (RVR) models for estimating Prkachin and Solomon Pain Intensity. The best results were achieved by training an additional RVR model that consolidated the predictions from the 3 previously trained RVR models. The system [79] used a pyramid HOG for shape information and a pyramid LBP for appearance information, offering a more automated and objective approach to pain monitoring.

Pedersen [80] implementation used a 4-layer contractive autoencoder, along with SVM, which resulted in an effective pain detection system at the frame level. Egede et al [81] extracted features using both deep learning models and handcrafted methodologies. Facial landmarks, HOG, and deep vectors drawn from pretrained VGG-16 [82] and ResNet-50 [83] models were used. Rudovic et al [84] introduced a personalized federated deep learning technique for pain estimation derived from facial images. This approach involved using a compact convolutional neural network (CNN) architecture across various clients without the need to share their facial images. Contrary to the full sharing of model parameters, the personalized federated deep learning technique keeps the last layer localized. Hosseini et al [85] used a pretrained ResNet-18 model on the large emotion recognition dataset FER+ [86] and used transfer learning techniques to improve accuracy and performance. Huang et al [87] proposed a pain-awareness multistream CNN approach for feature extraction, focusing on specific regions most relevant to pain

XSL•FO
RenderX

expression instead of entire face images. Semwal and Londhe [88] proposed an Ensemble of Compact CNNs using 3 compact CNNs (variants of VGG, MobileNet, and GoogleNet) and integrating their predictions using the average ensemble rule. Kharghanian et al [89,90] developed a 4-layer convolutional deep belief network, trained as convolutional restricted Boltzmann machines to extract features. Semwal et al [91] introduced a novel fusion method for pain severity assessment in unconstrained environments using a decision-level fusion of 3 distinct features: data-driven red, green, blue color model (RGB) features, entropy-based texture features, and complementary features from both RGB and texture data. Using 3 CNNs (VGG-TL, ETNet, and DSCNN) with transfer learning, entropy texture network, and dual stream CNN, the model and various data augmentation techniques avoid overfitting and improve performance. The system demonstrates a 94% F_1-score on a self-generated dataset from an unconstrained hospital setting.

Alghamdi and Alaghband [92] presented a facial expressions–based automatic pain assessment system using 2 concurrent subsystems that analyze both the full face and upper half of the face through pretrained CNNs, such as VGG16, InceptionV3, ResNet50, or ResNeXt50. Dai et al [93] developed a real-time pain detection system by mixing pain and emotion datasets for optimal real-time performance and conducting a cross-corpus test. The study experiments with both AU-based and non–AU-based methods, ultimately implementing the method on a robot for frozen shoulder therapy, thus emphasizing the need for balanced and ecologically valid pain datasets and the importance of real-world application and testing. Karamitsos et al [94] use the Haarcascade frontal face detector (OpenCV) for face detection; then, faces undergo gray scaling, histogram equalization, cropping, mean filtering, and normalization. The CNN is built upon a modified VGG16 architecture, achieving an impressive 92.5% accuracy. Barua et al [95] used a shutter blinds–based model inspired by spontaneous facial expressions and patch-based learning to achieve >95% accuracy in pain detection from facial images, leveraging transfer learning for efficient deep feature extraction. The model uniquely uses horizontal dynamic-sized patches, or "shutter blinds," to mine hidden facial signatures. Semwal et al [91] assess pain severity in unconstrained hospital environments using a decision-level fusion of 3 distinct types of features: data-driven RGB, entropy-based texture, and complementary features. They used 3 CNNs (VGG-CNN with transfer learning, entropy texture network, dual stream CNN) and various data augmentation techniques to avoid overfitting. The system demonstrates a 94.0% F_1-score on a self-generated dataset from an unconstrained hospital setting.

Li et al [53] introduced a video-based infant monitoring system to analyze infant pain using 3 databases: Train-Data, Data-Clinic, and Data-YouTube. Using Fast Region-Based Convolutional Neural Network with object tracking and a hidden Markov model, the system precisely detects infant expressions and states. With a significant dataset from varied sources, including >16,000 images and real-world clinical videos, the approach offers enhanced accuracy and reliability in infant pain detection. Zamzmi et al [96] introduced a neonatal CNN that uses a cascaded architecture with 3 convolutional branches. This design merges image-specific and general information for pain detection. The neonatal CNN demonstrated 91% accuracy and 0.93 AUC on the Neonatal Pain Assessment Dataset and 84.5% accuracy on the Infant Classification of Pain Expression dataset. Witherow et al [97] developed Facial Expressions Fusing Betamix Selected Landmark Features (FACE-BE-SELF), a novel deep adaptive method for adult-child facial expression classification. It fuses facial landmark data with deep feature representations, achieving domain-invariant classification. Using a unique mixture of beta distributions, facial features are selected based on expression, domain, and identity correlations. The FACE-BE-SELF method stands out by concurrently adapting adult-child domains, providing a unified expression representation for both groups. Compared to standard approaches, it surpasses in aligning latent representations of expressions across age groups.

Vision-Based Spatiotemporal Features

Bargshady et al [98] present an ensemble deep learning model that combines a 3-stream hybrid neural network with CNNs to extract facial features and classify pain levels. The VGG-Face, integrated with principal component analysis (PCA), is used for early feature extraction, while a 3-layer hybrid of CNN and bidirectional LSTM is developed for late fusion classification. This approach, tested on multiple pain databases, surpasses competing models with an accuracy of >89%. Sparse Autoencoders for Facial Expressions-Based Pain Assessment [57] reconstructs the upper part of the face from input images and then feeds both the original and reconstructed images into 2 concurrent and coupled InceptionV3 using Sparse Autoencoders. This dual-input approach emphasizes the upper facial features, essential for pain detection. By eliminating the need for conventional preprocessing steps such as face detection and adeptly handling varying head poses, Sparse Autoencoders for Facial Expressions-Based Pain Assessment offers enhanced performance and accuracy across multiple datasets, even in challenging profile views. Karamitsos et al [94] modified temporal convolutional network algorithm and processed facial features extracted from fine-tuned VGG-Face and PCA combined with hue, saturation, and value color spaces. The temporal convolutional network–based approach showcases faster performance and higher efficiency, achieving an accuracy of 92.44% and an AUC of 85%. Bargshady et al [99] propose an enhanced joint hybrid CNN-Bidirectional LSTM network model by leveraging a fine-tuned VGG-Face for feature extraction and apply PCA to focus on the most significant features, improving computational efficiency. These features are then classified by a CNN-Bidirectional LSTM network hybrid network into 4 levels of pain intensity.

The 3D CNNs have gained attention in several studies. Tavakolian and Hadid [100,101] created a 3D CNN that captures dynamic facial representations from videos and emphasizes the typical use of a fixed temporal kernel depth in research, which often misses capturing different time ranges. In the study by Huang et al [102], a hybrid network by combining 3D, 2D, and 1D CNNs has been introduced to extract spatiotemporal, spatial, and geometric features from image sequences. Wang et al [103] used the convolutional 3D network for pain expression

XSL•FO
RenderX

recognition, which primarily uses a 3×3×3 convolutional layer. However, this method often fails to capture the full spectrum of facial expression variations. To address this, they combined 3 distinct features: 3D CNN, HOG, and geometric features using support vector regression for pain estimation. They integrated the convolutional 3D network for spatiotemporal facial feature extraction and used the HOG in 2D images for geometric information to discern pain levels in facial expressions. De et al [104] present a deep learning architecture, the Decomposed Multiscale Spatiotemporal Network (DMSN). It uses 3 innovative blocks, DMSN-A, DMSN-B, and DMSN-C, to efficiently capture varied facial dynamics across conditions such as depression and pain. DMSN-A block focuses on pain, which might vary rapidly. It uses a sequence of 3×1×1 temporal convolutions, capturing short to long temporal ranges. The studies by Granger and Cardinal [105] and Praveen et al [106] implemented weak-supervised domain adaptation, focusing on a shift from general affective expressions to specific pain expressions. Their framework used an inflated 3D CNN [107] with 3 convolutional layers and 3 inception modules, extracting both spatial and temporal data from videos.

Physiological Signals

Overview

While facial expressions are commonly used to identify pain, physiological signals are also a valuable modality for automatic pain detection. As detailed in the Pain Mechanism section, pain triggers changes in physiological signals, such as increased heart rate and skin conductivity, due to the activation of the SNS and peripheral nervous system [108]. Conversely, changes in physiological signals can indicate the presence of pain. However, extracting discriminative information from physiological signals is challenging. By contrast, they are objective indicators of pain because they cannot be artificially controlled [109], while exterior signals, such as facial expressions and gestures, may be unreliable, as individuals can deliberately disguise their behaviors. It makes physiological signals more reliable than exterior signals. In addition, physiological signals can be measured during daily life, while video and hand gestures can only be measured in laboratory settings. Thus, researchers have invested significant effort in exploring the feasibility of using physiological signals for pain assessment. Recent advances in sensor technology, signal processing, feature extraction, and ML algorithms are essential to the success of physiological signal–based automatic pain assessment.

This section provides a comprehensive review of the latest developments in pain detection approaches based on physiological signals. Four key components are exploited: (1) the use of modalities, (2) measurement devices, (3) feature extraction methods, and (4) ML models. The use of modalities refers to the type of physiological signals used for pain detection, including electroencephalogram, fMRI, electrocardiogram, and EDA. Measurement devices include both wearable and nonwearable devices, encompassing cardiac monitors, skin conductivity sensors, temperature sensors, accelerometers, and more. Feature extraction methods are techniques used to extract informative features from physiological signals, such as time-domain features, frequency-domain features, and time-frequency features. Finally, ML models, such as SVM, artificial neural networks, and random forest (RF), are used to classify pain based on the extracted features.

Electroencephalogram as a Pain Indicator

Electroencephalography is a noninvasive technique widely used in the automatic detection of pain. The electrodes detect electrical activity and amplify it, producing a graphical representation of the brain activity over time. Electroencephalogram recordings typically show a series of waveforms or oscillations that are grouped into different frequency bands, such as delta, theta, alpha, beta, and gamma. These frequency bands have been associated with different mental states and cognitive functions. Various studies have shown the potential of electroencephalogram-based pain detection, and different approaches have been proposed to extract discriminative features from electroencephalogram signals for pain classification. For instance, Panavaranan et al [110] extracted the power spectral density of an electroencephalogram using fast Fourier transform and used SVM to classify thermal pain. Hadjileontiadis et al [54] proposed a novel approach that analyzes wavelet higher-order spectral features of an electroencephalogram to predict tonic cold pain. Vijayakumar et al [111] extracted time-frequency wavelet representations of independent components from electroencephalogram data and trained a RF model to classify pain levels, achieving an intrasubject accuracy of 93.26%.

The use of electroencephalogram techniques for pain detection has great potential to provide objective measures of pain, as these methods directly measure brain activity related to pain perception. However, these techniques also have limitations, including high cost, limited availability, and the need for specialized expertise for data analysis.

fMRI as a Pain Indicator

fMRI is a powerful neuroimaging tool that measures changes in blood flow within the brain as a proxy for neural activity. By measuring changes in the blood oxygen level–dependent signal, fMRI can indirectly map changes in neural activity in response to a specific stimulus, such as a painful stimulus.

The fMRI technique has been widely used in pain research, revealing a network of brain regions that are activated by painful stimuli. These regions include the primary and secondary somatosensory cortex, thalamus, insular cortex, and anterior cingulate cortex, among others. The activation of these regions is believed to be involved in the sensory and affective components of pain processing.

Activation of these regions is thought to be involved in the sensory discrimination aspects of pain processing. Thus, neuroimaging techniques allow us to visualize and quantify brain activities and then quantify pain. It is frequently used in the research of automatic pain assessment. Wager et al [112] used the least absolute shrinkage and selection operator ML regression algorithm to recognize induced heat pain by assessing the fMRI activity patterns. Shen et al [60] derived primary, dorsal, and ventral visual networks from blood oxygen level–dependent fMRI scans by using independent component

XSL•FO
RenderX

analysis and used a ML algorithm SVM to distinguish between patients with chronic low back pain and healthy volunteers and achieved an accuracy of 79.3%. Tu et al [59] proposed a novel sliced inverse regression–based fMRI decoding method to reduce the fMRI data dimension and showed overperformance compared to traditional regularization-based decoding analyses (principal component analysis and discriminant analysis, partial least squares-discriminant analysis, and least absolute shrinkage and selection operator). Robinson et al [58] scanned fMRI and applied ML algorithms to classify patients with fibromyalgia and healthy volunteers.

Electrocardiogram as a Pain Indicator

An electrocardiogram is a widely used technique to measure the electrical activity of the heart and its changes during each cardiac cycle. The electrocardiogram waveform consists of several characteristic waves and intervals that correspond to the different phases of the cardiac cycle, including the P wave, QRS complex, and T-wave. By analyzing the size, shape, and timing of these waves and intervals, a wide range of cardiac conditions, such as arrhythmias, heart attacks, and heart failure, can be diagnosed. The use of electrocardiograms in pain detection assumes that pain can cause a physiological stress response, leading to cardiovascular changes that are related to the pain stimuli. The autonomic nervous system responds to pain by increasing sympathetic tension and decreasing parasympathetic tension, leading to an increase in heart rate and blood pressure. By analyzing the electrocardiogram signal, features that reflect the autonomic nervous system status, such as heart rate variability (HRV), can be extracted and used to detect pain.

Several studies have shown the potential of electrocardiograms for pain detection. Walter et al [34] collected electrocardiogram data from 90 subjects using heat as pain stimuli and created the BioVid dataset, which also included skin conductance level, sEMG, and video data. Adjei et al [56] performed spectral analysis on electrocardiogram data and extracted HRV features, such as the low-frequency (LF) component and high-frequency (HF) component, which were significantly correlated with pain level. Jiang et al [64] extracted time-domain and frequency-domain HRV features from electrocardiogram data to classify pain level and obtained an AUC of 0.82 in the receiver operating characteristic curve.

However, there are also studies that suggest a lack of correlation between HRV and pain level. Meeuse et al [113] found no significant correlation between HRV features and heat pain level in their study. It is important to note that an electrocardiogram alone may not be sufficient to accurately detect pain, and other physiological signals, such as skin conductance and electromyography, may need to be considered as well. Furthermore, individual differences in pain perception and the variability of pain stimuli may affect the reliability of pain detection using an electrocardiogram.

EDA as a Pain Indicator

EDA, also referred to as galvanic skin response, is a physiological gauge of the skin's electrical conductance. This conductance changes according to the functioning of sweat glands within the skin [114]. The measurement of EDA is a noninvasive process involving the placement of 2 electrodes, often on the fingers or palms. Activation of the SNS, triggered by situations such as stress or pain, leads to increased sweat gland activity, causing a rise in the skin's electrical conductance.

Within the context of automated pain recognition, EDA serves as a valuable indicator due to its reflection of SNS activity [115], which is closely linked to the body's response to pain. Numerous research studies have highlighted EDA's potential in pain detection. For instance, in the BioVid dataset developed by Walter et al [34], EDA was used as one of the methods, revealing a correlation between EDA features and the intensity of pain.

sEMG is another important tool for measuring EDA in automatic pain detection. sEMG can measure the electrical activity of muscles and has been used to measure facial expression [116] or muscle movement of specific body parts, such as the back muscles [117]. These measures can provide additional information about the pain experience and may be used in combination with other modalities for better pain detection accuracy [118].

Devices

Data collection is indeed crucial in research, especially in statistical and ML-based studies. It is essential to ensure that the data collected are accurate, informative, and clean. However, selecting the right measurement devices is crucial for obtaining high-quality data.

Table 3 is a summary of previously used measurement devices in pain assessment studies. Figure 4 [115-117] presents 3 typical types of devices used in physiological signal–based pain assessment: wristband, headset, and chest band. The importance of wearable devices in this context cannot be overstated; they enable ubiquitous, real-time data collection [119,120], especially with the rise of body sensor networks. This technological advancement allows for extensive data gathering in wearable and remote settings, making continuous monitoring both feasible and affordable.

There are several studies that have evaluated the usability and reliability of different measurement devices. Researchers can refer to these studies when choosing measurement devices for their own research. Ajayi et al [123] evaluated the Empatica E4 by comparing the results with nurse-recorded data and pooling questionnaires from participants. Nazari et al [124] tested the reliability of Bioharness and Fitbit measures of heart rate and activity at rest status. Rawstorn et al [125] evaluated the BioHarness by testing it on volunteers with both sinus rhythm and atrial fibrillation during simulated daily activities as well as low-, moderate-, and high-intensity exercises. Loberg et al [126] evaluated 4 different respiratory effort sensors and compared them with a respiratory sensor from NOX Medical as the golden reference device.

Feature Extraction

Overview

In the field of ML, pattern recognition, and image processing, feature extraction is a crucial step that involves transforming raw data into informative and nonredundant features to facilitate subsequent learning and generalization. Physiological signals typically carry implicit information that needs to be revealed through appropriate feature extraction techniques. While deep learning methods often generate features automatically, traditional ML methods require manual feature extraction.

For physiological signals, time window segmentation is commonly used to extract features. This involves segmenting the signals into chunks of equal time intervals and generating a row vector for each segment with 1 feature value for each feature, for example, the mean value of the segmentation. Physiological signal features can be classified into 4 categories: time-domain, frequency-domain, time-frequency-domain, and space-domain features.

Time-domain features describe the statistical and morphological properties of physiological signals, such as maximum value, SD, entropy, and mean R-R interval in electrocardiogram signals. Frequency-domain features characterize the spectral properties of signals, such as LF band power and low-high frequency ratio. Time-frequency-domain features consider both time-domain and frequency-domain properties simultaneously to account for the short duration and changing nature of physiological signals. Space-domain features, such as multispectral imaging and topography, are used to represent topographic characteristics of brain activity features, including electroencephalograms, fMRI, and fNIRS.

The complexity of physiological signals can guide feature selection. Signals with high stochastic stationarity and low signal-to-noise ratio, such as photoplethysmography and EDA, are considered low in complexity and can be represented by 1 or 2 feature domains. Signals with low stochastic stationarity and high signal-to-noise ratio, such as electrocardiogram, electroencephalogram, and fMRI, are high in complexity and require 3 to 4 feature domains to capture all relevant information. Nowadays, numerous Python libraries are available that facilitate the rapid extraction of features in physiological signals [127,128], electroencephalograms [129], video [130], and audio [131] domains. A summary of the commonly used features is presented in Table 4.

Brain Activity Features

Physiological signals, including electroencephalograms, fMRI, and fNIRS, have unique characteristics that require specific feature extraction techniques. Electroencephalogram signals, for example, have high topological complexity as multiple channels are measuring simultaneously. They can be divided into different frequency bands, such as delta, theta, alpha 1, alpha 2, beta 1, beta 2, gamma 1, and gamma 2. To assess pain, Panavaranan et al [110] used power spectral density features calculated using fast Fourier transform. Hadjileontiadis et al [54] combined continuous wavelet transform with higher-order statistics and spectra to create a new feature space for electroencephalograms. Rissacher et al [55] found temporal

XSL•FO
RenderX

parietal alpha of electroencephalograms to be a useful feature for pain assessment.

In fMRI, Tu et al [59] proposed a novel dimension reduction method by incorporating singular value decomposition into sliced inverse regression to overcome the limitations of sliced inverse regression when dealing with high-dimensional data. This method was used to assess pain, achieving 77.61% binary classification accuracy.

There are various feature extraction approaches for electroencephalogram signals, as summarized by Behzadfar et al [145]. For brain activity signals in general, van der Miesen et al [146] outlined the state and progress in pain detection using these signals.

Electrocardiogram Features

Unlike general statistical feature extraction methods, electrocardiogram feature extraction involves more human experience on electrocardiograms and is more interpretable. Shaffer et al [132] provided an overview of HRV features, covering time-domain, frequency-domain, and non-linear measures. Time-domain and frequency-domain features are widely used in pain assessment studies. On the BioVid dataset, Werner et al [147] derived mean resting rate, root mean square of successive differences, and slope resting rate from the electrocardiogram signal. Gruss et al [148], Campbell et al [149], and Kachele et al [150] used the same 3 features in their studies. Kachele et al [150] also applied 4-level wavelet decomposition on detected R peaks to extract the mean alpha 1 coefficients. Jiang et al [64] extracted time-domain features, such as average interval between normal heart beats, SD of normal heart beat intervals, root mean square of successive differences, and percentage of successive RR intervals that differ by more than 20 ms, and frequency-domain features, such as LF, HF, and LF or HF, from an electrocardiogram and attained an AUC of 0.82 for induced electrical pain and an AUC of 0.75 for induced thermal pain.

Apart from HRV, other features have been used for various purposes. For instance, some studies have used morphological features, such as QRS complex duration and amplitude, T-wave amplitude, and ST-segment changes, for diagnosing cardiac abnormalities [150].

EDA and Electromyography Features

EDA and electromyography are critical tools in pain detection because they measure physiological responses that are directly linked to the autonomic nervous system's reactions, which vary significantly with pain perception [114,151]. Walter et al [133] systematically gathered and summarized feature extraction methods for EDA or electromyography signals from previous research and categorized them into mathematical groups of (1) amplitude, (2) frequency [152], (3) stationarity [136], (4) entropy [153], (5) linearity [144], and (6) variability. In total, 33 different features were listed, and their efficiency in pain assessment on the BioVid dataset was proved. Then, Gruss et al [148] deployed the feature table and derived it to 39 features. Campbell et al [149] also developed a feature list based on the study by Walter et al [133]. They also proposed a ML-based feature selection approach that deploys univariate feature selection and sequential forward selection for 100 epochs, with cross-validation as the metric to explore the optimal feature set. From their results, a relationship table between features and pain was displayed, illustrating the discriminative strength of features. In addition, amplitude, power, and unique functional features of electromyography signals are noted as useful in all different feature sets. Table 4 summarized the features used in previous studies.

Models

Overview

In the field of ML, the "no free lunch" theorem has been referred to often when talking about model selection [154]. This theorem illustrates that "any two optimization algorithms are equivalent when their performance is averaged across all possible problems," which implies that no single algorithm always has the best performance for all ML tasks. Thus, appropriate model selection is necessary for the success of ML-based pain assessment. In this section, we compare different ML algorithms by illustrating their advantages and disadvantages and their applicable scenarios. Table 5 provides a summary of the prevalent ML algorithms used in pain assessment.

Table 5. Summary of the prevalent machine learning algorithms used in pain assessment studies.

Model	Advantages	Disadvantages	Reference
Support vector machine	• Suitable for small datasets • Takes advantage of kernel functions	• Low performance in multiclass tasks	[64,71]
Decision tree	• Easily interpretable • Computation friendly	• High risk of overfitting • Discards correlations between features	[155]
Random forest	• Applicable on large datasets • Fixes the overfitting problem of decision tree • Easy to parallelize	• Low performance on low-dimensional datasets • Time consuming	[156,157]
Neural networks	• High performance with large amounts of data • Flexible with layer configurations	• Uninterpretable • Computation consuming	[158,159]

RenderX

SVM for Pain Classification

The first commonly used ML model in physiological signal–based automatic pain detection is SVM [64,71]. SVM is a type of generalized linear classifier that classifies data in a supervised learning way [160]. Its decision boundary is the maximum margin hyperplane for learning samples. SVM also includes kernel tricks, which makes it a substantially nonlinear classifier. The final decision of SVM only depends on the support vectors, which makes it suitable for small sample learning. On the contrary, SVM lacks the ability to provide restoration of variables to the formation of derived predictors [161], which is important in some areas such as financial prediction and health applications. In addition, SVM requires delicate preprocessing and tuning to acquire the best performance. Panavaranan et al [110] applied polynomial kernel SVM on electroencephalogram data and obtained an accuracy of 96.97%. Gruss et al [148] used SVM on the BioVid dataset and gained 90.94% accuracy on pain tolerance classification. In addition, Jiang et al [64] obtained an AUC of 0.82 with the use of SVM. More recently, Badura et al [71] achieved 94% accuracy using Gaussian kernel SVM.

Decision Tree for Pain Classification

Unlike SVM, decision tree is known for its interpretable characteristic. The decision tree algorithm is a method of approximating the value of a discrete function [162,163]. It is a typical classification method that uses an induction algorithm to generate readable rules and decision trees and then uses decision-making to analyze the new data. Essentially, a decision tree is a process of classifying data through a series of rules. Because of their inherent interpretability, tree-based algorithms help ML processes move beyond the "black box" model [164]. By contrast, due to the simple structure of tree-based models, overfitting easily happened on tree-based models [165]. Besides, they lack the ability to deal with missing data due to the continuity of tree structure.

RF for Pain Classification

RF is an algorithm that integrates multiple trees through the idea of ensemble learning. Its basic unit is a decision tree, and essentially, it belongs to a large branch of the ML "ensemble learning" method. Intuitively, each decision tree acts as a classifier, so for a given input sample, N decision trees will produce N classification results. RF integrates all classification voting results and designates the category with the most votes as the final output, which is a "bagging" idea. With the tree base and bagging theory RF holds, it has advantages such as preventing overfitting, easy to parallelize, and friendly with high-dimensional data [166]. In contrast, RFs require more time for training and prediction compared to decision trees. Vijayakumar et al [111] applied RF on 25 subjects' electroencephalogram data and obtained 89.45% accuracy. Naeini et al [167] used RF on the BioVid dataset and achieved an accuracy of 79%. Werner et al [168] used RF on their new "X- ITE" dataset and achieved 94.3% accuracy for phasic electrical pain classification.

Neural Networks for Pain Classification

NN have also been used by scholars for automatic pain detection [158,159]. NN abstracts the human brain neuron network from the perspective of information processing, establishes a certain simple model, and composes different networks according to different connection structures. Thanks to the development of the digital society, the amount of data available for ML has grown substantially. NN, which can go deep in its layer structure, can reveal implicit information from data. Therefore, as the amount of data grows, the performance of NN keeps increasing, while traditional algorithms, such as SVM and RF, are limited. Nevertheless, NN has the defect of "black box" characteristic. Such uninterpretability keeps NN from blooming in certain fields, such as text and code analysis [169], judicial decision, and artificial intelligence medicine, because such fields require a clear, understandable, and interpretable decision-making process. Martinez et al [170] used NN on the BioVid dataset and obtained 82.75% accuracy on multitask classification. Jiang et al [69] applied an artificial neural network on 30 subjects and gained an average accuracy of 83.3%. The deviation of neural networks is widely used in automated pain assessment, such as CNN [156], RNN [171], and LSTM neural network [172].

Audio Analysis

Infant crying is a common sign of discomfort, hunger, or pain. It conveys information that helps caregivers assess the infant's emotional state and react appropriately. Crying analysis can be divided into two main stages: (1) the signal processing stage, which includes preprocessing the signal and extracting representative features; and (2) the classification stage. We classified the existing methods of signal processing stage into (1) time-domain methods; (2) frequency-domain methods; and (3) cepstral-domain methods.

Time-domain analysis is the analysis of a signal with respect to time (ie, the variation of a signal's amplitude over time). Linear prediction coding is one of the most common time-domain methods for analyzing sounds. The main concept behind linear prediction coding is the use of a linear combination of the past time-domain samples to predict the current time-domain sample. Other time-domain features that are commonly used for infants' sound analysis are energy, amplitude, and pause duration. Vempada et al [49] presented a time-domain method to detect discomfort-relevant cries. The proposed method was evaluated on a dataset consisting of 120 cry corpuses collected during pain (30 corpuses), hunger (60 corpuses), and wet diaper (30 corpuses). We want to note that the paper does not provide information about the stimulus that triggered the pain state or the data collection procedure. The infants' age ranges from 12 to 40 weeks. All corpses were recorded using a Sony digital recorder with a sampling rate of 44.1 kHz. In the feature extraction stage, two features were calculated: (1) short-time energy, which is the average of the square of the sample values in a suitable window; and (2) pause duration within the crying segment. Part of these features were used to build SVM, and the remaining features were used to evaluate its performance. The recognition performance of pain cry, hunger cry, and wet diaper cry were 83.33%, 27.78%, and 61.11%, respectively. The average recognition rate was 57.41%.

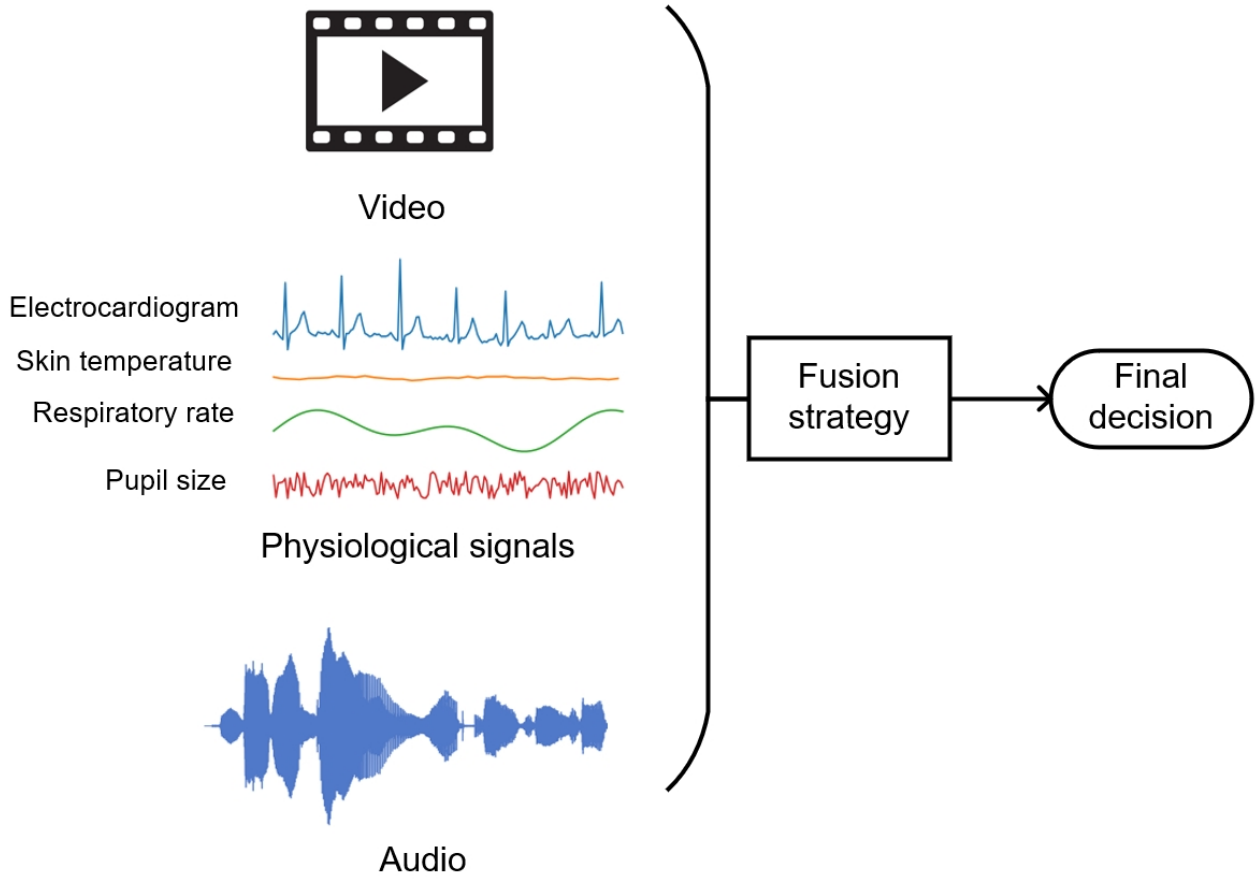
RenderX

Pupil Size

The measurement of changes in pupil size has been shown to be a promising physiological indicator of pain intensity. Pupil size can be used to monitor the effects of painful stimuli in the brain. The pupil dilates in response to pain due to the activation of the sympathetic branch, which releases norepinephrine, and the inhibition of the parasympathetic branch, which is responsible for constriction of the pupil. This section discusses the mechanism of using pupil dilation as a pain indicator and literature reviews of using pupil dilation for automated pain assessment.



The pupil dilation is a complex physiological response regulated automatically by 2 muscles in the eye, the sphincter pupillae and the dilator pupillae. The sphincter pupillae is controlled by the parasympathetic system to contract the pupil, while the dilator pupillae is dominated by the sympathetic system to dilate the pupil [50].

Höfle et al [51] investigated the influence of different luminance conditions on pupillometry for pain detection and found that the baseline pupil size values significantly differed under different luminance conditions, while the peak dilation remained the same. Bertrand et al [173] explored the influence of gender and anxiety on pupil dilation for pain detection and concluded that pupil dilation changes similarly in both men and women and are exacerbated in the presence of anxiety. Connelly et al [52] conducted an experiment on 30 children undergoing elective surgical correction of pectus excavatum and found that maximum pupil size, percent change in pupil size, and maximum constriction velocity were the most related features to pain intensity. Chapman et al [174] reported a delay of 1.25 seconds in 20 adult volunteers under noxious stimulation, while Eisenacha et al [175] reported a peak in pupil size with a lag of 4.25 seconds after the onset of heat pain on 28 adult volunteers. Wang et al [176] found that the pupillary response together with ML algorithms could be a promising method of objective pain level assessment by measuring pupillary response during induced cold pain on 32 subjects.

Multimodal Pain Detection

Including more modalities can possibly increase information density, which leads to increased accuracy. Thus, researchers have been increasingly turning to multimodal approaches to enhance the accuracy and reliability of automated pain assessment systems. These approaches combine information from multiple modalities, such as biomedical signals and facial expressions, to provide a more comprehensive understanding of the patient's pain experience. Furthermore, a multimodal approach can capture a more nuanced and diverse range of pain responses, which is particularly important given the wide variation in pain perception among individuals with different characteristics and cultural backgrounds. Figure 5 presents a typical flow of multimodal pain assessment.

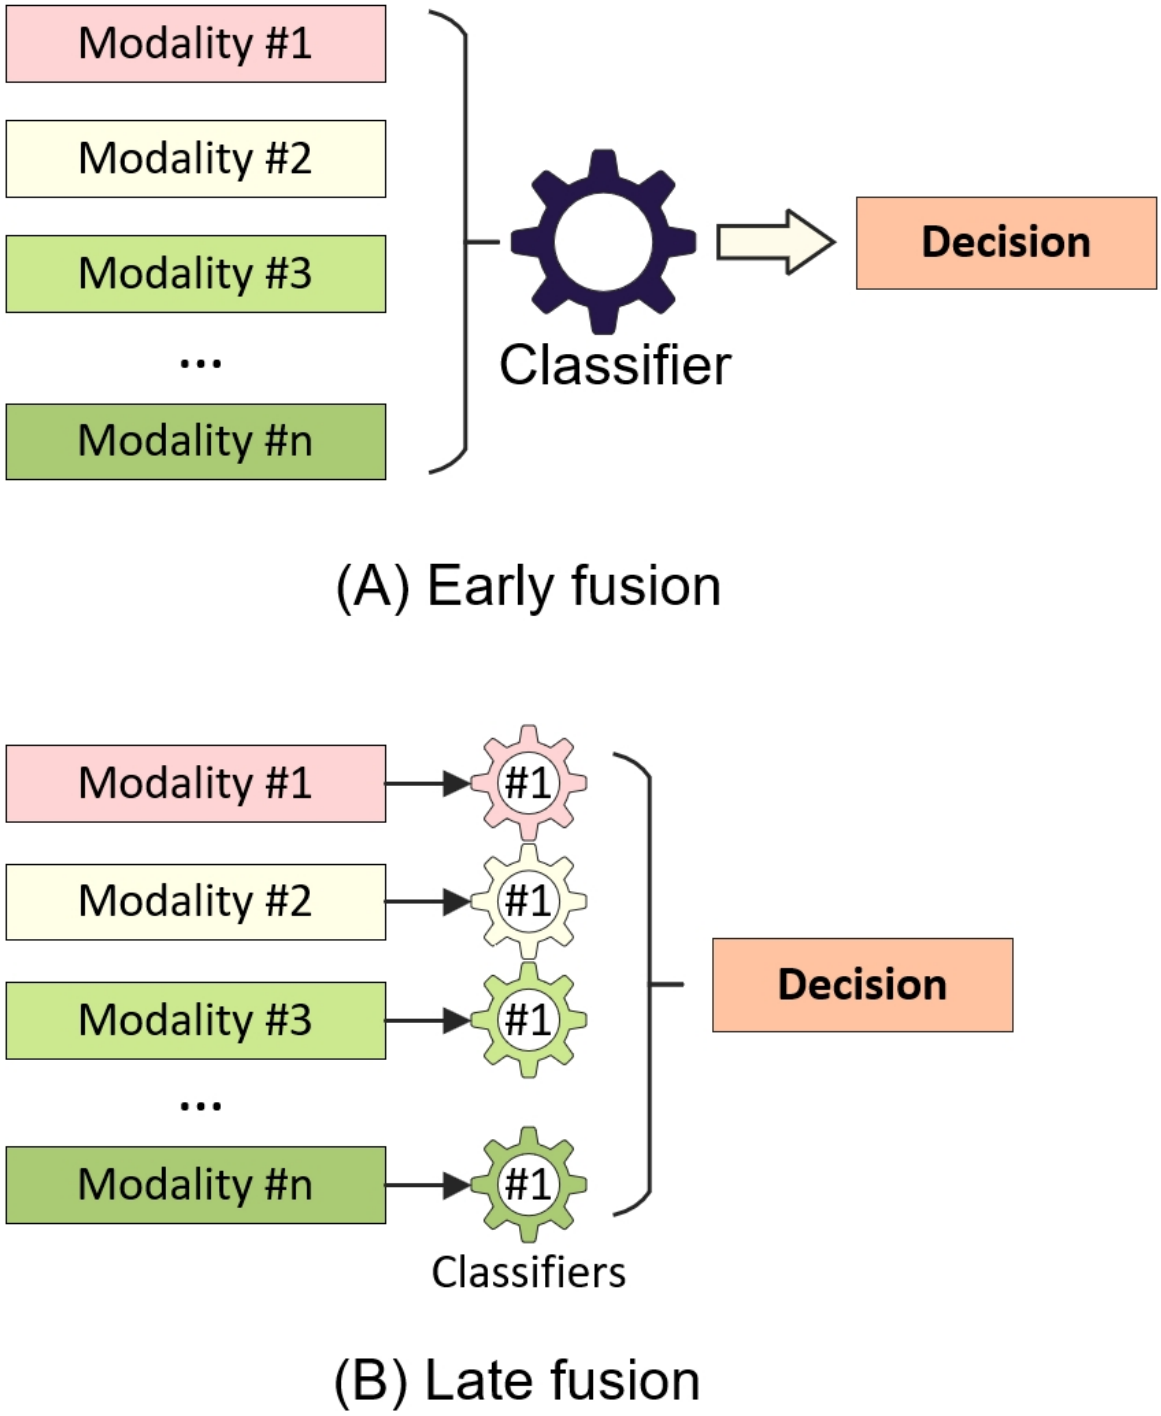


Figure 5. Multimodal pain assessment.

XSL•FO
RenderX

Fusion strategies commonly used in multimodal pain assessment can be categorized into early fusion and late fusion. Early fusion involves the combination of features from different modalities before the training of a classifier, while late or decision fusion combines the predictions of individual classifiers after training. Common methods of combining predictions include fixed methods such as taking the mean or product and trainable methods such as using a pseudoinverse. Figure 6 illustrates the early and late fusion strategies. Some research has explored combining early and decision fusion by merging specific features at the feature level and then fusing those with other features at the decision level [46].

Figure 6. Fusion strategies.

The first study to combine video and physiological signals for automated pain detection was conducted by Werner et al [147], who used an early fusion strategy to concatenate features from both modalities. The optimal fusion set is found to be the combination of all video and physiological signals, achieving accuracies of 80.6% and 77.8% for person-specific and generic classifiers, respectively, in detecting baseline and highest tolerable pain using a RF ensemble–based classifier. Kachele et al [177] applied both early and late fusion strategies using SVM with linear kernel and RF for recognizing baseline and

XSL•FO
RenderX

highest tolerable pain, achieving accuracies of 68.2% and 76.6% for early and late fusion, respectively.

Continuing the BioVid dataset, Kachele et al [178] applies early and late fusion techniques with new features included, achieving slightly better results with late fusion (83.1%) than early fusion (82.7%). Thiam et al [179] proposed a hierarchical fusion architecture that divides multimodal data into 3 subsets. These subsets are used for the first layer of RF training, followed by pseudo-inverse mapping, multilayer perceptron mapping, and a final layer that combines both pseudo-inverse and multilayer perceptron fusion mapping. Kessler et al [180] took advantage of the fusion strategy proposed by Thiam et al [179] and applied it to remote photoplethysmography.

Other studies focus on incorporating additional modalities, such as audio. Velana et al [37] published the SenseEmotion database, which captures video, physiological signals, and audio for the first time. Thiam et al [181] merged features from video, physiological signal, and audio data on the SenseEmotion dataset, exploring different data fusion strategies, including early fusion, group late fusion, and individual late fusion. Results show that individual late fusion outperforms other strategies slightly on leave-subject-out experiment, while group late fusion slightly outperforms on user-specific task. There is also a dataset for neonatal pain assessment that includes video, audio, and physiological signals [46,171].

Recent studies have explored new fusion approaches. Bellmann et al [182] proposed a dominant channel fusion approach that identifies the most relevant input channel and combines it with the remaining channels to create an ensemble of classifiers. Bellman et al [183] proposed a novel late fusion approach that combines a mixture of experts and stacked generalization approaches and is assessed on different datasets involving the biophysiological modalities electromyography, electrocardiogram, and EDA. Thiam et al [159] proposed an information theoretic approach that uses a deep denoising convolutional autoencoder to learn and aggregate latent representations based on each input channel.

However, it is evident that late fusion, using multiple models as part of an ensemble learning approach, requires significantly more computational power and storage space compared to early fusion methods. As pain assessment is an emerging field, the current focus is predominantly on enhancing predictive accuracy rather than on resource use, and discussions on model complexity are relatively scarce. However, with the advent of Tiny ML and the rise of edge computing [184], running large models on microprocessors becomes challenging. Consequently, early fusion might gain popularity on edge devices, where the ability to run simpler, more compact models efficiently is crucial. This shift could make early and lightweight fusion approaches more viable and preferred in scenarios where computational resources are limited. In addition, with the increasing inclusion of multimodal data, we can envisage future fusion methods potentially incorporating recently developed self-attention algorithms [185].

Discussion

The pain assessment field is faced with several challenges and opportunities for future development. This section will focus on 3 areas of concern—data, ML techniques, and ethical considerations—and then propose future research directions.

Data

Automatic pain assessment is challenged by the limited availability of clinical pain data, as most studies have focused on experimental or induced pain. Widely used datasets such as BioVid, BP4D+, and X-ITE are collected from healthy volunteers and use external thermal or electrical pain. These studies are conducted under consistent experimental conditions that differ from real-world scenarios. Furthermore, induced pain has different mechanisms than disease pain, which encompasses different types of pain, such as nociceptive and central pain. Therefore, it is important to test models trained on experimental data using clinical pain data. In addition, more clinical pain data should be collected to facilitate the development of automatic pain assessment models and enable their use in clinical trials.

Pupil dilation has been identified as a promising indicator of brain activity and pain levels. However, in previous studies, pain was often used as the stimuli for measuring brain activity, rather than the focus of the study. Consequently, only a few studies have directly correlated pupil dilation with pain levels. A potential research direction is to include pupil dilation in the automatic pain assessment modality family. Pupil dilation has been shown to be effective in affective computing, with datasets such as the MAHNOB-HCI and SEED containing eye-tracking data that demonstrate the contribution of pupil data to arousal detection. As pain can also be regarded as physiological arousal, transferring pupil dilation to automatic pain assessment studies is a worthwhile area of research.

Personalization of Pain Responses

In the following subsection, we explore personalized pain detection, focusing on the considerable differences in pain experiences among individuals. Pain perception varies widely due to a mix of biological factors and social-psychological influences. These differences are shaped by demographics such as gender, age, and ethnicity, which are linked to varying rates of chronic pain. In addition, factors such as genetic predispositions and psychological processes also significantly impact pain responses, whether in clinical settings or experimental scenarios. Importantly, these elements interact in complex ways, crafting the unique pain experiences of everyone. Research has highlighted that genetic markers associated with pain can differ across genders and ethnicities and interact with psychological aspects such as stress, affecting pain perception. These myriads of interacting factors culminates in a distinctive set of influences for each person's experience of pain [186].

Jiang et al [187] introduced a method that enhances pain assessment by incorporating personalized features. They used ML to analyze individual pain data, enabling the model to tailor its predictions to each patient's unique physiological and psychological characteristics. This approach improves the accuracy of pain management by adapting to personal pain

XSL•FO
RenderX

profiles. Casti et al [188] developed a platform to improve pain diagnosis by leveraging personalized data. Using a combination of visual, speech, and physiological indicators, they used ML techniques to tailor assessments to individual patient profiles, enhancing the precision and effectiveness of pain management strategies. Martinez et al [189] proposed a method to refine pain estimation by integrating personalized features. They used ML to analyze individual facial expressions, allowing the model to adjust its predictions based on each person's unique facial expressiveness score. This approach enhances the accuracy of Visual Analog Scale estimations by adapting to individual pain profiles [189].

Most papers on personalized pain assessment claim personalization at the model level, focusing on enhancing ML models to suit individualized approaches or using ML techniques to delve deeper into databases for extracting personalized information to improve predictions. The predominant reliance on public databases for research is evident, as most researchers use these readily available datasets. This reliance restricts personalization efforts to the data provided by these databases, making highly tailored training challenging. In addition, most pain-related datasets globally are derived from experiments involving artificially induced pain, which must pass rigorous ethical or clinical trial reviews, further limiting the quantity of available data. Looking to the future, personalization will undoubtedly be a crucial focus. It is foreseeable that researchers will collect more personalized data during experiments, including variables such as personality traits and ethnicity. This will likely lead to the generation of more nuanced datasets that include varied physiological responses to different pain stimuli, enhancing the granularity and effectiveness of personalized pain management solutions.

Real-Time Pain Detection

Building on our earlier discussion about the personalization of pain responses, it is essential to delve into another critically relevant clinical application: real-time monitoring [190]. The goal of such monitoring is not just to detect pain but to enable timely and effective interventions that can significantly enhance patient outcomes. Real-time monitoring of pain becomes particularly crucial in postoperative care, where accurately gauging a patient's pain levels is vital for adjusting analgesic dosages. This not only helps in managing the pain effectively but also minimizes the risk of both undermedication and overmedication, which can lead to complications such as opioid dependency or inadequate pain relief. In ICUs, the stakes are even higher. Many patients in ICUs are unable to communicate due to their conditions or sedation, making verbal reports of pain unreliable. Here, real-time monitoring systems can play a transformative role by continuously tracking pain indicators through physiological signals such as heart rate, blood pressure, and facial expressions. These data can then be analyzed to provide a dynamic, real-time assessment of pain, informing caregivers when an intervention is necessary. Moreover, real-time monitoring integrates seamlessly with the concept of personalized pain management. By continuously collecting and analyzing data specific to each patient, health care providers can tailor their interventions more precisely to the individual's pain profile and response to treatment. This approach not only improves the quality of care but also enhances patient comfort and satisfaction. As technology advances, the potential for real-time pain monitoring grows. Innovations in wearable technology, ML algorithms, and data integration are paving the way for even more accurate and responsive pain management systems. These systems promise to transform how pain is managed in health care settings, making care more proactive, patient centered, and effective.

In the academic sphere, the development of real-time pain monitoring is primarily concentrated on 2 aspects: improving model efficiency to enable fast judgments suitable for real-time applications and developing practical tools such as wearable devices and mobile apps to facilitate widespread implementation. Enhancing the processing speed of models involves not only maintaining accuracy but also integrating advanced ML technologies, such as deep learning. Meanwhile, the development of tools such as wearables and mobile apps allows for the noninvasive collection of physiological data and real-time analysis, helping patients and health care providers to promptly assess pain levels and treatment effectiveness. This combination of improved models and practical tools is driving pain management toward more precise, personalized, and proactive solutions. Kong et al [191] introduced a smartphone app that enhances real-time pain detection using EDA signals collected from a wrist-worn device. They tested the app with thermal grill and electrical pulse data, demonstrating high accuracy in pain detection with a RF model. This approach offers a practical solution for objective, near–real-time pain assessment in everyday settings. Dai et al [93] address automatic pain detection using a mix of pain and emotion datasets to enhance model robustness, achieving 88.4% accuracy. They criticize CNNs for overfitting on biased data and validate their method through experiments on a humanoid robot in physiotherapy, emphasizing the importance of real-time, real-world testing and assessing the system's practical utility and accuracy.

In summary, the advancement of real-time pain monitoring represents a significant enhancement in health care, enabling precise and timely interventions that are tailored to the unique needs of each patient. This technology not only improves the accuracy of pain assessments but also enriches the quality of care by integrating cutting-edge ML models and wearable technologies. As this field continues to evolve, it holds the promise of transforming pain management into a more responsive, personalized, and patient-centered practice.

ML Techniques

Although deep learning has revolutionized computer vision and physiological signal analysis, traditional ML algorithms still dominate the field of physiological signal–based automatic pain assessment. One possible reason for this is that deep learning requires extensive data, which is time consuming and resource intensive to collect. Therefore, studies often include only a small number of participants, typically in the tens, making it difficult to gather comprehensive datasets.

In this context, transfer learning, a prominent topic in artificial intelligence, offers a promising alternative solution. Transfer learning involves applying knowledge gained from a source

XSL•FO
RenderX

domain to a new target domain, which can be particularly useful in scenarios where data collection is challenging. Differing data distributions between the source and target domains can lead to performance degradation if models are applied directly. Transfer learning helps bridge this gap, ensuring better model performance across different settings [192].

Kächele et al [193] proposed an adaptive confidence learning method for personalizing pain intensity estimation systems, demonstrating the efficacy of transfer learning in this field. Feature extraction involved specific preprocessing steps for each signal type, such as bandpass filtering and artifact correction for electromyography. A multistage ensemble classifier was applied to learn the confidence of a regression system. This method involved selecting confident samples from unlabeled data of the test participants to iteratively adapt the model. Their experiments showed that the adaptive learning approach significantly improved the performance of pain intensity estimation.

Chen et al [194] implemented "TrAdaboost," a transfer learning algorithm, to improve facial expression recognition, including pain expressions. They used the PAINFUL database, which contains video sequences of 25 patients with shoulder injuries, encompassing 48,398 frames of spontaneous pain expressions. The primary challenge addressed was the variability in pain expressions across different individuals. They proposed an inductive transfer learning algorithm to develop person-specific models. This algorithm first trains a set of weak classifiers on source data from multiple subjects and then selects the most relevant classifiers for the target subject. Experimental results showed that inductive transfer learning significantly improved pain detection accuracy. For example, the AUC for pain detection increased from 0.769 to 0.782 with just 10 target samples and reached 0.891 with 100 samples. Furthermore, this approach drastically reduced training time compared to traditional methods, making it feasible for rapid retraining in clinical settings.

While traditional ML remains prevalent in automatic pain assessment due to data constraints, transfer learning presents a viable alternative. It addresses the challenges associated with varying data distributions and limited dataset sizes, enhancing model robustness and performance. Future research should explore the potential of transfer learning algorithms further, integrating them into clinical practice to improve pain management outcomes.

Ethical Considerations

Automatic pain assessment raises several ethical concerns that need to be addressed. One primary concern is the privacy and security of patients' health data. The use of physiological signals, such as facial expressions, speech patterns, and pupil dilation, to assess pain levels can lead to the collection of sensitive health data. Therefore, it is essential to ensure that the data collected are secure and protected from unauthorized access.

Another ethical consideration is the potential for bias in automatic pain assessment models. ML models are only as good as the data they are trained on, and if the training data are biased, the model will be biased too. Bias can result in inaccurate pain assessment, leading to inadequate pain management and, in some cases, even harm to patients. Therefore, it is crucial to ensure that the data used to train the models are representative and unbiased.

Future Directions

Automated pain assessment has made significant strides in recent years, leveraging technological advancements and data-driven approaches to enhance the accuracy and efficiency of pain detection. However, several promising directions for future research remain unexplored. Addressing these areas could lead to the development of more sophisticated and reliable automated pain assessment systems.

First, integrating data from various sources, such as pupil dilation, voice analysis, and body movement, could offer a more comprehensive understanding of pain. This requires a more comprehensive, clinical, and clean database to be released. Second, exploring novel deep learning architectures, including transformer-based models and generative adversarial networks, may yield improved performance in pain assessment tasks. These architectures could capture intricate patterns and dependencies within pain-related data, leading to enhanced predictive capabilities. Third, collaboration with health care professionals is crucial to validate the effectiveness and reliability of automated pain assessment systems in real-world clinical settings. Integrating these systems into clinical workflows could provide valuable insights and assist health care providers in making informed decisions. Finally, using transfer learning can provide new insights. In scenarios where large, annotated datasets are scarce, exploring transfer learning techniques and methods to adapt models to smaller datasets could prove beneficial. These approaches could enable the development of accurate pain assessment models even with limited training data.

Conclusions

This survey reviewed the current advancements in automated pain assessment using ML techniques. Traditional pain assessment methods, reliant on self-reports and observational scales, face significant limitations, particularly for patients who are noncommunicative. We explored various modalities for automated pain detection, including facial expressions, physiological signals, audio, and pupil dilation. While each modality has its strengths, combining multiple modalities can enhance accuracy but also introduces challenges in data fusion and model complexity. Despite progress, challenges remain, such as the scarcity of diverse clinical pain datasets and ethical concerns regarding patient privacy. Personalized pain assessment models are also necessary due to variability in pain perception across populations. Future research should focus on developing more robust algorithms and leveraging deep learning and transfer learning. Collaborative efforts to create comprehensive pain datasets are crucial, as is integrating real-time pain monitoring into clinical practice. In summary, automated pain assessment has the potential to transform pain management. Continued interdisciplinary research and collaboration are key to overcoming current challenges and fully realizing these technologies' benefits.

Abstract

Background: Physician autonomy has been found to play a role in physician acceptance and adoption of artificial intelligence (AI) in medicine. However, there is still no consensus in the literature on how to define and assess physician autonomy. Furthermore, there is a lack of research focusing specifically on the potential effects of AI on physician autonomy.

Objective: This scoping review addresses the following research questions: (1) How do qualitative studies conceptualize and assess physician autonomy? (2) Which aspects of physician autonomy are addressed by these studies? (3) What are the potential benefits and harms of AI for physician autonomy identified by these studies?

Methods: We performed a scoping review of qualitative studies on AI and physician autonomy published before November 6, 2023, by searching MEDLINE and Web of Science. To answer research question 1, we determined whether the included studies explicitly include physician autonomy as a research focus and whether their interview, survey, and focus group questions explicitly name or implicitly include aspects of physician autonomy. To answer research question 2, we extracted the qualitative results of the studies, categorizing them into the 7 components of physician autonomy introduced by Schulz and Harrison. We then inductively formed subcomponents based on the results of the included studies in each component. To answer research question 3, we summarized the potentially harmful and beneficial effects of AI on physician autonomy in each of the inductively formed subcomponents.

Results: The search yielded 369 studies after duplicates were removed. Of these, 27 studies remained after titles and abstracts were screened. After full texts were screened, we included a total of 7 qualitative studies. Most studies did not explicitly name physician autonomy as a research focus or explicitly address physician autonomy in their interview, survey, and focus group questions. No studies addressed a complete set of components of physician autonomy; while 3 components were addressed by all included studies, 2 components were addressed by none. We identified a total of 11 subcomponents for the 5 components of physician autonomy that were addressed by at least 1 study. For most of these subcomponents, studies reported both potential harms and potential benefits of AI for physician autonomy.

Conclusions: Little research to date has explicitly addressed the potential effects of AI on physician autonomy and existing results on these potential effects are mixed. Further qualitative and quantitative research is needed that focuses explicitly on physician autonomy and addresses all relevant components of physician autonomy.

Introduction

The use of artificial intelligence (AI) systems in medicine has increased significantly in recent years. AI in medicine can take a number of forms and fulfill a number of tasks, ranging from risk prediction or diagnosis and screening to AI-powered clinical decision support systems (CDSS) [1]. AI systems have also been introduced across a range of medical specialties, including oncology, pulmonology, and radiology [2].

Physician autonomy has been found to play a role in physician acceptance and adoption of medical technologies [3], and in particular, AI [1]. Although physician autonomy has become an increasingly important concept in recent decades [4-7], there is still no consensus definition in the literature. However, physician autonomy is generally seen as including both clinical freedoms, as well as social and economic freedoms [6,7]. The former concerns physician autonomy in clinical practice, including their control over the diagnosis and treatment of patients and over evaluations of their care. The latter concerns the autonomy of physicians as professionals, including their choice of specialty and control over the nature and volume of their tasks [5]. A number of recent reviews have found that the feared loss of physician autonomy represents a barrier to the acceptance of AI [1,8-10]. However, although these reviews (partially) address physician autonomy as a barrier to acceptance, there is little research so far focusing primarily on the effects of AI on physician autonomy. Furthermore, such reviews rarely systematically address both clinical, social, and economic freedoms.

Our aim is to begin to fill this gap by performing a scoping review of qualitative studies on AI and physician autonomy. In particular, this review addresses the following research questions: (1) How do these studies conceptualize and assess physician autonomy? (2) Which aspects of physician autonomy are addressed by these studies? (3) What are the potential benefits and harms of AI for physician autonomy identified by these studies? To address research question 1, we investigate whether and how the studies include physician autonomy as a research focus in their interview, survey, and focus group questions. To answer research question 2, we identify the components of physician autonomy addressed by the studies based on the 7-component model proposed by Schulz and Harrison [5]. For each of these components, we then inductively form subcomponents based on the results of the included studies. To answer research question 3, we summarize the potential benefits and harms of AI for physician autonomy reported by the included studies in each subcomponent. These questions lend themselves to a scoping review approach, rather than a systematic review since we aim to answer broader conceptual and methodological questions, rather than perform a risk of bias assessment or meta-analysis [11].

Methods

Search Strategy

We performed a scoping review of qualitative studies on AI and physician autonomy and drafted the paper according to the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) checklist (Multimedia Appendix 1) [11]. We searched MEDLINE and Web of Science using a search string based on the following combination of concepts: “Physician” AND “Artificial Intelligence” AND “Autonomy” AND “Qualitative Research.” The complete search terms for both databases (including Medical Subject Headings terms and keywords) can be found in Multimedia Appendix 2. The cutoff date for the search was November 6, 2023.

Screening

After removing duplicates, the titles and abstracts of the remaining studies were screened by 2 authors (JD and LH) according to predefined inclusion and exclusion criteria (Textbox 1). This was followed by a screening of the remaining full texts. Disagreements and concerns regarding the results were resolved in consultation with a third researcher (JG).

Textbox 1. Inclusion and exclusion criteria.

Inclusion criteria

- Empirical, qualitative, or mixed methods study
- Focus on artificial intelligence (AI) in clinical care
- Physician autonomy addressed in the study
- The study population includes physicians
- English or German language

Exclusion criteria

- Nonempirical or purely quantitative study
- No focus on AI
- Focus on AI in veterinary medicine or public health
- Physician autonomy not addressed in the study
- The study population does not include physicians
- Language other than English or German

XSL•FO
RenderX

Data Extraction and Synthesis

For each included study, we first extracted relevant study characteristics, including country, design, and study population, as well as the AI system under consideration. We also ascertained whether the included studies explicitly include physician autonomy as a research focus and reviewed supplemental material, where available, to determine whether their interview, survey, and focus group questions explicitly name physician autonomy or implicitly include aspects of physician autonomy. We then extracted the qualitative results of the studies, categorizing them into 7 components of physician autonomy introduced by Schulz and Harrison [5]. This categorization contains 3 social and economic freedoms (Textbox 2) and 4 clinical freedoms (Textbox 3).

Textbox 2. Social and economic components of physician autonomy [5].

Choice of specialty and practice location

- Potential limitations on autonomy include market restrictions, bureaucratic restrictions, and educational restrictions

Control over earnings

- Potential limitations on autonomy include workload controls, fee schedules, reimbursement rates, salaried status, and control over permitted earnings

Control over the nature and volume of medical tasks

- Potential limitations on autonomy include hierarchical management, contractual obligations, and the need to share scarce resources

Textbox 3. Clinical components of physician autonomy [5].

Acceptance of patients

- Potential limitations on autonomy include compelling physicians to accept or reject certain patients based on geography, medical specialty, or insurance status

Control over diagnosis and treatment

- Potential limitations on autonomy include individual and aggregate constraints on tests or prescription costs, preset budgets, enforcement of clinical protocols, and gatekeeping

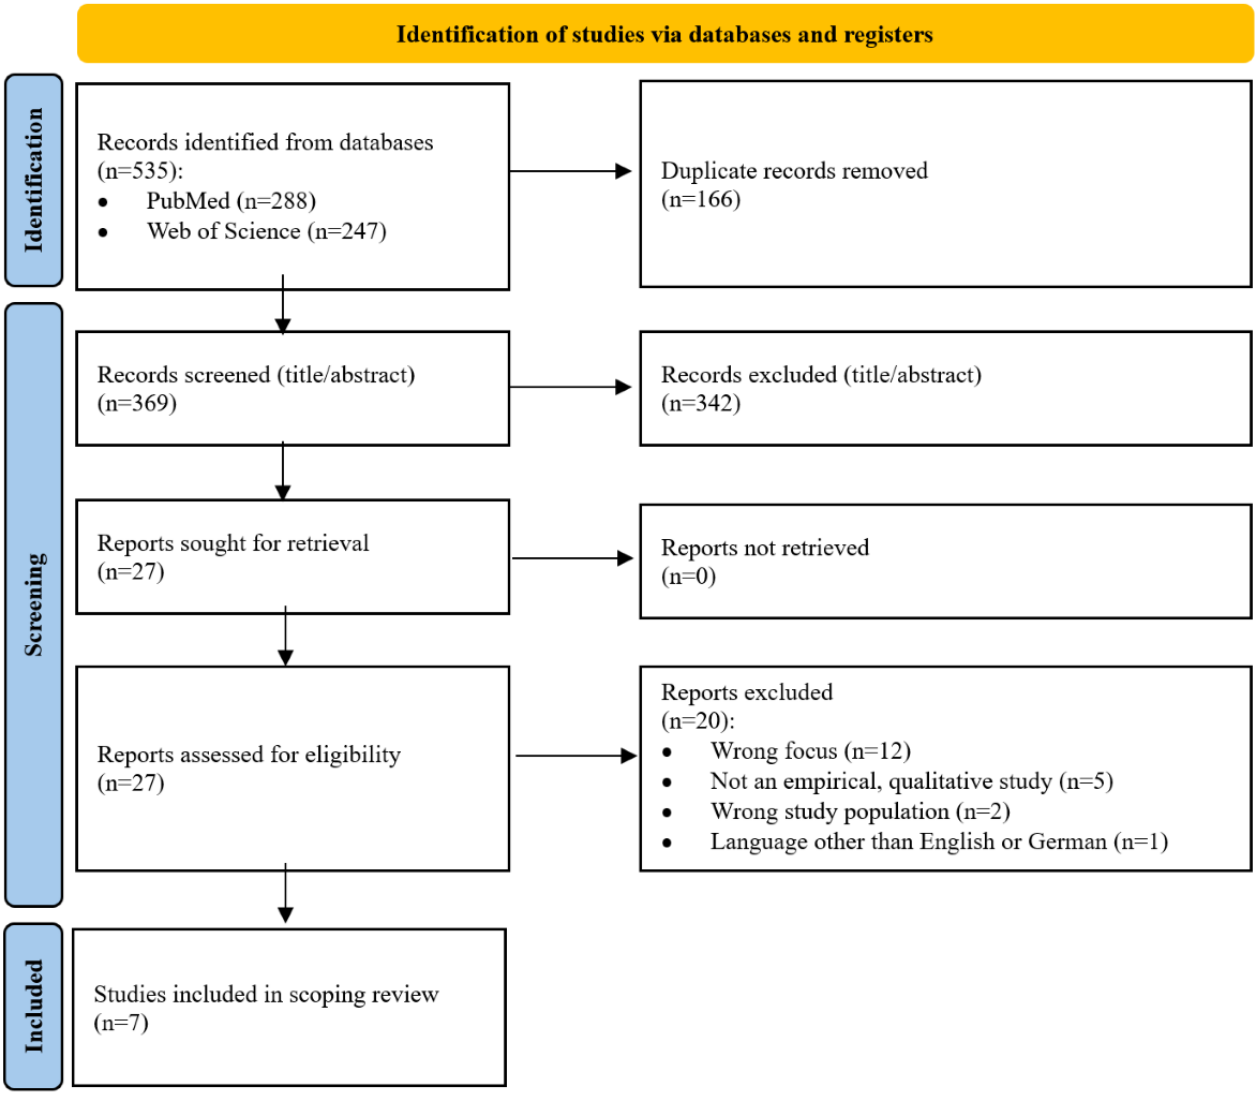
Control over evaluation of care

- Potential limitations on autonomy include peer review, medical audit systems, and comparative information on care outcomes

Control over other professionals

- Potential limitations on autonomy include limitations on physicians' ability to directly manage other health professionals and include precise instructions in referrals for diagnosis or therapy

To paint a more detailed picture of the effect of AI on physician autonomy, we inductively formed subcomponents from the results in each component. To avoid overgeneralizing based on individual participants and studies, we only considered subcomponents that were addressed by at least 2 included studies. Finally, we summarized the potentially harmful and beneficial effects of AI on physician autonomy in each of the inductively formed subcomponents.



Results

Selection of Sources of Evidence

The search yielded 369 studies after duplicates were removed (Figure 1). Of these, 27 studies remained after titles and abstracts were screened. After full texts were screened, we included a total of 7 qualitative studies [12-18].

XSL•FO
RenderX

Figure 1. Flowchart showing the selection of sources of evidence.

Study Characteristics

All 7 included studies had a cross-sectional design; most studies (n=5) used (qualitative) semistructured interviews, which 1 study [13] combined with a focus group. The remaining studies used co-design workshops [16] and a mixed methods survey consisting of both quantitative and qualitative items [15] (although we focus only on the qualitative results). More than half of the studies (n=4) were conducted in Europe; 2 studies were conducted in Asia and one in Australia (Table 1). Radiologists [13,17] and general practitioners (GPs) or primary care physicians [16,18] were the focus of 2 studies each, while the remaining studies recruited participants across multiple specialties. Some studies also included further groups, such as patients or family members [12,18], medical students [15], and radiographers [13], in addition to physicians. The most common form of (medical) AI investigated was CDSS (n=3). Digital disease surveillance systems and documentation assistants were investigated by 1 study each. The remaining 2 studies investigated various forms of AI in medicine. However, only 1 study [17] explicitly recruited participants who had experience with medical AI systems; the remaining studies merely provided participants with vignettes or videos of possible AI systems.

Conceptualizing and Assessing Physician Autonomy

The studies differed significantly in how they conceptualized physician autonomy and to what extent physician autonomy was the focus of their research. In particular, only 1 study [17] explicitly named (the effect of AI on) physician autonomy as a research focus (Table 2). The remaining studies focused on expectations and acceptance of or views and attitudes toward AI.

Table 2. The role of physician autonomy in the included studies.

	[12][a]	[13]	[14]	[15]	[16]	[17]	[18]
Physician autonomy is an explicit focus of the study						✓	
Questions explicitly include physician autonomy			✓			✓	
Questions implicitly include physician autonomy	✓		✓		✓	✓	

[a]The interview questions reference "autonomy," but not explicitly physician autonomy.

Only 2 of 7 included studies [14,17] explicitly included physician autonomy in their interview, survey, or focus group questions, and of these, only one study [17] uses a concrete theoretical framework for physician autonomy. Nevertheless, more than half of the studies (implicitly) included at least some aspects of physician autonomy in their interview questions, even if they did not explicitly relate them to physician autonomy. The remaining studies did not include physician autonomy in their interview questions but did identify aspects of physician autonomy in their participants' responses. Therefore, although most studies did not explicitly name physician autonomy as a research focus or in their interview questions, the qualitative results of all studies include a number of themes related to physician autonomy. We categorized these results into the 7 components of physician autonomy proposed by Schulz and Harrison [5] and formed 2-3 subcomponents for each component, described in the following sections.

Social and Economic Subcomponents of Physician Autonomy

For the choice of specialty and practice location, we identified two subcomponents: (1) AI replacing physicians and (2) AI replacing specialties. Three studies [12,15,16] reported that physicians feared becoming redundant or being replaced by AI. This represents an (indirect) threat to physician autonomy in choosing their specialty and practice location, as this choice will not be available to physicians who have been replaced by AI. In contrast, however, participants in 2 studies [12,16] argued that AI cannot or will not replace physicians, either because fully autonomous medical AI was seen as unrealistic (at least in the near future) or because AI was seen as unable to perform core tasks of (human) physicians, such as empathy and human warmth or communication.

A number of studies also addressed the risk of certain physician specialties, such as GPs [16] and radiologists [13,17], being replaced by or becoming mere assistants of AI—a direct threat to physician autonomy in choosing specialty and practice location. However, 2 studies [13,17] also found that radiologists were seen as less vulnerable to replacement by AI since their roles encompass a wide range of challenging activities (including complex diagnoses and patient relationships), which AI cannot replace as easily as routine reporting activities.

For control over the nature and volume of medical tasks, we identified three subcomponents: (1) the effect of AI on workflow and efficiency, (2) the ability of physicians to personalize and

XSL•FO
RenderX

customize AI tools, and (3) involving physicians in AI design and creation. Participants in all 7 studies [12-18] believed that AI could increase efficiency by redefining workflows, taking over mundane and repetitive administrative tasks, and allowing faster decision-making. This would help address workforce shortages and free up more time for physicians to pursue other, more preferred tasks, such as research or treating complex cases. In this way, AI could enhance physician autonomy over the nature and volume of their tasks. However, participants in 3 of these studies [14,16,17] also expressed hesitation about the time-saving potential of AI, noting that additional time and effort may be required to input required data, fix errors, and train both physicians and AI systems.

Two studies [14,16] addressed further subcomponents relevant to physician control over the nature and volume of medical tasks. At the micro level, these studies addressed the ability of physicians to personalize and customize AI systems. In particular, AI systems may also enhance physician autonomy over the nature and volume of their work through personalized and adaptive features [16], although physicians in 1 study did not find AI customizability necessary [14]. At the macro level, both studies [14,16] addressed the importance of involving physicians in the design and creation of AI systems. While not every physician can be involved in the cocreation of AI, this would nevertheless increase the control of physicians as a group over the AI systems they will be working with. Table 3 shows the distribution of the components or subcomponents for social and economic freedoms among the included studies. Note that none of the included studies addressed control over earnings.

[b]Not applicable.

Clinical Subcomponents of Physician Autonomy

For control over diagnosis and treatment, we identified two subcomponents: (1) the (direct) effect of AI on clinical decision-making and (2) the effect of AI on physicians' expertise and skills. Five studies [12-14,16,18] reported concerns that AI may negatively affect physicians' clinical decision-making autonomy; participants in most of these studies [12-14] agreed that physicians should remain the final authority in clinical decision-making. Participants in other studies were less concerned about this risk, arguing that AI systems will not negatively affect physician autonomy when their adoption is voluntary [14] or when they are used as only one of many criteria informing physicians' clinical decisions [17].

In contrast, 4 studies [12,14-16] reported that AI systems may enhance physician autonomy in clinical decision-making, particularly for less experienced physicians, by affirming their decisions and increasing decision certainty, providing inspiration and offering new possibilities of care, or helping clinicians adhere to guidelines (note that while Amann et al [12] describe better adherence to guidelines as a positive effect of AI, a close reading of Schulz and Harrison [5] suggests that strict adherence to guidelines may, in fact, decrease physician control over diagnosis and treatment).

All but 1 study [12,14-18] addressed the risk of automation bias, or the overreliance of physicians on AI systems, particularly when the use of such systems is mandated [14]. In addition to diagnostic errors [17], this overreliance may lead to deskilling and loss of expertise, especially in younger generations of physicians [12,14], indirectly reducing physicians' control over diagnosis and treatment by making some courses of action unavailable. Participants in 2 studies [13,17], however, were less concerned about this risk. For example, radiologists in 1 study [13] argued that their wide array of high-level tasks made them less vulnerable to deskilling by AI.

Conversely, 4 studies [12,13,15,16] found that AI systems may enhance the expertise and skills of physicians, thereby increasing rather than decreasing their control over diagnosis and treatment. For example, AI may assist physicians who are struggling to be empathetic by suggesting empathetic statements [16] or providing relevant and up-to-date information, especially for novice physicians [15].

XSL•FO
RenderX

Concerning control over the evaluation of care, we identified two subcomponents: (1) the effect of AI on the risk of medicolegal consequences for physicians and (2) the effect of AI on evaluations of care by patients. All but 1 study [12-17] addressed the risk of medicolegal consequences resulting from the use of AI systems. On the one hand, physicians feared the liability issues that may arise from disagreeing with AI decisions or recommendations [15,16], particularly in light of potential data biases in AI systems. On the other hand, they feared that AI systems may be used as auditing tools [16], retrospectively assessing physician's consultation and treatment records for potential errors in diagnosis or treatment. While many study participants agreed that the responsibility—and liability—for medical decisions involving AI rests with physicians as the final decision makers [12,14,17], a number of participants suggested that other actors, such as developers [12], host units [13], or hospitals [14], could share this responsibility (in full or in part).

Five studies [12,14-16,18] addressed the effects of AI on patient evaluations of care. On the one hand, participants in most of these studies feared that patients would negatively react to the use of AI because dependence on AI may undermine patients' faith in the competence of physicians and their recommendations [15,16], because intransparency about AI's use of patient data may threaten patient trust in physicians [18] or because patients may simply prefer human physicians [14]. On the other hand, some studies suggested that patients may approve of the use of AI as an evidence-based approach that can lead to improved care outcomes [14,15], and while Amann et al [12] found that patients should have a say when it comes to the use of AI, Huang et al [14] found that many physicians felt it unnecessary to discuss AI use with patients.

Finally, we identified two subcomponents for control over other professionals: (1) indirect control and (2) direct control, which were addressed by two studies each. Indirect control refers to the status and prestige of physicians (individually and as a profession) in relation to other professionals, including other physicians. While Jussupow et al [15] found that AI systems were seen as leading to a loss in status and prestige for physicians in general, Lombi and Rossero [17] suggested that the advent of AI may present an opportunity for radiologists to reconfigure their professional identity and actually increase their status and prestige by becoming proficient in these technologies.

Direct control refers to the ability of physicians to directly influence or exercise authority over other professionals, including other physicians. While 2 studies [14,17] addressed this component, they conceptualized the effect of AI on professional control in different ways and no overarching themes emerged between them. On the one hand, Huang et al [14] found that senior physicians would encourage junior physicians to use AI and that physicians would, in fact, be influenced by colleagues to adopt AI. On the other hand, Lombi and Rossero [17] found that AI may transform and expand radiologists' interprofessional collaboration (including with nonclinical professionals). AI was seen as threatening professional boundaries and risking a loss of radiologist authority to other clinical professionals but was not seen as challenging radiologists' professional boundaries or authority concerning nonclinical professionals [17]. Table 4 shows the distribution of the components or subcomponents for clinical freedoms among the included studies. Note that none of the included studies addressed the acceptance of patients.

Potential Benefits and Harms of AI for Physician Autonomy

The main results of the included studies in each subcomponent are summarized in Textboxes 4 (for social and economic freedoms) and 5 (for clinical freedoms). For 6 of 11 subcomponents, we found mixed results concerning the potential benefits and harms of AI for physician autonomy. In particular, studies disagreed on whether AI will increase or decrease workflow efficiency, enhance or impede clinical decision-making, improve or worsen physician skills and expertise, lead to patient approval or disapproval, and increase or decrease physician status or prestige. Studies were also split on how AI will affect physicians' direct control over other professionals.

Textbox 4. Potential benefits and harms of artificial intelligence (AI) for social and economic freedoms, indicated by (+) and (–), respectively. Circles indicate relevant findings that are neither harms nor benefits.

Choice of specialty and practice location

AI replacing physicians (n=3)

- (+) AI (currently) lacks the capabilities, such as empathy, necessary to replace physicians
- (−) AI may replace physicians in the future

AI replacing specialties (n=3)

- (+) Radiologists are less vulnerable to AI replacement due to their wide range of challenging activities
- (−) AI may replace radiologists in the future
- (−) AI may replace general practitioners in the future

Control over the nature and volume of medical tasks

AI and workflow or efficiency (n=7)

- (+) AI can increase efficiency by handling mundane activities, freeing up time for other tasks
- (−) AI may decrease efficiency due to the time and effort required for data input, error correction and training

AI customization or personalization (n=2)

- (+) AI may support physicians through personalized and adaptive features

Involving physicians in AI design or creation (n=2)

- (o) Physicians should be involved in AI design or creation

For 2 subcomponents (AI replacing physicians and AI replacing specialties), we found mixed to negative results. On the one hand, the studies that addressed these 2 components found that physicians and some specialties (radiologists and GPs or primary care physicians) may be at risk of replacement by AI. On the other hand, the studies gave a number of reasons why physicians and some specialties may be less vulnerable to such replacement, at least in the near future. However, while these results are not fully negative, we did not find any results indicating that AI may improve physician autonomy in these subcomponents.

XSL•FO
RenderX

Textbox 5. Potential benefits and harms of artificial intelligence (AI) for clinical freedoms, indicated by (+) and (–), respectively. Circles indicate relevant findings that are neither harms nor benefits.

Control over diagnosis and treatment

AI and clinical decision-making (n=7)

- (+) AI may enhance clinical autonomy by increasing decision certainty and providing inspiration
- (−) AI may harm clinical decision-making autonomy
- (o) Physicians should remain the final authority in clinical decision-making

AI and physician expertise or skills (n=7)

- (+) AI may enhance physicians' expertise
- (−) AI may lead to loss of expertise through overreliance and automation bias

Control over evaluation of care

AI and medicolegal consequences (n=6)

- (−) AI decisions and recommendations may lead to liability issues for physicians
- (−) AI systems may be used as post hoc auditing tools
- (o) Developers, hospitals, or other actors should (partially) share responsibility for medical decisions involving AI

AI and patient evaluations of care (n=5)

- (+) Patients may approve of AI use (eg, due to improved outcomes)
- (−) AI may lead to patient disapproval or mistrust
- (−) AI may undermine patients' faith in physicians' care

Control over other professionals

AI and indirect control over other professionals (n=2)

- (+) AI may offer radiologists an opportunity to increase their status and prestige
- (−) AI systems may lead to a loss in status and prestige for physicians in general

AI and direct control over other professionals (n=2)

- (+) AI may expand radiologists' interprofessional collaboration with nonclinical professionals
- (−) AI may threaten radiologists' authority over other clinical professionals
- (−) Physicians may be influenced by peers and superiors to adopt AI

In contrast, we found general agreement between the included studies for the remaining 3 subcomponents. For AI customization or personalization, this consensus was positive: both studies addressing this component found that customizable AI systems would support physician autonomy. Furthermore, there was agreement between studies that AI represented potential harms (but not benefits) to physician autonomy in the AI and medicolegal consequences component. Finally, both studies that addressed involving physicians in AI design or creation found that such involvement should take place (although this more accurately represents a recommendation or demand rather than a potential benefit or harm).

Discussion

Principal Results

These results show that research on the potential effects of AI on physician autonomy is still in its nascency. In particular, there is no consensus definition or operationalization of physician autonomy in qualitative research. Most studies did not name physician autonomy as a focus of their research or explicitly include physician autonomy in their interview, survey, or focus group questions. In fact, only 1 study [17] specified a clear theoretical framework for physician autonomy. These results align with existing research on the professional autonomy of nurses, which has been found to face challenges due to inconsistent definitions and inappropriate measures of nurse autonomy [19] and the confounding of the clinical and nonclinical aspects of nurse autonomy [20].

No studies addressed a complete set of components of physician autonomy (as defined by Schulz and Harrison [5]). Furthermore, coverage between components varies significantly: while all 7 studies addressed control over the nature and volume of medical tasks, control over diagnosis and treatment, and control over the evaluation of care, none of the included studies addressed control over earnings and acceptance of patients.

XSL•FO
RenderX

We identified a total of 11 subcomponents for the 5 components of physician autonomy that were addressed by at least 1 study. For most of these subcomponents, studies reported mixed results concerning the potential harms and benefits of AI for physician autonomy. A notable exception addressed by most studies was AI and medicolegal consequences, with studies reporting only potential harms for this subcomponent. AI customization or personalization was the only subcomponent in which only potential benefits were reported, although this subcomponent was only addressed by 2 studies. Overall, there is a need for further research that focuses specifically on physician autonomy and includes a full conception of its components and subcomponents.

Some of the results within subcomponents align with recent reviews of the academic literature, which have found positive effects of AI on clinical and administrative workflow or efficiency or patient-physician trust [21,22]. A recent review of the "grey literature" also found that clinical and administrative AI applications impact physician job autonomy, skills, and professional relationships [23]. However, not all of these results are reported by the reviews as components of physician autonomy.

Limitations

However, the methodological limitations of our scoping review should be considered when interpreting our results. In particular, we identified only 7 studies that fit the inclusion criteria. Furthermore, although 4 of 7 studies [12,14,17,18] were published in 2023, only 1 study [14] specified a data collection period later than 2021 and 3 studies completed their data collection before the end of 2020. Considering the rapid evolution of AI in medicine, such as the recent introduction of large language models such as ChatGPT [24,25], there is a clear need for additional, up-to-date research on physician autonomy and new AI systems.

Furthermore, we included only qualitative studies in this review. In our view, expanding our scope to include a full systematic review of quantitative studies on AI and physician autonomy would have been premature, as the field is comparatively new and because we were focused particularly on how physician autonomy is defined and conceptualized by researchers and participants. However, the subcategories we have identified provide a useful roadmap for future systematic reviews of quantitative studies on physician autonomy and AI, and such reviews should be conducted.

Our review may also have missed further studies that were not included in the databanks we searched or that did not explicitly mention (physician) autonomy. However, these studies may still be relevant: while we assigned study results to components of physician autonomy in order to form inductive subcomponents, most of the included studies do not conceptualize physician autonomy as covering each of these components. For example, subcomponents such as AI and workflow or efficiency, AI and physician expertise or skills, or AI and patient evaluations of care were addressed by a number of studies, but usually not explicitly related to physician autonomy. This indicates that there may be further studies that address relevant components without explicitly mentioning autonomy. This should also be considered when conducting future systematic reviews of quantitative studies on physician autonomy and AI. In particular, search terms related to specific subcomponents (but not physician autonomy) may lead to the inclusion of additional relevant studies.

Future research should also explicitly include the 2 components that were not addressed by any of the studies in our review: control over earnings and acceptance of patients. In particular, one should not conclude from our review that AI will have no effect on physician autonomy for these components. Such a conclusion seems implausible since examples of possible effects are easily constructed. For example, if AI systems were to take on the role of gatekeepers and play some part in deciding which patients can be seen by which physicians, this would represent harm to physician autonomy. Instead, the absence of these components from our review should be taken to indicate that respondents (or researchers) did not conceive of control over earnings and acceptance of patients as (relevant) aspects of physician autonomy.

Studies also differed in their definition of AI, which complicates evidence comparison and synthesis. While some studies considered AI-based CDSS, others considered different AI systems or AI innovations more broadly, and while 1 study [17] recruited participants who had actual working experience with AI systems, most merely presented participants with vignettes describing possible AI systems. This means that most studies report only the potential harms and benefits of AI (as feared or hoped for by participants), not actual harms and benefits. As a systematic comparison of the effects of different types of AI systems on physician autonomy was not possible with only 7 included studies, our scoping review is further limited to a broader discussion of the potential effects of AI in general. However, further research should analyze these differences in effect, based (where possible) on evaluations of actual AI systems, rather than vignettes.

Initial evidence also suggests that participants in different regions or cultures perceive different potential harms and benefits of AI for physician autonomy. For example, Huang et al [14] found that views on (the effects of AI on) some aspects of physician autonomy differed between physicians in Singapore and India, while Wong et al [18] discuss the fragility of doctor-patient trust specifically in China. While we were unable to analyze these differences due to the limited number of studies, future research should more thoroughly investigate such cultural and geographic differences in attitudes toward both AI and physician autonomy.

Overall, our results are based on a limited number of studies and should be seen as opening, rather than closing, lines of inquiry into the effects of AI on physician autonomy. Fully understanding these effects will require an ambitious research program. First, there is a need for further qualitative studies focusing explicitly on physician autonomy. Second, a definitive understanding of AI and physician autonomy will require quantitative studies using validated and reliable instruments designed for this purpose. Finally, the current literature focuses almost exclusively on self-reported physician autonomy. However, it may also be possible to measure the effect of AI

XSL•FO
RenderX

on physician autonomy using objective quantitative indicators, such as the number of alerts and reviews triggered by AI systems or test results from experimental studies of physician expertise. Future research should consider if and when the use of such indicators in addition to self-reported assessments of physician autonomy is appropriate.

Conclusions

Little research to date has addressed the potential effects of AI on physician autonomy. Existing results on AI and physician autonomy are mostly secondary findings or merely part of larger analyses into physicians' attitudes toward and acceptance of AI. Most studies addressed physician autonomy only indirectly in their research focus and interview, survey, or focus group questions.

While 3 of the components of physician autonomy proposed by Schulz and Harrison [5] were addressed by all included studies, 2 components were not addressed by any studies. In eleven (inductively formed) subcomponents, the included studies reported a number of potential effects of AI on physician autonomy. However, results were mixed, with studies reporting both potential harms and benefits of AI for physician autonomy in most subcomponents.

In conclusion, further qualitative and quantitative research is needed that focuses explicitly on physician autonomy and addresses all relevant components of physician autonomy. Where possible, research on the effects of AI on physician autonomy should be based on real experience with AI systems, rather than vignettes, and consider the differences between different AI systems and between physicians in different cultural and geographic settings.

Acknowledgments

All authors contributed to the study's conception and design. JD and LH devised the search strategy and performed the screening. JG was consulted to resolve disagreements. JG, JD, and ES performed the data extraction and synthesis. JG and LH drafted the manuscript, which was edited, discussed, and approved by all authors. No funding was received to assist with the preparation of this manuscript. We acknowledge support for this publication by the DFG, Deutsche Forschungsgemeinschaft, and the Open Access Publication Fund of Bielefeld University.

Abstract

Background: Neglected tropical diseases (NTDs) are the most prevalent diseases and comprise 21 different conditions. One-half of these conditions have skin manifestations, known as skin NTDs. The diagnosis of skin NTDs incorporates visual examination of patients, and deep learning (DL)–based diagnostic tools can be used to assist the diagnostic procedures. The use of advanced DL-based methods, including multimodal data fusion (MMDF) functionality, could be a potential approach to enhance the diagnostic procedures of these diseases. However, little has been done toward the application of such tools, as confirmed by the very few studies currently available that implemented MMDF for skin NTDs.

Objective: This article presents a systematic review regarding the use of DL-based MMDF methods for the diagnosis of skin NTDs and related diseases (non-NTD skin diseases), including the ethical risks and potential risk of bias.

Methods: The review was conducted based on the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) method using 6 parameters (research approach followed, disease[s] diagnosed, dataset[s] used, algorithm[s] applied, performance achieved, and future direction[s]).

Results: Initially, 437 articles were collected from 5 major groups of identified sources; 14 articles were selected for the final analysis. Results revealed that, compared with traditional methods, the MMDF methods improved model performances for the diagnoses of skin NTDs and non-NTD skin diseases. Algorithmically, convolutional neural network (CNN)–based models were the predominantly used DL architectures (9/14 studies, 64%), providing feature extraction, feature fusion, and disease classification, which were also conducted with transformer-based methods (1/14, 7%). Furthermore, recurrent neural networks were used in combination with CNN-based feature extractors to fuse multimodal data (1/14, 7%) and with generative models (1/14, 7%). The remaining studies used study-specific algorithms using transformers (1/14, 7%) and generative models (1/14, 7%).

Conclusions: Finally, this article suggests that further studies should be conducted about using DL-based MMDF methods for skin NTDs, considering model efficiency, data scarcity, algorithm selection and use, fusion strategies of multiple modalities, and the possible adoption of such tools for resource-constrained areas.

Introduction

Background

Neglected tropical diseases (NTDs) are the most prevalent diseases, affecting more than 1 billion people worldwide, as estimated by the World Health Organization (WHO), and particularly impact people living in the world's tropical areas who are among the poorest, most vulnerable, and outcast groups [1]. They have a devastating impact on people's physical, mental, and social well-being [1,2]. According to the WHO [2,3], NTDs represent 21 different diseases that include Buruli ulcer, Chagas, dengue and chikungunya, dracunculiasis, echinococcosis, foodborne trematodiases, human African trypanosomiasis, cutaneous leishmaniasis (CL), leprosy, lymphatic filariasis, mycetoma, chromoblastomycosis and other deep mycoses, noma, onchocerciasis, rabies, scabies and other ectoparasitoses, schistosomiasis, soil-transmitted helminthiases (STH), snakebite envenoming, taeniasis/cysticercosis, trachoma, and yaws.

Once a particular disease occurs, proper diagnostic measures should be in place. Although each disease has its own diagnostic procedures, most NTDs can be diagnosed using skin-related symptoms; 18 of the 21 NTDs recognized by the WHO have primary skin indicators or associated clinical features and are thus called skin NTDs [4,5]. The diagnosis of skin diseases relies on a visual examination of the skin of affected patients; therefore, the diagnosis of skin NTDs requires visual inspections of patients' skin. This inspection can be enhanced by integrating technological interventions.

Current diagnostic research suggests that the diagnosis of skin NTDs can be enhanced using artificial intelligence (AI)–enabled diagnostic systems to overcome the challenges of these diseases [6]. On the other hand, the diagnosis of NTDs often involves a combination of different types of clinical data, possibly from diverse sources, such as patient medical records, visualization of patient skin, and laboratory tests. Hence, in light of current achievements, the use of AI-enabled diagnostic systems, particularly deep learning (DL)–based systems that incorporate multimodal data fusion (MMDF) techniques, has potential for the diagnoses and recognition of skin-related NTDs.

How are such systems developed to assist the diagnosis of skin NTDs? Answering this question seems quite difficult, as there are very few similar research-based systems that are publicly available to be able to analyze their approaches. Therefore, how can we approach this issue and analyze the methods, tools, and techniques used in previous studies to develop DL-based systems with MMDF for skin NTDs? To address this issue, we conducted a systematic review of previous studies applying MMDF techniques for skin NTDs and non-NTD skin diseases, since both groups of diseases can be diagnosed using common dermatological approaches to examining skin manifestations.

Although the specific diagnostic procedures to be used might be different, from the dermatological point of view, the general procedures for skin NTDs or non-NTD skin diseases remain the same: visual examination of the skin along with patient data processing [7]. Accordingly, in DL-based diagnostic research such as experimenting with MMDF for skin NTD diagnosis, particularly for leprosy [8], and using MMDF for multiple non-NTD skin diseases [9], the DL models learn to examine skins using clinical images (both cited studies used dermoscopic images) and integrate textual clinical data to predict the disease. This clearly shows that the MMDF methods used for non-NTD skin diseases can be adopted for skin NTDs because the 2 skin disease groups share the same general procedure.

Hence, this article presents a deeper analysis of DL-based MMDF techniques that are demonstrated in previous studies for the diagnosis of skin NTDs and non-NTD skin diseases using the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) method. This approach was used to analyze the methods, data fusion techniques, algorithms, and related aspects used for specific diseases so as to demonstrate the potential of using those techniques for the diagnosis of skin NTDs. The studies analyzed in this review confirmed that the use of MMDF techniques outperformed traditional diagnostic models that implemented DL methods without MMDF [9-12]. In view of these facts, this study aimed to conduct a systematic literature review to provide a deeper analysis and appraisal of previous studies using the PRISMA method, guided by the following questions:

- What DL methods or approaches were used for the diagnosis of NTDs or non-NTD skin disease(s)?
- Which data fusion methods were used for skin disease diagnosis tasks?
- What types of medical data were integrated to demonstrate the MMDF method for the diagnosis of skin disease(s)?
- Which algorithms were used, and how did each algorithm perform in the proposed DL-based MMDF diagnostic model?

DL and Diagnosis of NTDs

In real-world clinical settings, efficient disease diagnostic processes are basically carried out by using multiple types of medical data that are taken from different sources and different formats or modalities, including textual patient information and clinical images such as X-rays, dermoscopic images, or even patient skin images. The integrative use of diverse modalities of medical data can enhance the diagnostic processes, thereby enhancing the quality of health care services, by using machine learning (ML) algorithms, including DL methods. Technically, this process of integrating multiple modalities of data (possibly taken from different sources) is called MMDF [13,14].

MMDF techniques are playing vital roles in developing intelligent disease diagnostic systems for different diseases, such as in dermatology [15]. In this regard, MMDF techniques are advancing diagnostic accuracy, where these methods outperform baseline methods, as presented in [16]. Regarding the diagnosis of NTDs, including skin NTDs, there have been efforts toward the use of AI-based diagnostic tools built using ML approaches. In this regard, Ali et al [17] used ML methods for early prediction of schistosomiasis and concluded that the CatBoost model achieved the highest accuracy, at >80%. Furthermore, since skin NTDs are diagnosed using skin manifestations, deploying DL-based approaches for the diagnoses of these diseases could have the potential to support

XSL•FO
RenderX

and enhance the diagnostic processes, as confirmed by recent studies (eg, [8,18,19]) that applied DL methods and algorithms using skin images for the diagnosis of skin NTDs. All the aforementioned studies used ML and DL methods to diagnose skin NTDs and achieved remarkable results in terms of diagnostic accuracy.

However, based on extensive exploration, we found that there were very few efforts toward the implementation of MMDF methods in AI-based diagnostic platforms for skin NTDs, except for 2 studies found very recently. To this end, Barbieri et al [8] conducted a study that demonstrated MMDF methods for the diagnosis of leprosy and claimed that they achieved higher accuracy in distinguishing leprosy (Hansen disease), which is one of the most widely spread NTD types globally, with 120,000 new cases being reported every year [20]. A recent study by Achary et al [21] implemented the MMDF method using a generative adversarial network (GAN)–enabled multimodal diagnostic framework using a recurrent neural network (RNN)–based architecture for merging multimodal data.

Data Fusion Techniques and Approaches

Overview

Data or information fusion represents the use of data or information from different sources in different formats or modalities for interpretation in all tasks that require any type of parameter estimation or prediction using data or information [22]. Data fusion, including MMDF, is the process of combining different data streams that include different dimensionality, resolution, and types of data to generate information in a form that is more understandable by or usable to an end user or system [22,23]. Although the fusion techniques represent individual methods used to achieve the data fusion process, there are 3 main fusion techniques for integrating multimodal data: early fusion, joint fusion, and late fusion.

Feature-Level Fusion or Early Fusion

Feature-level fusion refers to the process of integrating multiple input modalities into a single feature vector before feeding into one single ML model for training, where the input modalities can be joined in many different ways, such as concatenation or pooling [24,25]. This fusion technique is suitable for combining similar feature sets at the early stage of model development if data of similar modalities are to be collected from different sources.

Intermediate Fusion or Joint Fusion

This type of fusion combines learned feature representations from intermediate layers of neural networks with features from other modalities as input to a final model, and it is implemented with neural networks due to their ability to propagate loss from the prediction model to the feature extraction model(s) [26].

Model-Level Fusion, Decision-Level Fusion, or Late Fusion

Late fusion uses predictions from several models to make a final decision, where different modalities are used to train separate models and the final decision is made using an aggregation function to integrate the predictions of the different models. The aggregation functions might include averaging, majority voting, weighted voting, or a metaclassifier based on the predictions from each model. The choice of aggregation function is usually empirical, and it varies depending on the application and input modalities [26,27]. This fusion technique is more like an ensemble learning method, where the abilities of different models are combined to make up for the biases and errors of a single model to achieve better performance [28].

Fusion Approach

Apart from the data fusion techniques used to actually merge different modalities of multimodal data, the fusion approach is a major aspect that defines the general perspective toward solving a given data fusion problem. The approaches can be described as presented in the following sections.

Feature Fusion

This is a data integration technique used to aggregate multiple feature sets extracted from multiple input data to generate a single feature set [24]. In image processing problems, it refers to the fusion of feature vectors of training images extracted from a shared weight network layer and feature vectors composed of other numerical data [25]. It helps to learn image features fully for the description of their rich internal information [29].

Model Fusion

Also known as late fusion, model fusion represents a fusion approach that combines different models. The study by AlDahoul et al [30] combined 2 deep neural networks (DNNs), including a binary normal/attack classifier and multi-attack classifier, to train a DNN for network anomaly detection. As mentioned by Shoumy et al [24], the model fusion technique uses the connection between experimental data under different modalities.

Image Fusion

Image fusion is a fusion approach that combines different images and generates informative images by integrating images obtained from different sources [31]. Wang et al [32] suggested that aggregating medical images helps to enhance diagnostic accuracy. This claim was demonstrated by fusing clinical images and dermoscopic images using deep convolutional neural network (DCNN) methods, which achieved an overall accuracy greater than 80%. Although clinical images are clinically captured photographs, dermoscopic images represent images taken by dermatologists using dermoscopy devices [33].

Multimodal Data Fusion

Multimodal data represent the different formats or modalities of data, such as text, image, video, and audio. An MMDF approach is used for combining particular modalities to derive multimodal representation [12,13,23,34]. This approach has multiple applications for health care systems, as it allows the combination of diverse modalities of data, such as the textual medical history and clinical images of patients (such as skin images from patients), to form a single multimodal dataset that can be used to train diagnostic models using ML and DL methods.

Significance and Novelty of the Review

This study presents a systematic review regarding the use of DL-based MMDF techniques for the diagnosis of skin NTDs. However, the current literature reveals a lack of previous studies that have applied MMDF techniques for the diagnosis of skin NTDs, marking a critical gap. Hence, the study used an alternative approach by incorporating studies conducted on skin NTDs and non-NTD skin diseases, as both types of diseases are diagnosed using skin manifestations. Based on the gaps, this study analyzed studies that applied MMDF techniques, thereby presenting the first systematic review to our knowledge that analyzes methods using both skin NTDs and non-NTD skin diseases. Furthermore, the study identified a series of promising approaches to apply MMDF techniques for skin NTDs, all marking the novelty of this study. Overall, this review highlighted key current gaps and future research directions, which can motivate further research in the area.

Methods

As the basis for conducting and reporting this systematic review, we followed the steps recommended by the PRISMA model [35,36], as described in the following sections.

Search Strategy

To acquire all relevant articles regarding the application of DL-based MMDF methods for the diagnosis of skin NTDs, we conducted a comprehensive and systematic literature search by establishing a search strategy designed to maintain both depth and breadth. Accordingly, beginning with the identification and selection of relevant article sources, the search was performed across 5 different categories of sources, as described in the following sections.

Search Engine (Google Scholar)

Strategically, we started the search process using the free web-based search engine that has the broadest indexing coverage of scholarly literature, Google Scholar. We used this search engine for 2 major purposes: identifying a wide range of articles and supplementing major databases to be searched.

Bibliographic Databases

Primarily, we identified 2 major bibliographic databases based on 2 perspectives, the subject matter and problem domain of this study. First, as a medical-focused study, the PubMed database was selected and primarily used to find relevant articles that deal with the diagnosis of skin NTDs and non-NTD skin diseases using AI-based methods. Second, the web-based searchable bibliographic database, ScienceDirect (Elsevier), was included to extract more full-text articles. We selected these 2 databases because they have wide multidisciplinary coverage and robust indexing mechanisms.

Publishers

In addition to the databases, we conducted targeted searches of specific publishers' platforms to make sure that there were no specialized articles remaining. Accordingly, we selected IEEE Xplore to specifically acquire articles in the area of technology, given that DL-based methods have wider applications for disease diagnosis, including skin NTDs and other skin diseases. MDPI (a publisher of open-access scientific journals and books) and Springer Nature were also selected.

Specialized Journals

We conducted targeted search operations of specific journals to ensure that we captured all the studies that focused on NTDs, and we included the following sources. African Journals Online (AJOL), a prominent source of literature on health and tropical medicine in Africa, was included to look for studies that are of specific relevance and research focus, as this study was based in Africa. Similarly, Tropical Medicine and Health and PLOS (as it specifically incorporates PLOS NTD) were included due to their direct relation to the topic of our study, and related studies were acquired from these journals.

Gray Literature Searching

This method allowed us to explore specific journals and nondatabase sources obtained from academic social networks using Mendeley (reference management software). Generally, all these sources were selected based on the broader indexing coverage of the search engine, the relevance of the databases to the research topic, the scope and reproducibility of this study, and the collaborative decision of the authors.

To complete the search process, search terms guided by the research keywords were formulated by choosing terms that are highly relevant to the core topics, contents of the articles, and objective of this study. Using the Boolean operators ("AND" and "OR") to systematically combine the selected search terms, 6 different search terms were developed that include the following search terms: [((((("Neglected Tropical Diseases") OR ("NTDs") OR ("skin related Neglected Tropical Diseases") OR ("Skin-Related Neglected Tropical Diseases") OR ("Skin NTDs") OR ("tropical diseases")) AND (("Diagnosis") OR ("diagnostic model") OR ("classification model"))) AND (("Deep Learning") OR ("DL") OR ("Convolutional Neural Network") OR ("CNN") OR ("Deep Neural Network") OR ("DNN") OR ("Recurrent Neural Network") OR ("RNN"))) AND (("Data Fusion") OR ("Data Fusion Techniques") OR ("Data Fusion methods") OR ("Multimodal medical Data") OR ("Multimodal Data Fusion") OR ("Multimodal Data Fusion Techniques")))]. The final set of search terms was used on each of the selected article sources to deeply search and filter relevant articles. The complete list of sources and the search terms prepared and used in each source are presented in Table S1 in Multimedia Appendix 1.

Finally, all the search results were exported to EndNote to create a library using titles of the articles to identify each article, which was used for relevant article selection performed in a 5-level screening process.

Eligibility Criteria

Not all articles are critically relevant for the review concerning the integration of MMDF techniques based on DL methods for the diagnosis of skin-related NTDs. Hence, a set of inclusion criteria were applied. Articles were included that had an appropriate level of similarity and relationships in the topics and contents with the search keywords used to deeply search

XSL•FO
RenderX

and filter the articles, demonstrated DL methods for the diagnosis of skin NTDs or non-NTD skin diseases with proper evaluation of the methods used, demonstrated proper use of MMDF techniques for the diagnosis of skin NTDs or non-NTD skin diseases, used privately collected and targeted datasets, and presented original research containing full-text content published in peer-reviewed journals or conference proceedings.

Similarly, a set of exclusion criteria were used. These criteria included articles that did not use DL-based MMDF methods, used DL-based MMDF methods for diseases other than skin diseases, were review articles and articles without full text, were published in languages other than English, and were published prior to the year 2014.

Article Search

The 2 searching methods ("basic search" and "advanced search") were applied to the selected article sources. First, the ordinary (basic search method) was used, in which general titles and the research keywords were entered in the regular search box of each of the data sources and searched. Second, the advanced search option was used with the proposed search terms, which allowed us to specify relevant options to include subject areas, related topics, and publication dates to obtain articles that were relevant to the topic by narrowing the search results. Using both of the search methods and search terms, the search was conducted in each of the selected article sources, search engine, bibliographic databases, publishers, and specific journals. By specifying article publication dates, articles published between the years 2014 and 2025 were collected and prepared for screening. Furthermore, literature sources outside the popular publishers and nondatabase sources, which included academic web portals, academic libraries, and research sites, were also consulted to add relevant content.

Relevant Article Selection

The entire article selection process was conducted based on the PRISMA method, which is an evidence-based minimum set of items for reporting systematic reviews and meta-analyses [35,36]. The use of multiple sources, especially the search engine, created duplication of databases, journals, and article files. This required systematic screening procedures. We conducted the first-level screening based on external duplicate removal. External duplicates occur when the same article is acquired from different sources, especially when using search engines and different databases. Hence, for the first-level screening, the articles were screened, mainly in a manual approach using the titles. The next levels of screening were performed using software tools such as EndNote and Rayyan. As a reference management tool, we used EndNote to create a library of the collected articles, manipulate the articles, process the collected articles, and automatically deduplicate files in the library. Finally, for higher-level screening, Rayyan, the AI-based free online software tool [37], was used mainly to speed up the literature screening process based on title, author names, abstracts, study area, and full texts in the article library exported from EndNote.

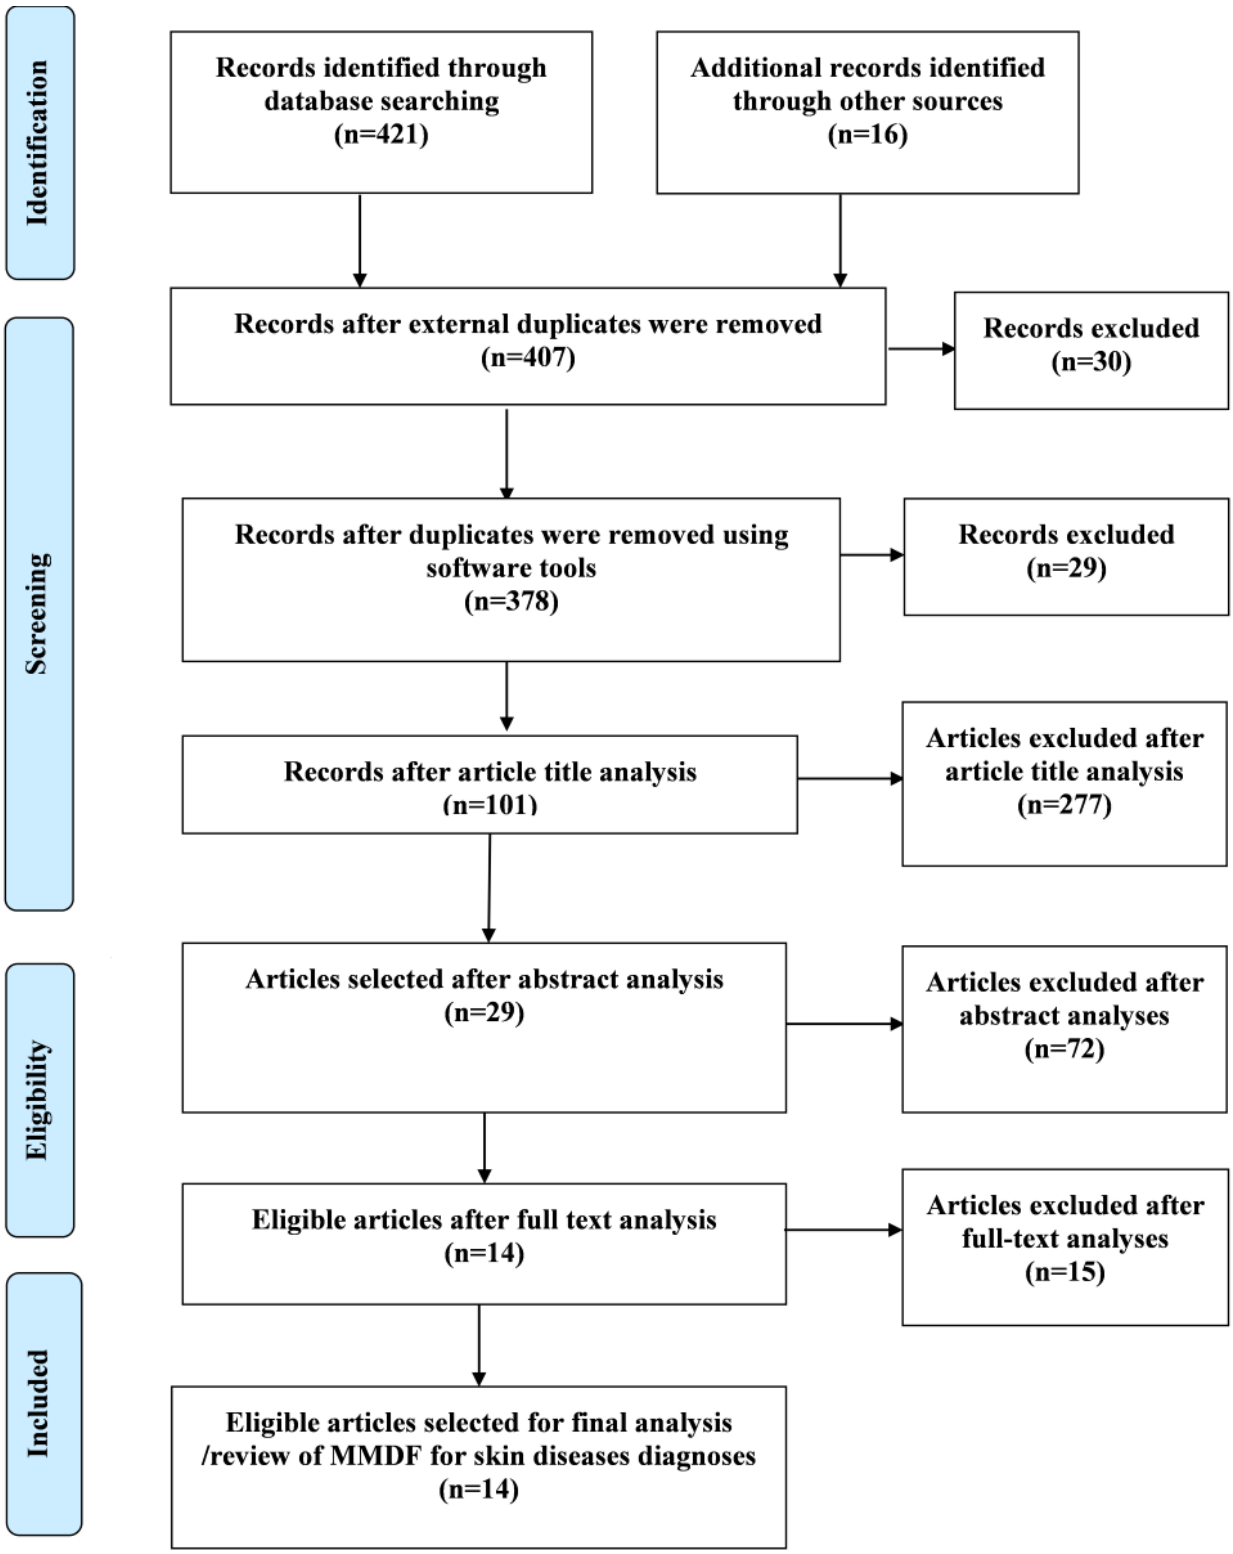
Ethical Considerations

As a review study, we followed strict ethical procedures throughout the entire process of this study, starting from problem formulation, article exploration, evaluation, and analysis, up to reporting. Furthermore, for the articles reviewed in this study, we analyzed the papers for potential ethical issues since all the articles reviewed used data collected from patients. This study did not involve any human or animal participants, clinical trials, or any data related to patients or clinical trials. Therefore, a specific ethical assessment was not sought for this study, as the study presented only the methodological analysis of previously published studies applying DL-based MMDF techniques for the diagnosis of skin NTDs and non-NTD skin diseases.

Quality Assessments

For the quality assessment of the included studies, we used the QUADS-2 (quality appraisal for diverse studies) tool, which is recommended for use in systematic reviews to assess factors such as the risk of bias and applicability issues of diagnostic research studies. Assessments are carried out based on 4 domains, namely patient selection, index test, reference standard, and flow and time [38]. As a DL-related study involving medical diagnostics, using the QUADS-2 assessment tool, we evaluated the selected studies for potential biases that might arise from the methods related to patient selection and algorithmic biases.

Results



Collected Articles

Overall, 421 articles were acquired from the 7 major sources identified (databases, publishers, and specific journals) and the search engine, while 16 articles were collected from the gray literature search. We then implemented a series of screening operations on the collected articles in order to identify the most relevant set of articles. The first-level screening resulted in 30 articles being screened out as a result of external duplicates, which allowed us to select 407 articles. Second, the use of EndNote software resulted in the removal of 27 duplicate articles, as the articles were acquired from 10 different sources (5 categories, including the search engine) organized in different folders. The automatic deduplication process continued in Rayyan, which identified 2 pairs of duplicated articles and removed 2 of them, resulting in 378 unique articles. The overall article selection process is outlined using the PRISMA flowchart in Figure 1.

For the third-level screening, the online software tool Rayyan was further used to screen based on article title, and in the process, 101 articles that had a direct relationship with the current topic of the study were selected. The fourth-level screening was conducted using abstract analysis, and 29 articles were identified. Finally, only 14 articles were found to be eligible for the final analysis after full-text analysis to check eligibility of the 29 articles identified during the fourth round of screening.

XSL•FO
RenderX

Figure 1. Article selection for systematic literature review following the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart. MMDF: multimodal data fusion.

Distribution of Articles

The application of the specified searching methods in the selected sources resulted in 437 articles published between the years 2014 and 2025, as shown in Table 1, depicting the distribution of the collected articles based on their sources. As shown, Google Scholar allowed us to collect 188 articles (188/437, 41.2%) from 9 different sources. These included PubMed, ScienceDirect, IEEE Explore, MDPI, Springer Nature, AJOL, NCBI, PLOS, and Tropical Medicine and Health, creating duplication of sources (databases, publishers, and journals).

Further analysis was performed regarding the sources of the articles with respect to the first 2 initial levels of screening, as shown in Table 1. From the 437 articles initially collected, the first-level screening allowed us to select 407 articles by

XSL•FO
RenderX

excluding 30 articles. We further excluded 29 duplicate articles during the second level of screening by merging the sources into one big library in EndNote, resulting in 378 articles to be further screened.

Table 1. All collected articles and their distribution by article databases or search engine (N=437).

Source	Articles initially collected, n (%)	Articles after first-level screening (n=407), n (%)	Articles after second-level screening (n=378), n (%)
Google Scholar	188 (43)	173 (42.5)	166 (4.4)
IEEE Explore	68 (15.6)	61 (15)	55 (14.6)
ScienceDirect (Elsevier)	49 (11.2)	49 (12)	42 (11.1)
Springer Nature	45 (10.3)	43 (10.6)	38 (10.1)
MDPI	37 (8.5)	33 (8.1)	33 (8.7)
Mendeley	21 (4.8)	20 (4.9)	17 (4.5)
PubMed	13 (3)	13 (3.2)	13 (3.4)
Other	16 (3.7)	15 (3.7)	14 (3.7)

Distribution of Articles by Publication Year

During the third level of screening, 101 articles relevant to the topic and published between the years 2014 and 2025 were selected using title analysis, as shown in Table 2.

As shown, the selected articles included recent studies, with 3% (3/101) published in 2025 and 2% (2/101) published in 2024. The majority of the studies were published in 2023 (30/101, 29.7%).

Table 2. Distribution of articles after the third-level screening by publication year (n=101).

Year	Results, n (%)
2014	1 (1)
2015	1 (1)
2016	1 (1)
2017	1 (1)
2018	4 (4)
2019	3 (3)
2020	15 (14.9)
2021	14 (13.9)
2022	26 (25.7)
2023	30 (29.7)

Distribution of Articles by Methods Used

Finally, the 101 articles were further analyzed based on their research approach, which represents the main analysis parameter of this study. This analysis categorized the studies into 6 groups according to the specific methods, tools, and techniques used. The first group included articles using DL-based MMDF methods for the diagnosis of skin NTDs, representing 2% (2/101) of the selected articles. The second group included articles that implemented only DL-based methods for the diagnosis of skin NTDs, representing 6.9% (7/101) of the selected articles. The third group included articles that implemented DL-based methods for the diagnosis of non-skin NTDs, representing 4% (4/101) of the articles. The fourth group comprised articles that used DL-based MMDF methods for the diagnosis of non-NTD skin diseases, representing 20.8% (21/101) of the selected articles. The fifth group included articles that used only DL-based methods for non-NTD skin diseases, representing 48.5% (49/101) of the selected articles. Finally, the last group included articles that demonstrated other forms of data fusion methods, representing 17.8% (18/101) of the articles.

Accordingly, 87.1% (88/101) of the selected articles used DL-based methods for non-NTD skin diseases, and 48.5% (49/101) used DL methods for the same non-NTD skin diseases. The remaining 20.8% (21/101) of the articles used MMDF for non-NTD skin disease diagnoses, and 17.8% (18/101) of the articles used other forms of fusion, such as feature fusion, model fusion, and image fusion. Of the selected articles, 12.9% (13/101) applied DL-based methods for the diagnosis of NTDs in general, of which 4% (4/101) implemented DL-based methods for the diagnosis of non-skin NTDs (NTDs that have no skin

XSL•FO
RenderX

manifestations such as STH [39]). However, none of the articles implemented MMDF techniques, apart from recommending MMDF for future work, like in [19]. Only 2% (2/101) of the articles applied DL-based MMDF methods for the diagnosis of 2 different skin NTDs, leprosy [8] and malaria and dengue [21]; only dengue is a skin NTD. The remaining articles presented reviews and mixed approaches of DL-based methods for NTD diagnosis and were hence excluded from the final analysis. These results showed that the MMDF method has not been used to its potential for AI-based diagnosis of skin NTDs. Table 3 presents the articles demonstrating DL-based methods for skin-related and non-skin NTDs.

Table 3. Review of the deep learning (DL)–based methods for skin neglected tropical diseases (skin NTDs) and non-skin NTDs.

Citation	Publication year	Study approach	Disease(s) diagnosed	Dataset(s) used	Algorithm(s) used	Performance achieved
Skin NTDs						
[6]	2023	Clinical photo, transfer learning	5 skin NTDs	1709 images from 506 patients	CNN[a] (VGG16, ResNet50)	ResNet50 accuracy (Tasks 1 and 2: 84.63% and 84.17%, respectively)
[19]	2022	Data collection, preprocessing, SVM[b] optimized by BHO[c]	Buruli ulcer, CL[d], and leprosy	1054 images (420 Buruli ulcer, 262 CL, 372 leprosy)	SVM, BHO	Accuracy, F_1-score, recall, and sensitivity: 96%, 89%, 90%, and 92%, respectively
[18]	2023	Siamese-based FSL[e], metalearning on small dataset	Leprosy	368 leprosy, 28 non-leprosy, 151 patients	Siamese network, HAC[f]	FSL accuracy (training: 91.25%; testing: 73.12%)
[40]	2024	DL method using clinical photos	5 skin NTDs	1709 images of 506 patients (data store)	CNN (VGG16, ResNet50)	Accuracy: 70%; ResNet50 higher than VGG16
Non-skin NTD						
[39]	2022	WSI[g], KK[h] stool thick smears	STH[i]	16,990 annotated helminth eggs	CNN (ResNet101 COCO)	Precision: 94.9%; recall: 96.1%
[41]	2021	Crowd-sourced annotated images	STH	41 digitized stool samples (10,319 cropped images)	CNN (MobileNet-V2)	AUC[j] (crowd: 0.728; expert-annotated: 0.932)
[42]	2024	Digitization of slides, visual analysis, KK method	STH	Stool samples (n=1335) collected from school children	CNN (ResNet50), YOLOv2	High sensitivity (80%) and specificity (98%) for *Ascaris lumbricoides*

[a]CNN: convolutional neural network.

[b]SVM: support vector machine.

[c]BHO: black hole algorithm.

[d]CL: cutaneous leishmaniasis.

[e]FSL: few-shot learning.

[f]HSL: hierarchical agglomerative clustering.

[g]WSI: whole slide imaging.

[h]KK: Kato-Katz.

[i]STH: soil-transmitted helminthiases.

[j]AUC: area under the curve.

As presented, the study by Yotsu et al [6] demonstrated the use of a DL-based diagnostic model for NTDs using skin images only and achieved 70% accuracy. Beesetty et al [18] conducted a study for leprosy skin lesion detection using a Siamese neural network–based few-shot learning model and applying a hierarchical agglomerative clustering algorithm for a small clinical dataset and reported an accuracy of 73.12%. An optimized diagnostic approach was also proposed for NTDs by selecting 3 diseases and developing a model using support vector machine (SVM) and the black hole algorithm, achieving more than 90% accuracy [19]. A recent study [40] reported the creation of a DL model based on CNN architectures (VGG16, ResNet50) using clinical photos obtained from a previous data source to train the model. The studies of non-skin NTDs proposed DL models for the diagnosis of STH using images collected through different methods that included Kato-Katz, stool thick smears, and whole slide imaging [39,41,42].

Analysis of Fusion Techniques Used

Overview

Table 4 presents the review of the fusion methods other than MMDF techniques used by studies.

As shown, 5% (5/101) of the articles used feature fusion techniques, while 1% (1/101) of the articles implemented the image fusion technique for the diagnosis of non-NTD skin

XSL•FO
RenderX

diseases. Since the fusion methods used and diseases diagnosed did not directly fit into the objective of this study, these 5.9% (6/101) of studies were excluded from the final analysis. Finally, 13.9% (14/101) of the eligible articles were selected for the final analysis.

The 14 eligible articles used DL-based MMDF techniques for the diagnoses of skin NTDs and non-NTD skin diseases. Accordingly, 14% (2/14) of the articles implemented DL-based MMDF techniques for the diagnosis of 2 skin NTDs (leprosy and dengue), while 86% (12/14) of the articles described MMDF techniques for non-NTD skin disease diagnoses such as skin cancer, skin lesions, and other types of skin conditions. Table 5 presents a summary using 3 major parameters (method[s] used, algorithm[s] used, and corresponding performance achievements). The complete analysis is provided in Table S2 in Multimedia Appendix 1.

Table 4. Review of fusion methods other than multimodal data fusion (MMDF) for skin disease diagnoses.

Citation	Publication year	Study method or approach used	Disease(s) selected	Dataset(s) used	Algorithm(s) used	Performance achieved
[43]	2022	Multiclass skin lesion classification using feature fusion and ELM[a]	Skin disease (skin lesion)	HAM10000[b] and ISIC[c] 2018	SVM[d], KNN[e], DT[f], NB[g], ensemble tree, single hidden layer	Registered best accuracy of 94.36%
[32]	2021	Image fusion (clinical and dermoscopic): multilabeled deep feature	Skin cancer (melanoma)	Publicly available dataset	DCNN[h], CC[i], PCA[j]	Reported 81.3% accuracy
[44]	2019	Transfer learning and multilayer feature fusion network	Skin lesion	HAM10000 dataset	CNN[k]	High recognition (ROC[l]-AUC[m] 96.51)
[45]	2022	Applied feature fusion for manual and automatic feature extraction	Skin cancer	DermIS dataset	CNN, LSTM[n], LBP[o], Inception V3	Achieved maximum accuracy of 99.4%
[46]	2023	Dual-branch (feature) fusion network using DCNN, transformer branches	Skin disease (skin lesion)	Private dataset XJUSL	DCNN	Reducing parameters (11.17 million) improved accuracy by 1.08%
[47]	2023	Feature fusion: FBB[p], HFE[q], and VGG19-based CNN	Skin cancer (melanoma)	ISIC 2017, academic torrents	CNN	Registered 99.85% accuracy

Table 5. Summary of the review of the deep learning (DL)–based multimodal data fusion techniques for the diagnosis of skin disease.

Citation	Study method or approach used	Algorithm(s) used	Performance achieved
[8]	New dataset (skin lesion images, clinical data, demographic data), model training, and algorithms (elastic-net LR[a], XGB[b], and RF[c]) to combine image analysis with metadata	XGB, RF, LR, and 3 different models used (Model 1 using Inception-v4, ResNet-50), elastic-net LR model integration	Model 1: moderate (best accuracy of 66.6% and AUC[d] of 74.56%, elastic-net LR on metadata); Model 2: higher accuracy of 90%, AUC of 96.46%; RF on patient information achieved highest AUC of 98.74% on the testing patients
[9]	Multiplication-based data fusion using the metadata	CNN[e], the color constancy algorithm	Outperformed traditional baseline methods (*P* values<.5)
[12]	DNN[f]-based multimodal classifier (wound images and their locations): body map development, multimodal network	AlexNet + MLP[g], AlexNet + LSTM[h], ResNet50 + MLP, VGG16 + LSTM	Maximum accuracy on mixed class varied from 82.48% to 100%; maximum accuracy on wound class varied from 72.95% to 97.12% in various experiments.
[21]	GANs[i] and ensemble of BiLSTM[j], BiGRU[k], and RNN[l] models for classification and including an experimental evaluation	GANs, ensemble of BiLSTM, BiGRU, RNN, and CRNN[m]	Improved performance (precision by 4.9%, accuracy by 3.5%, recall by 3.5%, and AUC by 4.5%)
[48]	Combining multiple imaging modalities (dermatoscopic and macroscopic) with patient metadata	CNN: 2 ResNet-50 architectures, RF classifier	Binary (AUC 0.866 vs 0.784) and multiclass classification (mAP[n] 0.729 vs 0.598)
[10]	Combining images and metadata features: the (MetaBlock)	CNN using 5 pretrained models	Performed better than the other combination methods in 6 of 10 scenarios.
[11]	Performance analysis of classifiers and a naive combination of patient data and an image classifier	CNN	CNN: AUROC[o] of 92.30% (SD 0.23%) and balanced accuracy of 83.17% (SD 0.38%); naive strategy: accuracy of 86.72% (SD 0.36%)
[49]	DNN with 2 encoders and application of a multimodal fusion module with intramodality self-attention and intermodality cross-attention	CNN: CNN models (ResNet-50)	Accuracy: 0.768 (SD 0.022); balanced accuracy: 0.775 (SD 0.022); outperformed other metadata fusion methods (MetaNet, *P*=.035; MetaBlock, *P*=.028)
[50]	ViT[p] model, SLE[q], and MA[r] block	CNN: ResNet101, Densenet121, and ViT	Private dataset (accuracy: 0.816) and ISIC[s] 2018 (accuracy: 0.9381; AUC: 0.99)
[51]	Medical image analysis: preprocessing, feature extraction, classification or diagnosis, and the hold-out technique to split the dataset	CNN: 6 pretrained CNN models, HPO[t] algorithms	Average accuracy, sensitivity, specificity, precision, and DSC[u]: 9.94%, 91.48%, 98.82%, 97.01%, and 94.00%, respectively
[52]	Fusion of clinical skin image and patient clinical data, feature extraction, and attention mechanisms	CNN: VGGNet19, ResNet50, DenseNet121, and Inception-V3	Accuracy: 80.42% (improvement of about 9% compared with the model accuracy using only medical images)
[53]	TFormer[v]: transformer feature extraction backbone, MTP[w] block	Swin transformer, MLP, MTP block	Average accuracy of 77.99% and diagnostic accuracy of 80.03% on the Derm7pt dataset
[54]	Skin cancer prediction (clinical metadata and dermoscopic images), transfer learning (EfficientNetB3), and TabNet	EfficientNetB3, TabNet, and attention-based fusion	Consistently higher accuracy (98.69%) for classifying skin cancer on multiple datasets
[55]	2 distinct LLMs[x] (GPT[y]-4-turbo and Gemini-Pro-1.5) for generating clinical notes using cross-evaluation and consensus scoring methods (metrics of BLEU[z] score, ROUGE[aa] score, overlap coefficient, and Jaccard index)	ResNet-50, multimodal models (BERT[ab]-ResNet and ALBEF[ac]), and LLMs (for synthetic clinical note generation)	GPT-4-turbo outperformed Google Gemini Pro 1.5 at generating detailed and contextually rich clinical notes, with higher BLEU and ROUGE scores (0.87 and 0.84, respectively, compared with 0.81 and 0.78, respectively, for Gemini Pro 1.5)

[a]LR: logistic regression.

[b]XGB: eXtreme gradient boost.

[c]RF: random forest.

[d]AUC: area under the curve.

[v]TFormer: throughout fusion transformer.
[w]MTP: multimodal transformer postfusion.
[x]LLMs: large language models.
[y]GPT: generative pretrained transformer.
[z]BLEU: Bilingual Evaluation Understudy.
[aa]ROUGE: Recall-Oriented Understudy for Gisting Evaluation.
[ab]BERT: bidirectional encoder representations from transformers.
[ac]ALBEF: align before fuse.

Methods Used for Building Diagnostic Models

According to the results, 79% (11/14) of the articles primarily used CNN-based DL architectures, 14% (2/14) of the articles implemented transformer-based networks, and the remaining 7% (1/14) of the articles implemented an RNN-based architecture. The CNN-based studies used DCNN architectures such as VGG16, VGGNet19, ResNet50, ResNet101, DenseNet121, Inception-V3, AlexNet, and EfficientNetB3. Accordingly, for an accurate detection of leprosy [8], Inception-V4 and ResNet50 models were used for image analysis along with random forest (RF), eXtreme gradient boost (XGB), and Elastic-Net logistic regression (LR) for text-based tabular data analysis, with Elastic-Net LR being a regularization algorithm. For more than 2 modalities of data, such as 2 different image types and textual data, the use of separate CNN architectures such as ResNet-50 with a classifier model such as RF was used to build fusion models [48]. For images in a dataset having different sizes, a group of CNN architectures of AlexNet, VGG, ResNet, DenseNet, and SENet (Squeeze-and-Excitation Network) were used to extract visual features from 300 × 300-pixel images while using progressive neural architecture search network (PNAS) architecture for 224 × 224 sized images [9]. The diverse CNN architectures were also used with other algorithms such as VGG16 and multilayer perceptron (MLP), VGG19 and MLP, VGG16 and long short-term memory (LSTM), VGG19 and LSTM [12], or other combinations of the CNN architectures paired with other algorithms (like SVM, RF, and XGB) to extract textual and visual features in parallel. Transformer-based architectures, such as using the ResNet101 and DenseNet121 models with vision transformers (ViT) models and multimodal transformers with MLP, were also used to build MMDF models [50]. Furthermore, a hierarchical ViT architecture (for feature extraction), MLP, and a fusion architecture with a hierarchical multimodal transformer were used as one potential approach [53]. The other DL method used was the RNN-based architecture implementing an ensemble of RNN models using bidirectional LSTM (BiLSTM) for textual feature extraction, bidirectional gated recurrent unit (BiGRU) for image analysis, and a standard RNN layer for combining the extracted features from BiLSTM and BiGRU models [21] for skin NTD diagnosis.

Fusion Strategies Suggested for Skin Disease Diagnosis

The studies reviewed demonstrated 4 different fusion approaches that included feature fusion, model fusion, image fusion, and MMDF techniques, where 93% (13/14) of the studies we appraised applied MMDF approaches for integrating mainly clinical images and textual medical data. One study (1/14, 7%) used the MMDF approach to combine 3 different modalities of data: 2 imaging modalities (dermatoscopic and macroscopic images) with patient metadata [48].

In the study of leprosy diagnosis [8], the late fusion (decision-level fusion) method was applied using 2-step patient-level models using, first, a CNN architecture to predict the probability of leprosy based on skin lesion images (Model 1); second, ML algorithms (elastic-net LR, XGB, RF) to predict the probability of leprosy based on metadata (Model 2); and third, a combination of the outputs from both models given to a third model (Model 3) to train and predict the final output. The other study applied feature-level fusion (early fusion) by outlining a structure that used BiLSTM and BiGRU models for extracting multimodal features (image and text), followed by an RNN architecture to merge the feature representations from BiLSTM and BiGRU models and predict the final output (predicting the probability of malaria or dengue) [21]. An attention-based metadata processing block (MetaBlock), which uses metadata for enhancing features extracted from the images throughout the classification, can be another multimodal fusion strategy [10]. The naïve approach [11], combining patient data and the image classifier by replacing the image classifier with the patient data classifier on slides with low output scores for a whole slide image classifier module, is another fusion strategy described. Similarly, the feature concatenation method was used

XSL•FO
RenderX

to develop a wound classifier multimodal network by concatenating the image classifier and location-based classifier outputs [12]. A late fusion approach can also be adopted to integrate multiple modalities of data (2 image modalities) with textual data [48], where image feature vectors created from each feature extraction network were merged with the feature vector of the textual data. The other MMDF approach, inspired by the SENet network operation, was the use of a multiplication-based approach where feature importance was controlled by the metadata [9].

The other MMDF strategy is the transformer-based approach. Accordingly, a neural network with a multimodal transformer consisting of 2 encoders for feature extraction (image and metadata features), 1 decoder (to extract image features and fuse the multimodal information using the ViT model), a soft label encoder for the metadata, and a mutual attention block to fuse the different features [50], was used and showed promising results.

Similarly, a DNN with 2 encoders for extracting image and textual features, an MMDF module with intramodality self-attention and intermodality cross-attention capabilities, was used in [49], and the model outperformed other fusion models. In another study, a fusion system was developed using 4 procedures consisting of preprocessing the image and metadata, feature extraction using 6 pretrained models, feature concatenation (using CNN through convolutional, pooling, and auxiliary layers), and classification of skin disease [51]. In another study [52], a skin cancer diagnostic model was developed following 3 procedures: extracting features (skin images and patient clinical data using CNN architectures), using the attention mechanism (for handling the multimodal features), and developing a feature fusion model. The “divide and conquer” approach using transformers, as in [53], was the other MMDF strategy where a hierarchical multimodal transformer block was used to fuse multimodal image modalities (dermoscopic and clinical images), followed by a multimodal transformer postfusion block that used a cross-attention mechanism to combine the fused image features with textual patient data. The use of an attention-based fusion mechanism can be used to merge image features extracted by CNN architecture and clinical data processed by TabNet [54]. Another advanced fusion strategy can be the use of a dual-encoder architecture using separate models for extracting multimodal features (ResNet-50 for image analysis and bidirectional encoder representations from transformers [BERT] for text processing), followed by a joint-encoder architecture containing a mode that processes text and image data in parallel but, importantly, aligns these modalities before fusion [55].

Achievements of the MMDF Techniques for Diagnosing Skin Diseases

As the results are confirming, MMDF techniques outperform traditional baseline diagnostic approaches [9,10]; the majority of the studies reported that their proposed disease classification models achieved more than 80% accuracy, as reported in [8,10,11,48,50]. The use of the GAN-based framework for data augmentation to add additional training data improved the model accuracy by 3.5% compared with the traditional models experimentally trained by the same researchers [21]. The medical image analysis study based on feature extraction, feature concatenation, and classification methods [51] reported 99.94% accuracy in the classification of 7 selected skin diseases. Finally, the study that used 2 DNN-based encoders with multimodal fusion modules (intramodality self-attention and intermodality cross-attention) [49] reported a 76.8% accuracy.

Article Quality Assessments

After evaluating the quality of the articles, potential sources of bias were identified based on the 3 major categories of risk factors, namely data collection, dataset used, and development methodology used by the studies. Accordingly, 6 studies [8,11,12,21,48,50] used datasets collected from a particular population, which shows the potential risk of selection bias. In addition, the dataset sizes used in these studies were relatively small, leading to a potential risk of bias regarding model generalizability. The other 6 studies [9,10,49,51-53] used imbalanced datasets with an expected risk of overfitting, which leads to algorithmic bias. Finally, the use of synthetic data, as in [8] and [55], introduce a risk of bias due to previous latent biases inherent to the generative models used.

Discussion

Goal of the Study

The primary goal of this study was to present a systematic review of previous studies demonstrating DL-based MMDF techniques for the diagnosis of skin NTDs. However, led by the scarcity of articles, similarity of the diagnostic procedures used for both skin NTDs and non-NTD skin diseases, similarity of methods used, and results reported by the studies, this review focused on studies that used MMDF for diagnosing both skin NTDs and non-NTD skin diseases. In doing so, articles were collected and analyzed, and results obtained from the analysis were interpreted, as presented in the following sections.

Important Findings

Article Selection and Distribution

It was challenging to find publicly accessible articles on DL-based MMDF approaches for the diagnosis of skin NTDs, except for 2 recently published articles. The pathological similarity of the disease categories (both are dermatological cases) forced this review to focus on studies that used MMDF for the diagnoses of both skin NTDs and non-NTD skin diseases.

DL-Based Methods and the Preference for CNN

The use of CNN architectures by the majority of the studies (11/14, 79%), primarily for feature extraction and classification tasks, proved the effectiveness of CNNs at processing and analyzing multimodal data for skin-related disease diagnoses. The transformer-based architectures, through the use of ViT, attention-based mechanisms, and GAN-enabled augmentation methods, showed model accuracy improvements when used in MMDF systems for skin disease diagnosis.

Regarding the availability of diverse fusion techniques, the studies demonstrated different fusion techniques that included feature fusion, model fusion, image fusion, and MMDF.

XSL•FO
RenderX

Regarding the superior diagnostic accuracy of MMDF techniques, the MMDF techniques consistently outperformed the traditional, mostly single-modality diagnostic methods, as confirmed by the analyzed studies that reported superior classification accuracies.

Interpretations of Results

This systematic review of articles presented important dimensions in the area of DL-based MMDF methods, and the use of the PRISMA model made the article selection process more systematic and transparent.

Hereunder, we present methodological implications of applying MMDF for skin disease detection.

DL Methods and Architectures

Generally, the entire MMDF process can be achieved using 4 different DNN modules that perform data preprocessing, feature extraction, feature concatenation or combination, and disease classification, where feature extraction is the common task for all MMDF tasks. Hence, proper feature extraction models and tools should be used for the feature extraction tasks. In DL, CNN-based pretrained models such as ResNet50/101, VGG16/19, DenseNet, Inception, and similar DCNN architectures are the tools to use for image feature extraction. Similarly, the RNN architectures (such as LSTM, GRU, and standard RNN, including the bi-directional architectures [BiLSTM, BiGRU, RNN]) can also be the right tools to extract features, especially for sequential data like text, audio, and video. Furthermore, for larger textual data, large language models (LLMs) such as BERT and GPT can be used to contextualize the text data and extract features from the text data.

We found that CNN models are the predominant DL architectures, mainly due to their convenience and widespread use of CNNs, which resulted from the ability of CNNs to provide end-to-end learning and their ability to work on raw data without having prior knowledge [56]. However, although CNNs are effective for analyzing image-based data and RNNs are suitable for sequential and time series data, the choice of a particular DL architecture should be based on the type of input data from which the features are extracted. Thus, for feature extraction of input data representing multiple modalities (like image, text, audio, and video), using the combination of CNN and RNN architectures represents the proposed approach. The use of this approach for MMDF problems allows the MMDF models to use properly extracted spatial representations from CNNs as well as properly analyzed sequential or temporal representations from RNNs, leading to higher model performance. In addition, the use of other ML algorithms (RF, LR, MLP, XGB, and others like TabNet) with the DNN architectures will also contribute to performance achievements of MMDF models, as each algorithm has operational sensitivity for a particular data type other than image data. For instance, the RF algorithm performs well on textual data, XGB performs well on structured tabular data, and the LR algorithm can perform well on continuous numerical data.

Fusion Techniques and Approaches

One important observation regarding MMDF is the level at which the MMDF process takes place. The application of late or model fusion techniques for the diagnosis of skin-related diseases, such as skin NTDs, can be considered the potential fusion approach, though it requires further investigation using sufficient quality data with sufficient computing resources to demonstrate ensemble learning techniques. The intermediate level is a more appropriate level for fusing multimodal data, where a separate DNN network is used for individual feature extraction from each data modality. A separate layer concatenates the outputs of each network by combining the feature vectors of each modality from each network, followed by final processing layers such as pooling, normalization, and output layers to produce efficient predictions. This approach ensures effective data preprocessing by using a dedicated CNN architecture for modality-specific feature extraction targeting skin images and textual patient records. It also helps with creating bigger feature maps containing important features extracted from individual data modalities, which can improve the prediction accuracy of the diagnostic models. However, this technique is tedious, as it requires the development of an individual CNN model for each data modality, followed by another model for concatenation and prediction. Technically, most DL-based feature fusion tasks are performed at the intermediate level of data fusion. As a result, a potential problem might arise due to the addition of more features or dimensions that increase the complexity of the data, the curse of dimensionality. It is a problem resulting from high-dimensional data where the data have a large number of features, variables, or dimensions, often represented by the columns in a dataset [57]. To overcome this challenge, it is imperative to consider proper dimensionality reduction methods such as principal component analysis, which simplifies the existing variables to reduce the number of variables without losing the information contained in the initial data [58].

Regarding the fusion approaches, experiments are showing that prospective ML approaches, such as attention-based mechanisms and multimodal transformers, are demonstrating promising results for integrating multimodal data with the enhanced accuracy of DL-based diagnostic systems with multimodal data. In this regard, the attention mechanisms, such as the self-attention and cross-attention mechanisms, are showing promising results, as these techniques enable the capture of pertinent information from feature maps. This mechanism allows assigning different weights to different features, where features with larger weights are considered to be more important in the diagnostic process and vice versa, ensuring up to 2% performance superiority over other MMDF methods [49]. On the other hand, the use of multimodal transformers using the ViT model is another possibility that needs further investigation. Although these models outperform previous models in skin disease diagnosis by about 1%, unlike CNNs, ViTs are mostly data-intensive and require training models on public datasets with millions of labeled data [50]. In a DL-based MMDF application scenario for skin-related disease diagnosis, the integration of LLMs with image analysis models is one potential application. This method allows the integration of image data

XSL•FO
RenderX

with nontabular textual patient data, such as disease symptoms expressed in longer phrases or sentences and clinical notes. LLMs, such as BERT and GPT, can be used to extract features from textual data to be concatenated with other modalities of data such as images. Finally, as a potential future trend, a hybrid fusion approach using a combination of more than 2 data modalities and different fusion approaches can be an alternative approach, although deeper investigation with multiple datasets is required to confirm this claim.

Dataset Quality and Quantity

As a DL problem, the performances of the models can be impacted by data scarcity and the use of low-quality datasets, such as image resolution limitations, problems with annotation accuracy, and possible data imbalance among the skin diseases. Among the reviewed articles, 64% (9/14) of the studies used publicly available datasets; hence, issues of dataset sizes and data imbalances were not faced. Data scarcity was the major issue faced by the remaining 36% (5/14) of the studies that used private datasets specifically collected for the proposed diagnostic models. The problem of data scarcity can be addressed using an ML method called data augmentation, which can be used to artificially create data samples to increase the size and diversity of the dataset. The data augmentation process can be achieved in different ways, one of which is to implement data augmentation methods using built-in augmentation libraries during model training. The other method can use GAN-based generative models to increase dataset sizes through the creation of artificially synthesized data samples of a given data modality. The GAN-based method can be used as a data augmentation method applied both to the images and the clinical data [21]. The generative models also provide ways to generate artificially synthesized content such as text files, as in [55], for creating artificial clinical notes that were not part of the initial dataset, allowing them to address the problem of multimodal alignment. Multimodal alignment is a data modality imbalance problem that occurs when some data modalities (image, text, or video) appear to be rare, scarce, or unavailable, possibly due to difficulty acquiring them [59]. Hence, the GAN and LLM-based generative methods are potential solutions for maintaining dataset quality, quantity, and multimodal alignment. However, the use of these models, though critically useful in data-scarce scenarios, should be conducted with great care, giving attention to possible model performance issues when faced with real-world data.

Study Limitations

The major constraints of this study are attributed to the methodology and resource limitation problems. First, the lack of previous studies on the application of MMDF techniques for skin NTDs broadened the scope of this review to include studies that focused on non-NTD skin diseases. Although this approach introduced a minor methodological misalignment, it allowed the inclusion of 12 selected articles to extend the analysis on a broader range of MMDF techniques. Second, due to resource limitations, the study was designed to explore and analyze open-access articles only. This has limited the number of relevant articles being collected and analyzed, which might have an impact on the overall analysis of results. Third, the vastness of the problem has also had negative impacts on the full contribution of this review study due to time constraints. Therefore, to confirm these results, future work should expand the scope of the analysis by conducting large-scale, targeted investigations using a broader range of analytical parameters.

Article Quality Assessments

As a model development study, each study specifies the processes involved in the development and evaluation of the corresponding proposed diagnostic model for the identified disease. Accordingly, the potential issues observed in relation to the risk of bias mostly arise from the data collection, dataset creation, and model development processes leading to the issues of patient selection, dataset typicality, and algorithmic biases, because the studies used a dataset of a particular disease(s) from a specific location or they used a publicly available dataset. Although the studies present diverse sources of potential bias while developing their proposed DL model using MMDF techniques, each study implemented a particular method to overcome the potential risk of bias. For instance, generative models were used as data augmentation mechanisms to overcome the risk of bias due to data scarcity in [21], while [55] used synthetic data from the generative models to add textual data for multimodal model training. Although these measures helped to overcome the major DL problem (data scarcity) and achieve higher model accuracy, other potential risks of bias could arise as a result of using synthetic data.

Therefore, in every model development project, especially for diagnostic systems, the very first task during the inception of the project should be an in-depth analysis of the available resources (such as data), method(s) to be used, expected output, and potential risk of bias that might arise as a result of using a particular method or resource. Once identified, the potential risk of bias should be evaluated, and properly devised strategies for tackling the potential risk should be in place. Some of the strategies include defining the data requirements (including the type and source of the data); conducting data collection to address scarcity or class imbalance issues; and applying specific strategies for data preprocessing, feature selection, and feature engineering. Additionally, model selection, model optimization, and the use of established evaluation techniques should be considered to ensure the reliability of the models. Finally, professional and ethical criteria are required for any data acquired from external sources, including generative models.

Ethical Considerations

All the reviewed articles complied with the standard ethical principles, as the studies primarily involved patients and patient data to develop their intended models. However, almost all the previously identified risks of bias can also pose potential ethical issues, since every potential bias has a corresponding problem. Some of the problems include that a DL diagnostic model trained on a relatively small or unbalanced dataset could result in model overfitting, and a model trained on an entirely generated dataset could potentially be challenged when faced with actual real-world data (mostly resulted from data quality differences between the actual and synthetic data). All these flaws result in algorithmic biases, leading to misdiagnosis. Using a misdiagnosing DL model in real-time diagnostic environments

XSL•FO
RenderX

is a real danger to the well-being of individuals. It also goes against the ethical principles of the disciplines of medicine and computing. The problem could get much worse if diagnostic systems that use such misdiagnosing models were to be used in underserved areas that have limited resources, because in such areas, the problem of misdiagnosis could result in life-threatening health problems instead of overcoming the burden of diseases. Hence, comprehensive identification and mitigation of all potential sources of bias are required before model deployment. Additionally, as good software engineering practice, a full-fledged testing procedure should be conducted on the diagnostic models to ensure accurate diagnosis.

Contribution of the Review

Overall, this study's primary contribution is a critical appraisal of DL-based MMDF techniques for diagnosing skin diseases, including skin NTDs and non-NTD skin diseases. We identified key limitations and the research gaps and proposed the adoption of methods for the diagnosis of skin NTDs. We contributed to the literature by providing, to the best of our knowledge, the first systematic and comprehensive analysis of the applicability of DL-based MMDF techniques for diagnosing both skin NTDs and non-NTD skin diseases. In the process, further research gaps were identified, and corresponding solutions have been forwarded as future research direction. This contributes to the research community by giving insights into the areas that require further investigations, which was the primary goal of this systematic review.

Conclusion

With the aim of identifying and adopting DL-based MMDF techniques for skin NTD diagnosis, this review analyzed existing DL methods applied to both skin NTDs and non-NTD skin diseases. In this regard, the CNN-based models are the most suitable DL architectures for feature extraction and concatenation, while other DL architectures using RNN are also potential solutions. If text-based features are to be integrated, transformer architectures with attention mechanisms could achieve outperforming results, though it requires further investigation with a particular dataset. Generally, the use of DL-based tools that integrate MMDF techniques has the potential to enhance the diagnosis and management of skin NTDs by improving diagnostic accuracy, especially in resource-constrained settings.

Although studies have demonstrated the use of DL methods using skin images, including 2 recently published studies applying MMDF, there is a notable research gap regarding the implementation of MMDF techniques for the diagnosis of skin NTDs. This systematic review, thus, identified 3 critical gaps and suggested potential solutions for future work. First, due to the lack of previous studies applying MMDF techniques for the diagnosis of skin NTDs, this review has extended its scope to include studies focusing on non-NTD skin diseases, representing 86% of the total analyzed articles. In this regard, the findings of this review highlight that further studies are required regarding the application of DL-based MMDF techniques for the diagnosis of skin NTDs. Second, the availability of high-quality datasets (having diversified modalities and proper annotation and of sufficient quantity to train DL model) remains a challenge for conducting DL-based studies for skin NTD diagnosis. This scarcity hinders potential studies in the area, which highlights the need for efforts to develop and share large-scale, quality datasets. In addition, further investigations are required to research the applicability of synthetic data generated using generative models to address data scarcity and maintain dataset quality when developing diagnostic models for skin NTDs. Finally, the selected studies underscored promising results toward the application of MMDF techniques for skin NTDs with limited modalities of patient data (image and metadata). However, further studies are required to demonstrate the applicability of MMDF techniques for skin NTDs using more than 2 modalities, such as the combination of skin images, structured (tabular) patient data, and textual descriptions.

Abstract

The adaptive nature of artificial intelligence (AI), with its ability to improve performance through continuous learning, offers substantial benefits across various sectors. However, current regulatory frameworks are not intended to accommodate this adaptive nature, and they have prolonged approval timelines, sometimes exceeding one year for some AI-enabled devices. This creates significant challenges for manufacturers who must deal with lengthy waits and submit multiple approval requests for AI-enabled device software functions as they are updated. In response, regulatory agencies like the US Food and Drug Administration (FDA) have introduced guidelines to better support the approval process for continuously evolving AI technologies. This article explores the FDA's concept of predetermined change control plans and how they can streamline regulatory oversight by reducing the need for repeated approvals, while ensuring safety and compliance. This can help reduce the burden for regulatory bodies and decrease waiting times for approval decisions, therefore fostering innovation, increasing market uptake, and exploiting the benefits of artificial intelligence and machine learning technologies.

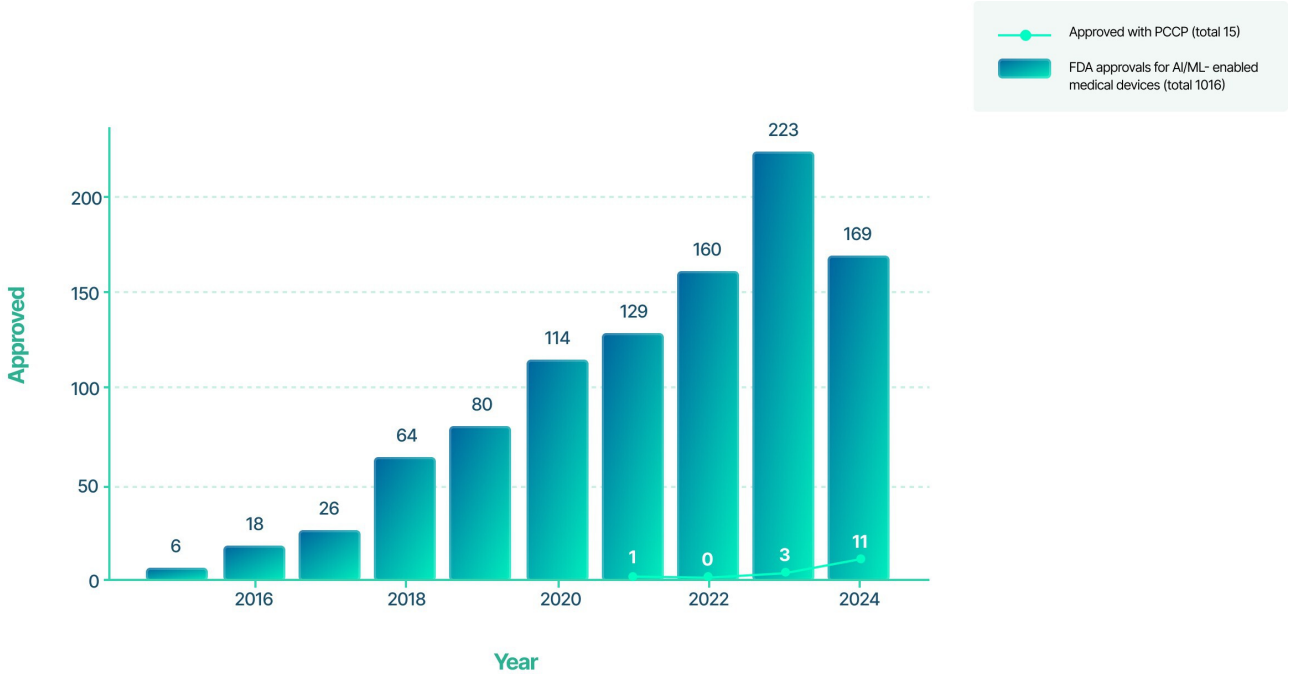
predetermined change control plans; artificial intelligence; health care; machine learning; regulation

Introduction

The use of artificial intelligence (AI) and machine learning (ML) technologies is growing exponentially across industries, and the amount of data gathered in health care and other sectors increases the impact and importance of such technologies as well as the need for regulatory frameworks that accommodate continuous learning. In health care, AI-ML technologies are being used to assist health care providers, aid diagnosis, personalize treatments, predict health problems, and improve patient care. One of the biggest advantages of AI-ML in software is its ability to improve performance by learning from new data and real-world use and experience. However, these technologies pose some unique challenges imposed by the dynamic learning typically involved in the development, deployment, use, and maintenance of such technologies. They are developed iteratively, which means that the software changes are continually applied, either manually or automatically [1].

The large majority of the health care tools that use AI-ML technologies are classified by most jurisdictions as software as a medical device (SaMD), which falls under stringent regulatory oversight. In the United States, the FDA categorizes SaMD based on risk levels (Class I, II, and III), determining the appropriate approval pathway, either the premarket approval (PMA), the 510(k), or De Novo classification. The FDA approved 95,147 devices up to the end of 2024 with the 510(k) or the De Novo pathway and a total of 1678 devices via the PMA pathway. Within the PMA pathway, a total of 53,315 PMA supplements were submitted, with an average of 3177 supplements per device. These supplements are documents required for a change affecting the safety or effectiveness of a device with an approved PMA. This highlights the need for

XSL•FO
RenderX



mechanisms to update devices while ensuring safety and effectiveness and with less burden for manufacturers and regulators, which is particularly relevant for devices with AI-ML technologies.

Traditional regulations were not intended to accommodate the adaptive nature of AI-enabled device software functions (AI-DSFs), which involve continuous learning strategies that affect the clinical safety, performance, and benefit of the device. The regulations state that devices should be used in their approved form, without subsequent changes that affect their functionality, which means that AI-DSFs could not get approval because they change dynamically without manufacturer supervision and, as a result, their updated state no longer conforms to the approved and tested state. If AI-DSFs do not change after market approval, there will not be a problem. However, this limits the benefits of continuous learning systems that can improve their quality and performance over time. Traditional regulations require devices to be "locked" upon approval or to submit a new submission for approval after modifications. These hinder continuous improvement and adaptation to new environments, often resulting in performance degradation when the device encounters scenarios that differ from those used for training the AI-ML technology. Consequently, data collected in the meantime is unused, limiting opportunities to enhance accuracy, safety, and effectiveness [2].

This problem raised the attention of jurisdictions that are developing novel, faster, and robust methods for devices that change after being placed on the market. In 2019, the FDA published a paper describing a potential approach to premarket review for AI-ML-driven software modifications. In this paper, a framework for modifications to AI-ML-based SaMD was proposed, promoting a mechanism for manufacturers to continually maintain the safety and effectiveness of SaMD [3].

Afterward, in 2021, the FDA issued a document with guiding principles for the development of medical devices with machine learning (ML) [4]. Later, in 2023, FDA, UK Medicines and Health Products Regulatory Agency, and Health Canada published 5 guiding principles for predetermined change control plans (PCCPs) in ML-enabled medical devices to ensure safety and effectiveness throughout the device's total product lifecycle [5]. More recently, the FDA published the marketing submission recommendations for a PCCP for AI-DSF, which supports the iterative improvement of AI-enabled devices with reasonable safety and effectiveness without the need for additional marketing submissions to implement each of the modifications outlined in a PCCP [6]. Up until the end of 2024, a total of 1.016 AI-ML-enabled medical devices have been approved by the FDA [7], 53 devices with PCCPs [8], and 15 AI-ML-enabled medical devices with a PCCP (Figure 1).

Figure 1. Artificial intelligence and machine learning-enabled medical devices approved by Food and Drug Administration over time. AI: artificial intelligence; FDA: Food and Drug Administration; ML: machine learning; PCCP: predetermined change control plan.

In the European Union (EU), the Medical Device Regulation (MDR) defines a rigorous certification process, and there is awareness of the limitations of the current legislation, as recommendations to monitor significant modifications, namely changes that violate compliance with existing regulatory requirements or any change to the preapproved intended purpose, have been included in the AI Act [9,10].

The EU, similarly to the United States, also proposed a regulatory framework for AI systems, but it follows a stricter and more granular approach. The EU AI Act applies to all AI systems across multiple sectors, and it classifies AI systems into risk categories. AI-ML-enabled medical devices are considered high-risk and lead to more strict requirements. Providers of high-risk AI systems must implement a quality management system, where it is necessary to outline, for example, risk management strategies, data governance, technical documentation, and postmarket monitoring. The EU AI ACT also emphasizes postmarket surveillance and requires

XSL•FO
RenderX

manufacturers to analyze how the AI system is performing after deployment. There is a clear focus on ensuring that high-risk systems have detailed documentation and plans for continuous monitoring, but there is a clear lack of guidance on how to deal with the changes to such devices and how to account for the adaptability of AI-ML technologies that are intended to continuously learn and change over time [11].

Changes predetermined by the manufacturer at the moment of initial conformity assessment should be defined and described, including technical solutions adopted to ensure continuous compliance of the AI system with the relevant requirement, but they shall not constitute a "substantial modification." However, there is no clear definition of what is considered substantial, and contrary to the FDA, the EU AI Act lacks objectivity on what can be accommodated as a modification without the need for repeated assessment of conformity [11]. In a question and answer document provided by the EU, it is stated: "This assessment has to be repeated if the system or its purpose are substantially modified." [12], which emphasizes the ambiguity and vagueness. The current regulatory framework still lacks detail on implementing algorithm change protocols, and even though the importance of postmarket performance monitoring is reflected in the EU AI Act, there are no specific guidelines [13]. This limitation is recognized and in Article 96 of the EU AI Act, where it states that the commission should develop guidelines on the practical implementation of the provisions related to substantial modification [11].

The key differences between the regulation of AI-ML medical devices in the United States and the EU are summarized in Table 1.

Table . Differences in AI[a]-ML[b] medical device regulation in the European Union (EU) and United States (US).

Regulation Aspect	European Union	United States
Regulatory bodies	Medical device regulation (MDR) and EU AI Act	FDA[c]
Approval pathways	CE[d] marking	510(k), De Novo, or PMA[e]
Risk classification	High risk	No explicit risk-based classification
Bias mitigation	Emphasis on fairness and transparency	Focus on diverse training data
Adaptability	Updates may require new conformity assessments and certifications	Allows iterative AI-ML model updates without full resubmission with PCCPs[f]
Postmarket monitoring	Strong emphasis with AI Act requiring continuous monitoring and reporting	FDA encourages postmarket surveillance and real-world performance monitoring

[a]AI: artificial intelligence.

[b]ML: machine learning.

[c]FDA: Food and Drug Administration.

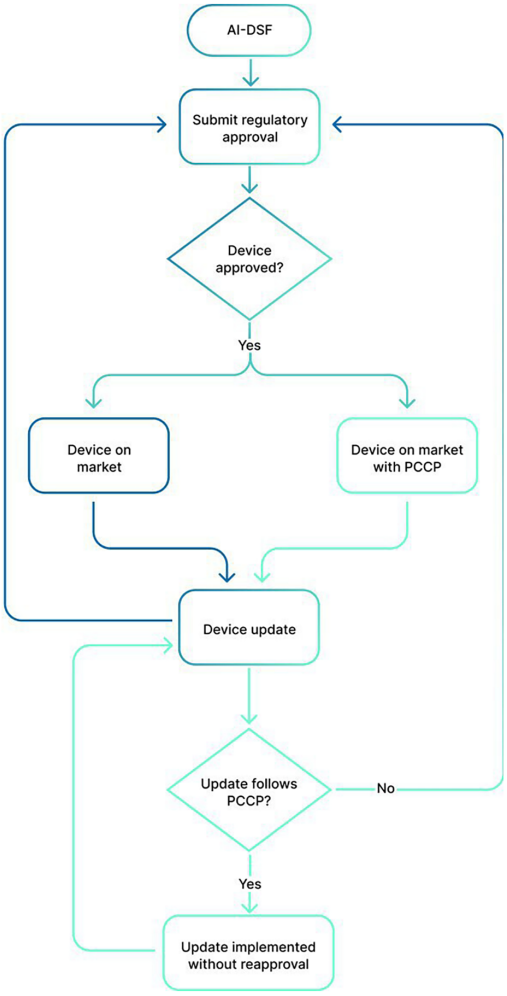
[d]CE: Conformité Européenne.

[e]PMA: premarket approval.

[f]PCCP: predetermined change control plan.

Despite ongoing regulatory efforts, significant uncertainty remains regarding how to address continuous learning AI-ML systems and their intrinsic modifications and which regulations and legislation manufacturers should look at. To address this, this paper aims to explore the challenges and opportunities associated with regulating the adaptive features of AI and to explore how PCCPs can guide the iterative development of AI-ML systems while ensuring safety, effectiveness, and quality. The paper explains the key concepts of PCCPs and outlines the guiding principles of PCCPs in order to establish its foundations. Afterward, it discusses the implications of PCCPs and presents reference case studies. Finally, it identifies ongoing challenges and proposes future directions.

Understanding PCCPs



PCCPs are regulatory mechanisms that allow manufacturers to implement preapproved modifications to systems or devices after market authorization while maintaining compliance with safety and performance standards.

Contrary to traditional control mechanisms, which assume that systems remain unchanged and are used in their approved form, PCCPs take into account the dynamic nature of AI-ML systems and exploit the benefits of continuous learning systems [14]. Traditional static validation methods for medical devices and AI-driven software rely on a fixed approval process, assuming that the system remains unchanged throughout its lifecycle. Nonetheless, this approach is insufficient for AI-ML systems due to their inherently dynamic nature. Unlike conventional software, AI-ML models evolve as they are exposed to new data, necessitating a regulatory approach that accommodates ongoing modifications while ensuring compliance and safety [15]. In this manner, PCCPs provide a structured regulatory mechanism that enables manufacturers to implement controlled AI-ML model updates without requiring extensive reapproval procedures. This adaptability allows manufacturers to refine AI-ML models through real-world data, mitigating risks associated with outdated static validation frameworks and clinical insights, leading to enhanced performance and improved outcomes. By preapproving modifications, PCPPs reduce the need for manufacturers to resubmit devices for approval after

XSL•FO
RenderX

every update, leading to fewer inefficiencies and delays and faster time-to-market [2,10]. Figure 2 shows the traditional regulatory approval process (in blue) and the one with a PCCP (in green).

Figure 2. Regulatory approval process: traditional - blue; with a PCCP predetermined change control plan - green. AI-DSF: AI-enabled device software function; PCCP: predetermined change control plan.

By including PCCPs in market submissions, manufacturers can proactively outline and secure premarket authorization for specific device changes. This reduces the need for additional submissions and subsequent regulatory approval, provided the changes are consistent with the preapproved PCCP established during the device's marketing authorization. The development of PCCPs can streamline the implementation of modifications, ensuring that updates meet established safety, efficacy, and quality standards without requiring repeated resubmissions [2,6]. PCCP encompasses some key aspects:

- Planned modifications: identification of software components subject to updates, such as model refinements and performance enhancements.
- Data lifecycle management: implementation of robust data management practices to maintain compliance and data integrity.
- Implementation and performance evaluation: establishment of clear metrics to validate modifications.

Manufacturers should focus on addressing the following 4 questions to ensure that PCCPs have the fundamental concepts:

- What are the planned changes?
- How will the data lifecycle be managed?
- How will the changes be performed?
- How will the performance of the model with the changes be evaluated?

To get approval for a device with a PCCP, the market submission must include a standalone PCCP section, outlining planned modifications, risk assessments, and validation procedures. The planned modifications should also be included and discussed in the cover letter of the marketing submission, in the device description, labeling, and other relevant sections required for safety and effectiveness assessment. In addition, the authorized PCCP should include 3 main sections [6]:

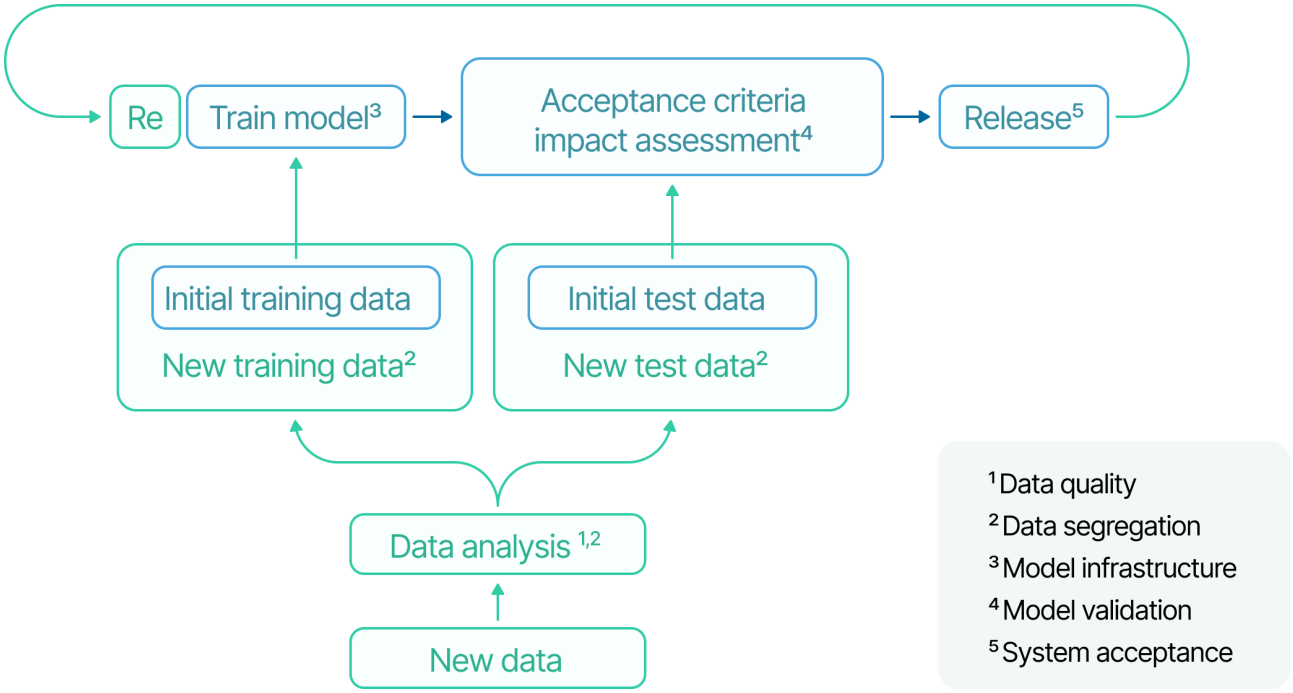
1. Description of modifications, including a detailed account of proposed changes and their rationale. It is recommended that these modifications be specific, validated, and verified. For example, it is important to define if the change will be implemented automatically, manually, or a combination of both. Distinguishing global from local changes is also an important point to clarify because, in local changes, the modifications are implemented differently on the market, based on specific characteristics. The modifications appropriate for inclusion in a PCCP are those intended to

XSL•FO
RenderX

maintain or improve the safety or effectiveness of the device, and, for AI-DSFs, they usually fall into one of the following types:

- Modifications related to quantitative measures, such as improvements in performance due to model retraining with new data;
- Modifications related to device inputs and compatibility, such as adding new inputs or transforming them, updates of the compatible software or hardware, and device interoperability;
- Modifications related to use and performance

2. Modification protocol, which should describe a structured approach for developing, validating, and implementing modifications, is outlined in the Description of Modifications section of the PCCP. In addition, it should also include verification and validation strategies for the modifications, with predefined acceptance criteria. It is relevant that this section includes 4 components:
   - Data management practices, to outline how new data will be collected, annotated, curated, stored, and used to train, tune, and test the AI-DSF; retraining practices, to identify processing steps that are subject to change and the methods that will be used to implement the modifications;
   - Performance evaluation protocols, to describe the processes that will be used to verify and validate the modified AI-DSF; Update procedures, to describe how the modifications will be implemented, either automatically, manually, or a combination of both, and the plan of communications to inform users
3. Impact assessment, which describes how the evaluation of benefits and risks, and the mitigation strategies associated with modifications are assessed, along with how they will be verified and validated through the activities detailed in the modification protocol. It should address how each modification impacts the device, including the risks of harm and bias; how each modification impacts others; and describe the cumulative impact of the implementation of all modifications.



As it will be detailed in section “Guiding Principles for PCCPs,” one of the guiding principles for PCCPs is stakeholder collaboration. Manufacturers, regulators, and end-users each have a determinant role in PCCPs. The developers are the ones responsible for the design, implementation, and documentation of PCCPs, and they should do it in line with guidelines published by regulators. The predefined modification should comply with the regulatory requirements and be transparent to end-users and regulators, providing them with evidence that the updates do not compromise safety or effectiveness. Engaging regulators in the early phases of the development of PCCPs may boost the possibilities of market approval, as they are the ones that define the criteria and procedures of acceptance and therefore can provide assistance for successful PCCPs. Finally, the end-users also play a role since they are the ones who benefit from PCCPs and can attest to the safety and effectiveness of the modifications implemented in the PCCP. Their role can be particularly relevant in postmarket surveillance mechanisms, considering they can be the first ones to identify problems and trigger potential modifications.

With PCCPs, manufacturers must plan the expected modifications and updates to AI-ML software, reducing some of the uncertainty intrinsic to such technologies. This brings benefits for the end-users, who are aware of the potential updates of a device and reduces uncertainty for developers and regulators, creating a clearer pathway for implementing improvements. Other benefits of PCCPs are their structured nature and the transparency they provide to all stakeholders, which increases trust and confidence between them. If a device has a PCCP, the stakeholders are aware of the possible updates and modifications and the corresponding monitoring and validation plans that will ensure the safety and effectiveness of the device.

By embedding PCCPs as a crucial tool within regulatory frameworks, manufacturers can reduce inefficiencies associated with frequent resubmissions while maintaining robust oversight, established mainly through transparency of intended refinements among regulators, manufacturers, and end-users, fostering trust in AI-driven health care innovations. A locked model is trained with the initial training data, it is tested, and if the acceptance criteria are met, the model is validated and released after approval. If new data are gathered or any other modification is implemented in one of the 5 stages, manufacturers would require a new market submission. With a PCCP, it is possible, for example, to update the model without the need for further market submissions. The new data are analyzed to ensure they have the quality required and respect the defined criteria. Then the data have to be segregated, and afterward, the model can be retrained. A new test set is created with previous and new data, which is used to ensure that the model matches the acceptance criteria defined in the modification protocol section, and if so, the model is released without further regulatory approval [16] (Figure 3).

XSL•FO
RenderX

Figure 3. Locked model (blue) and continuous learning model (green).

Guiding Principles for PCCPs

Principle 1: Transparency and Explainability

Manufacturers and developers must provide regulators and end-users with detailed information regarding the components of the AI-DSF that are prone to changes and the corresponding impact. For the approval of a market submission with a PCCP, it is essential to provide clear and appropriate information, along with detailed plans, to users and other stakeholders to ensure that they are aware of the device's performance and intended use before and after changes are implemented [5]. Regulatory expectations emphasize the necessity of version control and traceability to maintain oversight of modifications and ensure accountability. Proper documentation of each change is required to track updates over time, facilitating regulatory compliance and enabling thorough postmarket monitoring. The description of PCCPs should be publicly available on device summaries, for example, on the PMA summary of the safety and effectiveness document, or the 510(k) summary, or on the De Novo decision summary, depending on the pathway of premarket authorization. This description should include sufficient detail to provide transparency to stakeholders regarding safety and effectiveness. FDA recommends the inclusion in the public-facing documents of a summary with the following information: planned modifications, testing methods, performance requirements for the implementation of the modification, and means to communicate changes implemented following the authorized PCCP [6].

It is recommended that the labeling section of the market submission has a statement to inform that the device includes AI-ML technologies and has an authorized PCCP. In this manner, users are aware of the possibility of software updates and modifications that impact the device's performance, inputs, or use. FDA also recommends the inclusion of the following information in the labeling section to ensure transparency [6]:

- A description of the modifications made, including the rationale, supporting evidence, data used, changes in inputs and or outputs, updated performance, and validation methods;
- A version control framework that ensures all changes are documented systematically, including timestamps, revision history, and regulatory justifications;
- An overview of the process followed to implement the modifications;
- An explanation of how the implemented modification will be communicated, including updated instructions for use and version history tracking.

Beyond documentation, manufacturers should implement governance mechanisms to ensure that version control processes are both proactive and auditable. This involves establishing dedicated teams responsible for monitoring modifications, conducting impact assessments, and maintaining alignment with evolving regulatory requirements. In addition, AI-ML model updates should be linked to a structured approval pipeline, ensuring that any modification—whether minor parameter adjustments or major retraining efforts—is systematically reviewed and justified before deployment [17]. These efforts help mitigate risks associated with unintended model drift, bias accumulation, or performance degradation, reinforcing the safety and reliability of AI-driven solutions.

Principle 2: Risk Management

Continuous learning models require structured risk assessment frameworks to address concerns such as data drift and algorithmic bias. To increase the reliability and value of a PCCP, its design and implementation should be driven by a risk-based approach with proper principles of risk management. Performing a risk re-evaluation of the device after modifications is essential to determine the potential impact on the overall system's safety, effectiveness, and compliance with regulatory standards.

XSL•FO
RenderX

PCCPs must align risk categorization with regulatory classifications and include a structured risk management process that is reflected in the impact assessment section. By providing a comprehensive analysis, manufacturers can demonstrate that the proposed modifications will not introduce new, unmitigated risks, thereby ensuring compliance with regulatory standards and maintaining device safety [6].

The International Medical Device Regulators Forum uses a risk categorization principle based on 2 key factors: the significance of the information provided by the medical device to the health care decision and the state of health situation or condition. The former identifies the intended use: to treat or diagnose, drive clinical management, or inform clinical management. The latter identifies the intended user, disease, and population: critical, serious, or non-serious. Using these factors, the SaMD is classified into four categories, ranging from lowest (I) to highest risk (IV), as shown in Table 2 [3].

Table . Software as a medical device risk categorization based on significance of information and health situation or condition.

State of health care situation or condition	Significance of information provided by SaMD[a] to health care decision		
	Treat or diagnose	Drive clinical management	Inform clinical management
Critical	IV	III	II
Serious	III	II	I
Nonserious	II	I	I

[a]SaMD: software as a medical device.

In 510(k) premarket submission, the risk of the planned changes should be categorized similarly to the one used for the predicate device, and this risk category should not change. For example, it would not be feasible to include PCCP modifications that increase the risk category of the device. By providing a comprehensive analysis, manufacturers can demonstrate that the proposed modifications will not introduce new, unmitigated risks, thereby ensuring compliance with regulatory standards and maintaining device safety [6].

Principle 3: Robust Change Protocols

Modifications can be either manual, automated, or a combination of both (hybrid). Despite its type, it is important to define a robust protocol to define when and how to ensure the implementation of modifications. The modification protocol section of PCCPs should include this information on the retraining practice's part, where, among other information, the manufacturers should specify the triggers for retraining. Manufacturers should define clear triggers for updates, ensuring that changes are evidence-based and justified. Some examples of recognized triggers can be the acquisition of a given amount of new data, detection of drift in data, significant performance deviations (such as metrics degradation), or even a fixed cadence of weekly or monthly. In addition, modifications should consider the impact of new regulatory requirements, emerging best practices, or advancements in technology. This approach ensures that modifications remain effective and aligned with the device's intended use and regulatory requirements while maintaining the safety and efficacy of the AI-enabled software functions [5,6]. .

Principle 4: Stakeholder Collaboration

In 2024, the FDA published a guidance called "Requests for Feedback and Meetings for Medical Device Submissions: The Q-Submission Program" to outline the mechanisms available to manufacturers to get feedback for medical device premarket submission [18]. This guidance encourages manufacturers to leverage the introduced Q-Submission Program to get feedback on a proposed PCCP before submitting a marketing submission. In this way, regulators are engaged early in the development cycles, which can facilitate the approval processes for PCCP and allow manufacturers to proactively address any concerns that may arise during the development of their plans. The Q-Submission Program can be used to tackle issues and doubts that may arise in the development of a PCCP. Topics such as proposed changes to the PCCP, considerations for automatic updates, and modifications to the intentions of use are some examples of how appropriate FDA review division members can help manufacturers through the Q-Submission Program [6]. Early engagement with regulatory bodies and open communication between technical and regulatory teams play a critical role in expediting the approval of PCCPs. In this way, regulators are engaged early in the development cycles, which can facilitate the approval processes for PCCP and allow manufacturers to proactively address any concerns that may arise during the development of their plans. To ease and foster collaboration between stakeholders, the FDA intends to harmonize information and lay a foundation for PCCPs to support innovations in the digital health space [5].

Considering opinions and inputs from all stakeholders, the quality and integrity of PCCPs will improve, and international harmonization and stakeholder consensus on the core concepts of PCCPs will help support the advancement of responsible innovations in the digital health space. This iterative review process between stakeholders fosters regulatory confidence in the manufacturer's approach, enabling a smoother transition from development to market authorization, whilst assuring clarity on what constitutes a "significant" versus "minor" modification under a PCCP, reducing uncertainty regarding future update approvals. Significant changes, contrary to minor ones, include modifications that could significantly affect the safety or effectiveness of the device, such as changing the device's intended use. These changes often require a new marketing submission, which highlights the importance of early engagement with regulatory entities to verify the feasibility of using PCCPs. By promoting collaboration among stakeholders, the FDA supports the advancement of responsible innovations

XSL•FO
RenderX

in the digital health industry, ensuring that new technologies meet regulatory standards while addressing patient needs [5].

Principle 5: Continuous Monitoring and Feedback

Developing postimplementation monitoring systems and integrating real-world evidence are key aspects to consider before the market submission of a medical device with a PCCP. Manufacturers must develop comprehensive postmarket surveillance plans and procedures detailing real-world monitoring strategies and notification requirements for malfunctions and other safety concerns. It is the responsibility of the manufacturer to ensure ongoing safety and effectiveness of the device, which can be accomplished by implementing monitoring plans for adverse events, as well as performance metrics tracking. These monitoring activities highly depend on the type of device and the type of updates (whether manual or automated, and whether they are applied globally or locally) [6].

In addition, the manufacturers should also ensure that the modifications are implemented according to the PCCP, which highlights the need for well-defined monitoring means to guarantee compliance with the requirements and specifications set in the PCCP.

After approval of a PCCP, it is recommended that manufacturers develop standard operating procedures (SOPs), where they set the monitoring and evaluation processes. These SOPs should specify methods for collecting data on device performance, safety, and efficacy, as well as the management of this data. In addition, SOPs should also identify the personnel in charge of monitoring activities and the corresponding roles and responsibilities. With the implementation of these procedures, manufacturers guarantee that the modifications are in line with the PCCP and that the device consistently meets established safety and performance standards without requiring reapproval [2]. In the update procedures included in the modification protocol, the device monitoring plan should be detailed, and manufacturers should [6]:

- Detail the methods to track the events triggered by PCCP modifications, to ensure timely identification of issues;
- Have a risk-based plan to monitor the real-world performance of the device, allowing for adaptive responses to emerging patterns of data;
- Specify how changes in safety and effectiveness will be monitored and how frequently, including the frequency of these assessments;
- Detail the steps to tackle unexpected performance deficiencies or safety hazards, ensuring proactive risk management;
- Define criteria and plans to reverse an update and reset devices to previous versions, if needed, to maintain device integrity and user confidence.

Postmarket surveillance and monitoring can benefit from feedback provided by end-users, as it often offers valuable insights into device performance and potential issues. However, manufacturers must also implement strategies that allow them to monitor devices independently of user input. One effective approach is automated logging, in which devices securely transmit operational and performance data directly to the manufacturer's systems. At the same time, manufacturers should facilitate the contribution from end-users with simple mechanisms for flagging issues. Integrating these reports with automatic device logs and relevant data can ease the process for both the manufacturer and the user, ensuring that any problems are captured quickly and with sufficient context for effective resolution. By prioritizing continuous monitoring and feedback mechanisms, manufacturers can sustain the safety and efficacy of their devices, engage effectively with regulatory agents, and support ongoing innovation within the medical device field.

Implications of PCCPs in AI-ML Development

As mentioned before, transparency is one of the principles for PCCPs. Clear labeling is essential to provide information to users, including details describing the data used, data sources, the input variables and their relevance, the rationale behind model decisions, the aim of the output, and the supporting performance evidence. PCCPs require that manufacturers explicitly outline possible modifications, describing how they are going to be implemented and assessing their impact on performance, safety, and effectiveness. Without this, regulators will not give market approval. In this way, PCCP ensures enhanced trust, which builds confidence among users and stakeholders who have more access to details of the AI-ML technology that would be undisclosed if a PCCP were not submitted in the market approval submission [19].

During the development of PCCPs, manufacturers should accurately define the intended use populations and provide demographic information (race, ethnicity, disease severity, gender, age, etc), and intended environments of use (eg, hospitals, clinics, telemedicine, laboratories, radiology, and ICUs). With this approach, it is guaranteed that the device continues to operate on the defined and planned populations and environments even as modifications occur. To mitigate potential bias, it is required that manufacturers present details in PCCPs showing that the algorithms were tested on representative populations. The submission of a PCCP for market approval ensures that the device remains safe with the planned modifications, which is critical for addressing bias and ensuring the fairness of AI-ML technologies [19].

Overall, PCCPs ensure that the device will remain safe and performant under the specified modifications and enable manufacturers to use continuous learning AI-ML technologies. Thus, by integrating structured modification protocols, PCCPs foster responsible AI innovation while ensuring that safety and efficacy are not compromised.

Another benefit of PCCPs is the possibility of reducing delays and expediting times for approvals by minimizing the number of submissions for market approval. When the manufacturers submit a PCCP, it ensures that the AI-DSF will not need reapproval after updating the device with detailed modifications. In this manner, PCCPs have the power to streamline regulatory

XSL•FO
RenderX

processes, reducing the workload of regulatory entities and, consequently, decreasing the waiting times for approval.

To get the most out of AI-ML technologies, it is important to integrate PCCPs into modern software development practices such as continuous integration and delivery (CI-CD), which is a development practice where code changes are automatically built, tested, and deployed. It enables fast, frequent, and reliable updates and releases. CI-CD facilitates the validation of AI-DSF with automated testing, version control, validation gates, monitoring, and feedback loops. Thus, manufacturers of SaMD need to shift from waterfall-style development to more agile approaches to remain competitive and fully harvest the benefits of AI-ML technologies. The application of CI-CD in ML is already well established under a continuous workflow (Figure 4) [20].

Figure 4. Continuous integration and delivery in machine learning.

However, the implementation of CI-CD with regulatory compliance is challenging, particularly in medical software. To facilitate regulatory compliance, manufacturers should:

- Design a model architecture that facilitates modifications whilst maintaining compliance;
- Enforce procedures and generate automatic evidence, such as required documentation, reports, and audit trails to ensure that modifications are automatically documented and that they are in compliance with regulations;
- Implement risk analysis in the research and development process, including risk identification, evaluation, and development of mitigation plans;
- Automate documentation and testing processes to streamline compliance efforts;
- Keep traceability across and within different phases (design, training, validation, deployment, and postmarket monitoring).

To tackle some of these challenges, it is possible to use DevOps or MLOps-based deployment systems, which can improve automation and traceability [21].

This integration of PCCPs and CI-CD allows for faster time-to-market, enhanced quality, and increased flexibility [22]. This synergy positions AI-ML technologies as both agile and accountable, enabling responsible innovation in digital health while maintaining public trust and regulatory confidence.

Case Studies and Applications

The theoretical framework and guiding principles PCCPs provide a clear foundation, show their importance, and their true value. However, the benefits, limitations, and challenges can be better understood with examples of use in real-world scenarios. In this way, it is possible to better understand how they are implemented under varying conditions and how they adapt to specific contexts.

The FDA already approved several AI-DSFs for the health care sector, including tools to enhance diagnostic accuracy, automate processes, predict patient outcomes, improve workflow efficiency, and deliver personalized treatment plans.

For example, Clarius Mobile Health, a company specializing in Medical Equipment Manufacturing, develops products to make ultrasound imaging accessible, efficient, and convenient for health care professionals. Recently, they received FDA approval for Clarius OB AI, an AI tool that performs fetal biometry measurements to estimate fetal age, weight, and growth intervals. It can be used with the company's Clarius C3 HD3 wireless handheld ultrasound scanner and allows obstetrical prenatal monitoring.

The 510(k) summary submitted by the company clearly describes the device, the indications for use, and a summary of the PCCP. It includes 4 modifications and the corresponding

XSL•FO
RenderX

rationale, testing methods, and impact assessment, 3 of which were intended to improve performance: modification of model architecture, modification of model training methods and parameters, and modification of postprocessing algorithms. The company is going to assess this with a comparison of the model and clinical performance metrics between the original AI model and the modified one in clinical testing. For these modifications, a benefit-risk analysis was performed, identifying improved performance and generalization as benefits and overfitting and unintended bias as risks. For these risks, they also established a mitigation plan, including regularization techniques, cross-validation, dropout to avoid overfitting, and internal testing and verification to mitigate biases. The fourth modification is related to data input sources, and it intends to enable the use of the Clarius OB AI on updated versions of the 510(k)-cleared Clarius Ultrasound Scanner system. The modification protocol includes retraining of the model with new data sources and internal and clinical testing. In the impact assessment, the risk-benefit analysis is outlined, mentioning enhanced compatibility and flexibility as advantages, and data skewing and concept drift as risks, which will be mitigated with internal testing and verification datasets within the intended patient population.

Finally, the company also clarifies how they will ensure transparency and keep users informed by communicating modifications via the Clarius App (Clarius Mobile Health Corp) software update notifications and through updated labeling [23].

Another example is the model from Beacon Biosignals, a health technology company focused on accelerating the development of therapies for neurological, psychiatric, and sleep disorders. They have received FDA 510(k) clearance for SleepStageML, an ML software that automatically stages sleep from electroencephalogram (EEG) signals of clinical recordings to aid in the diagnosis and evaluation of sleep and sleep-related disorders. The software included an authorized PCCP comprising the following modifications, all of them to improve sleep staging performance within the intended use population [24]:

- Update of ML model: achieved with retraining with new training data, with new hyperparameters, loss functions, and optimizers, and with different model architectures;
- Update signal processing steps: accomplished with updates to the digital signal processing steps applied to the EEG signal before being used by the ML model;
- Update probability postprocessing: implemented with modification of the methods used to generate sleep stages from the model output;
- Update of signal quality check: achieved with the update of the thresholds used to check that the input EEG signals are analyzable

The PCCP also identified which of these modifications trigger the retraining of the model and states that the tests of modification will include software verification and validation testing, where clinical performance will be assessed. The company clearly defined the acceptance criteria for each of the modifications and clarified how updates would be communicated to users, ensuring that guiding principles 1, 3, and 5 were fulfilled.

Emerging Fields

The use of AI-ML technologies is not confined to health care. While health care remains the most mature and regulated domain for PCCP implementation, illustrated by concrete FDA-cleared examples such as Clarius OB AI and Beacon Biosignals' SleepStageML, the underlying principles of structured, prespecified change control are not unique to health care.

As AI-ML permeates diverse sectors, the need for a structured yet flexible approach to managing updates and evolutions becomes universal. Adopting PCCPs beyond health care could streamline innovation, reduce regulatory bottlenecks and complexity for manufacturers, improve time-to-market, and ensure trust in AI systems that operate in dynamic, real-world environments.

Although the regulatory context and risk thresholds might differ, the conceptual rationale for PCCPs can be meaningfully extended to other domains that rely on systems that must adapt safely to changing conditions and face similar challenges. Whether in finance, transportation, or education, the underlying question is the same: how can innovation continue without compromising safety and trust.

A comparative overview of how PCCPs may be applied across sectors, highlighting concrete examples of use cases, potential benefits, associated risks, and the current state of regulatory oversight, is provided in Multimedia Appendix 1. This cross-sectoral perspective underscores the generalizability of PCCPs as a framework for trustworthy AI, while reinforcing the unique depth of implementation achieved to date in biomedical applications.

Challenges and Limitations

Identifying, monitoring, and managing changes to ensure the protection of all stakeholders is the primary regulatory challenge of AI technologies in the health care domain. Each stakeholder, regulators, manufacturers, health care providers, and patients values and focuses on different aspects and components, leading to misalignment between technical, ethical, and legal expectations. Therefore, it is essential in the regulatory ecosystem to involve regulators, professional organizations, and service providers [10]. Current regulations are usually country-specific, reducing the global applicability of AI-ML technology and potentially increasing inequalities, as some countries may benefit more than others from such technologies. Creating harmonized and global regulations and guidelines for modifications of AI-DSF will be a challenge in the future that will need the collaboration of stakeholders and governments worldwide.

The development of a PCCP is time-consuming and resource-intensive, demanding expertise across multiple domains: regulatory, technical, clinical, and quality assurance. Implementation costs extend beyond development. Continuous monitoring, verification, and validation of AI-ML updates under

XSL•FO
RenderX

a PCCP demand ongoing investment in infrastructure (eg, data management systems) and personnel training. Real-world performance tracking—a core PCCP requirement—may necessitate additional software tools or third-party services, further elevating expenses. Manufacturers must also update quality management systems to align with PCCP processes, adding to operational costs. In addition, hospitals and other infrastructures also need to be updated since they handle their systems manually, providing data through informal reports rather than using automated or integrated systems. This increases upfront effort and costs for manufacturers, who must invest in establishing the necessary frameworks, tools, and documentation, imposing a high initial cost barrier. Furthermore, given the complex structure and requirements for the implementation of PCCPs, and the heterogeneous nature of AI-ML-enabled products and manufacturer operations, such costs are difficult to estimate beforehand. These expenses can strain small- to medium-sized enterprises, potentially limiting adoption to larger firms with greater financial capacity. While PCCPs aim to reduce long-term regulatory burdens by minimizing resubmissions, the initial and sustained financial outlay poses a challenge, particularly without clear cost-benefit data due to PCCPs' recent emergence. Regulatory bodies like the FDA acknowledge potential cost savings (eg, fewer submissions), but without peer-reviewed studies quantifying these against implementation expenses, the economic feasibility remains speculative. This level of professionalization associated with PCCP implementation may be manageable for large corporations with dedicated regulatory departments but represents a substantial hurdle for startups and small and medium enterprises (SMEs) seeking to enter the market. Consequently, the financial burden of PCCP adoption risks consolidating innovation within a limited pool of well-capitalized firms, potentially stifling broader market diversity and competitiveness.

In addition, PCCPs are complex to implement since AI-ML technologies have transboundary elements and, therefore, must comply with different regulations and jurisdictions. It is difficult to manage transnational cooperation and jurisdictional sovereignty [10]. For example, it is easier to get market approval in the EU than in the United States, which motivates companies to launch their product outside the United States. The FDA approval is often a longer and more expensive process, and if the product is intended to be used in multiple markets, manufacturers face additional challenges since separate regulatory approvals may be required in each country [2525].

Furthermore, the lack of global harmonization in regulatory frameworks further complicates the implementation of PCCPs across jurisdictions. The United States and the European Union, while both moving toward adaptive regulatory approaches, diverge significantly in terms of approval processes, expectations for modification protocols, and the maturity of their PCCP-related guidance. The FDA's framework emphasizes premarket clarity with detailed requirements for modification protocols, while the EU regulatory landscape—shaped by the MDR and evolving through the AI Act—still lacks equivalent specificity for AI-DSFs.

These disparities can force manufacturers to create jurisdiction-specific versions of their PCCPs or maintain parallel documentation and risk assessment pipelines, increasing operational overhead and regulatory uncertainty. Moving forward, mutual recognition mechanisms or modular PCCP templates adaptable to both United States and EU standards could help reduce duplication and facilitate safer, faster cross-border deployment of AI-ML-enabled medical technologies.

Moreover, these technologies are constantly changing and evolving rapidly, which urges the need for adaptable regulations that consider such changes. The new regulatory approaches should complement existing protocols, providing mechanisms to monitor changes and fill the gaps in the current governance regulations. New regulations should be flexible and accommodate rapid changes, therefore supporting innovation but without adding burden to pre-existing and well-established frameworks.

Future Directions

Approval of devices and products is associated with high waiting times for AI-DSF, and in the health care field, these waiting times tend to be even higher. For example, the average median wait time between the date the FDA receives the complete application and the decision date is 125 days [26]. However, the process to get approval begins much before the submission of the complete application and is often iterative. This highlights the need for faster mechanisms to approve market approval submissions for AI-ML technologies since such waiting times are sufficient to hinder the applicability, benefits, and use of such technologies. In addition, considering the adaptive nature of AI, it is not feasible to submit a market approval for each modification on the device.

Using a firm-based approach to regulate SaMD with AI-ML technologies shifts the focus of the regulation to the development process, giving more importance to quality systems and development processes. This seems to be the path to be followed by regulators for AI medical devices, enabling updates to existing approved products without the need for further approvals [27]. In addition, PCCPs are an interesting solution to avoid the need for market approval submission for each modification while maintaining the safety and effectiveness of the device. However, regulatory entities have to decrease waiting times for approval and make such a process more efficient. Using AI to manage PCCPs and decrease waiting times could be a tool to consider. A possible alternative or complement is to transfer the process of some devices to third parties, possibly automatically with AI, which would allow the FDA to focus on higher-risk devices, maintaining high-quality reviews and appropriate timing [28]. Establishing a framework for third-party certification of SaMD with lower risk would assist the FDA in tackling problems of internal expertise, streamlining the certification process, and improving the level of expert guidance the agency can offer [27]. This solution also introduces its own risks, such as conflicts of interest. Thus, it is important to request accreditation of certifiers, periodic audits, and publicly disclose the evaluation methodologies, criteria, and decision processes.

XSL•FO
RenderX

In addition, considering that the performance and functionality of AI-ML technologies highly depend on reliable and good data, it could be of great interest that jurisdictions create an entity responsible for facilitating the creation of datasets for AI development that adhere to regulations and standards. This would ensure that data comply with regulatory requirements for the development of AI-ML technologies and, consequently, reduce the premarket scrutiny of such technologies, considering that the models were developed using reliable datasets [27]. In the EU, there are some projects that aim to accomplish this. Some examples are CHAIMELEON [29], ProCancer-I [30], and EUCAIM [31], which can foster collaborative research, drive innovation, and ease the premarket examination.

As mentioned in the previous section, an issue with the mentioned regulations is that they are only valid for a given country, reducing the applicability of the AI-DSF and increasing inequalities. Thus, it is essential to develop regulations that comply with and integrate global standards. Governments should state which authorities are responsible for regulation and which components of AI systems are subject to it. Governing bodies should also clarify which existing regulatory mechanisms must or could be applied to systems with AI-ML technologies. For example, regulators can clarify how medical device regulation can be applied to AI-ML systems or add recommendations to existing approval requirements to monitor modifications of AI-ML-enabled devices, which was accomplished by FDA draft guidance [6]. More regulations and guidelines are required to help manufacturers develop PCCP for AI-ML technologies in a way that they integrate and comply with global standards, mitigating inherent risks of these technologies and ensuring that these tools are reliable, safe, and used worldwide. The design of new regulatory frameworks for AI-ML SaMD should not only involve medical device software experts but also experts on postmarket surveillance, real-world performance measurement, and clinical evaluation, as well as patient representatives.

In the future, it is also relevant that jurisdictions develop novel validation strategies that enable faster decisions on whether or not to approve an AI-DSF while maintaining safety and quality. Postmarket surveillance remains a key point in AI-ML technologies, where it is essential to guarantee that the devices AI-DSF are performing up to the quality standards to which they were approved and that updates do not decrease safety or effectiveness.

Creating platforms or templates to help manufacturers and companies create PCCPs compliant with FDA guidelines and regulations can also be an opportunity to foster innovation and the use and approval of AI-DSF, particularly in health care. Providing instructions and procedures to complete the 3 PCCP sections (Description of modifications, modification protocol, and impact assessment) and finding a way that manufacturers can easily replace text with their product-specific information can be a valuable tool to assist the market approval of AI-DSF with planned modifications. There is already an application for the lifecycle management of software called Ketryx (Ketryx Corporation) that helps companies build FDA-regulated software. The creation of more platforms and tools to automate and facilitate manufacturers and regulators to deal with changes to AI-ML technology can be of great interest to foster innovation. In addition, the creation of such templates, tools, and platforms can help SMEs overcome the limitations mentioned in the previous chapter by providing them with more support to adopt PCCPs. Regulatory entities should also foster the creation of consortia and resources to share knowledge and for mentoring.

In the future, it would be important to conduct studies to report and analyze the costs of implementing PCCPs and compare them with the traditional paths. This can help manufacturers, particularly SMEs, identify the investment needed and understand if submitting repetitive market submissions requires a higher investment than implementing PCCPs.

There are many regulations, including rules from public authorities and the private sector. Generally, AI-related regulations should be formulated by public bodies and regulatory oversight should adapt to the advancements of technology to avoid slowing down innovation. Future regulations should also take into account the domain of generative AI, which may need distinct legislation and guidelines. Current regulations and PCCPs are mainly focused on AI-ML models and do not address generative AI. Considering the fast adoption of such technology, it is essential to create standardized regulations to tackle problems of reproducibility, transparency, data privacy, security, and intellectual property. In fact, the FDA released an executive summary with a focus on the oversight of generative AI-enabled devices, which shows the pertinence of the topic and the need for regulations and guidelines [32]. Despite the current limitations, PCCPs could be adapted by requiring more granular change protocols that explicitly define permissible updates to model architecture, prompt-handling mechanisms, and training datasets. Furthermore, the principle of continuous learning of PCCPs is essential for generative AI-enabled devices, as robust postmarket performance monitoring can ensure safety and effectiveness after market entry. Monitoring mechanisms could be extended to include output sampling and quality benchmarking over time, ensuring that generative components maintain compliance and reliability.

Concluding Remarks

Considering the continuous and adaptive nature of AI-ML technologies, PCCPs emerge as an essential tool in the development and regulation of AI-DSF, ensuring that the benefits of continuous learning are exploited and systems evolve efficiently and safely. It empowers manufacturers to update AI-DSF within the constraints of safety and effectiveness without the need to make additional premarket submissions. This framework reduces the time and resources needed by manufacturers and regulators to approve AI-DSF.

Moreover, PCCPs enhance transparency, compliance, and trust among stakeholders and reduce regulatory burden. Promoting a culture of transparency and collaboration among all stakeholders, including developers, users, and regulators, can enable the creation of regulations, which are essential to ensure that AI-ML technologies are developed and used responsibly, with ensured safety, effectiveness, and reliability.

XSL•FO
RenderX

Regulators should actively seek input from stakeholders to gain insights into the challenges associated with developing, deploying, and monitoring AI-ML technologies. In addition, governments should be encouraged to disseminate best practices and standards for the use of AI and foster a research ecosystem that leverages public-private partnerships [25]. Acknowledging that adherence to regulatory guidelines can be time and resource-consuming, regulations must remain flexible to promote innovation and are developed globally.

With the current evolution of the adoption of AI-ML technologies, manufacturers with PCCPs and CI-CD pipelines will be well-positioned to deliver superior products. The future of AI-ML SaMD will be shaped by automation, adherence to regulations, and continuous evolution for the benefit of the patients and health care providers.

Abstract

The European Union's Artificial Intelligence Act (EU AI Act), adopted in 2024, establishes a landmark regulatory framework for artificial intelligence (AI) systems, with significant implications for health care. The Act classifies medical AI as "high-risk," imposing stringent requirements for transparency, data governance, and human oversight. While these measures aim to safeguard patient safety, they may also hinder innovation, particularly for smaller health care providers and startups. Concurrently, geopolitical instability—marked by rising military expenditures, trade tensions, and supply chain disruptions—threatens health care innovation and access. This paper examines the challenges and opportunities posed by the AI Act in health care within a volatile geopolitical landscape. It evaluates the intersection of Europe's regulatory approach with competing priorities, including technological sovereignty, ethical AI, and equitable health care, while addressing unintended consequences such as reduced innovation and supply chain vulnerabilities. The study employs a comprehensive review of the EU AI Act's provisions, geopolitical trends, and their implications for health care. It analyzes regulatory documents, stakeholder statements, and case studies to assess compliance burdens, innovation barriers, and geopolitical risks. The paper also synthesizes recommendations from multidisciplinary experts to propose actionable solutions. Key findings include: (1) the AI Act's high-risk classification for medical AI could improve patient safety but risks stifling innovation due to compliance costs (eg, €29,277 annually per AI unit) and certification burdens (€16,800-23,000 per unit); (2) geopolitical factors—such as United States-China semiconductor tariffs and EU rearmament—exacerbate supply chain vulnerabilities and divert funding from health care innovation; (3) the dominance of "superstar" firms in AI development may marginalize smaller players, further concentrating innovation in well-resourced organizations; and (4) regulatory sandboxes, AI literacy programs, and international collaboration emerge as viable strategies to balance innovation and compliance. The EU AI Act provides a critical framework for ethical AI in health care, but its success depends on mitigating regulatory burdens and geopolitical risks. Proactive measures—such as multidisciplinary task forces, resilient supply chains, and human-augmented AI systems—are essential to foster innovation while ensuring patient safety. Policymakers, clinicians, and technologists must collaborate to navigate these challenges in an era of global uncertainty.

Introduction

We are writing to discuss the implications of the European Union’s Artificial Intelligence Act (EU AI Act) on health care, particularly in the context of the current geopolitical climate. The AI Act, which is poised to become a landmark regulation, has significant ramifications for the development, deployment, and governance of AI systems in health care. At the same time, the geopolitical landscape, marked by increasing military expenditures in Europe, the threat of trade tariffs from the United States, and broader global instability, demands that we consider how these regulatory frameworks interact with the realities of a rapidly changing world.

This paper aims to explore these complex dynamics, highlighting the opportunities and challenges posed by the AI Act in the context of a rapidly evolving geopolitical environment. By examining the intersection of AI regulation, health care innovation, and global instability, we seek to provide a nuanced understanding of how nations can navigate these challenges to ensure that AI technologies are harnessed responsibly and effectively for the benefit of patients and health care systems worldwide.

The EU AI Act and Health care: A Brief Overview

The EU AI Act, adopted in 2024, represents a comprehensive attempt to regulate AI systems based on their risk levels [1]. For health care, the Act's classification of AI systems as "high-risk" is particularly relevant, as it encompasses technologies that directly impact patient care and outcomes. High-risk AI systems in health care include those used in medical devices, patient management, and diagnostic tools. These systems are subject to stringent requirements, including robust risk management, data governance, and human oversight. The Act also mandates transparency, ensuring that health care providers and patients are aware when AI is being used in decision-making processes [2].

However, the Act's focus on risk mitigation raises important questions about its potential impact on innovation. The health care sector is increasingly reliant on AI for tasks ranging from predictive analytics to robotic surgery [3,4], and the regulatory burden imposed by the AI Act could slow the pace of technological advancement. For instance, compliance with the Act requires significant investment in technical documentation, quality management systems, and cybersecurity measures [5]. While these requirements are essential for ensuring patient safety, they may disproportionately affect smaller health care providers or startups, particularly those developing or using high-risk AI applications such as diagnostic tools or patient management systems. Based on the "Study to Support an Impact Assessment of Regulatory Requirements for Artificial Intelligence in Europe" by the European Commission [6], compliance costs for a single AI unit could reach €29,277 (US $34,153) annually—a substantial burden for resource-constrained organizations. Startups may face additional challenges due to certification costs (€16,800 - 23,000 per unit equivalent to US $19,598-26831 per unit) and the complexity of meeting requirements for human oversight, data governance, and transparency. While the regulation targets only 10% of AI systems as "high-risk," health care innovations often fall into this category, potentially stifling innovation or diverting funds from research and development leading to a concentration of AI development in larger, well-funded organizations, potentially stifling competition and innovation However, the study notes that existing General Data Protection Regulation compliance (which overlaps with some AI Act requirements) might mitigate costs for some small and medium-sized enterprises, and sector-specific guidance could ease implementation. The lack of qualified notified bodies for certification may further delay market entry for smaller players.

Moreover, the current structure of the AI innovation ecosystem is marked by the dominance of "superstar" firms—large multinational technology corporations with extensive computational resources, proprietary data access, and deep regulatory expertise [7]. These firms are increasingly shaping the trajectory of AI development, including in the biomedical field, often through strategies of destructive creation that consolidate market power and marginalize smaller players. This dynamic has profound implications for health care AI, where dominant firms may prioritize scalable solutions that align with their commercial models rather than localized, need-based innovations. The AI Act's high compliance costs, while necessary for risk mitigation, may unintentionally entrench this asymmetry by privileging those with existing infrastructure for regulatory conformity. This raises important questions about market concentration, regulatory capture, and the diminishing space for entrepreneurial and community-based innovation in digital health.

In addition, digital health tools and AI-based health care solutions possess attributes of nonrival public goods, generating substantial positive externalities and knowledge spillovers. For example, AI algorithms trained on diverse population datasets can yield insights far beyond their initial application, contributing to broader epidemiological surveillance, health equity research, and public health policy. However, the social benefits generated by these tools are not always aligned with the private incentives of developers. This misalignment risks underinvestment in socially valuable innovations—particularly those targeting rare diseases, marginalized populations, or preventive health—unless appropriate policy mechanisms are established. A nuanced regulatory framework must therefore, account not only for risks and compliance but also for the collective value of AI in health care and its role in a broader innovation commons.

Nevertheless, it is important to acknowledge that several regulatory bodies and major medical technology firms have responded positively to the AI Act, viewing it not as a barrier but as an enabler of innovation and trust [8]. Leading manufacturers, including multinational medical technology companies, have started developing internal AI governance frameworks aligned with the Act's provisions, recognizing these as essential for building trust, enhancing market confidence, and maintaining global competitiveness. For instance, some companies have expressed support for classifying AI-based diagnostic tools as high-risk, arguing that clear regulatory requirements reduce legal uncertainty and promote safer, more consistent deployment at scale [9]. Regulatory authorities such as the European Medicines Agency and notified bodies have also underscored the value of early engagement through structured mechanisms like voluntary premarket consultations and regulatory sandboxes, which can facilitate compliance and shorten time-to-market for trustworthy AI-driven medical technologies [10].

Furthermore, adaptation strategies such as the integration of AI governance frameworks, including AI lifecycle management platforms and automated conformity assessment tools, are being actively adopted by industry leaders to meet the EU AI Act's compliance requirements efficiently [11,12]. These tools facilitate adherence to obligations like risk management, data quality, technical documentation, human oversight, and post-market monitoring. Some hospital systems have also begun building dedicated AI regulatory and ethics teams, often working alongside AI developers and clinical stakeholders to ensure agile yet compliant innovation pipelines, particularly given the classification of many health care AI systems as 'high-risk' under the Act [13]. These examples suggest that, while challenging, successful adaptation to the AI Act is

XSL•FO
RenderX

feasible—especially for organizations that proactively invest in regulatory preparedness and multistakeholder collaboration.

Geopolitical Uncertainty and Its Impact on Health Care

The geopolitical environment in which the AI Act is being implemented is fraught with uncertainty, and these external pressures could have profound implications for health care innovation. Europe is currently witnessing a significant increase in military expenditures, driven by the ongoing conflict in Ukraine and the broader rearmament of NATO member states. This shift in priorities has the potential to divert resources away from health care and other critical social services, including funding for AI research and development. In a context where health care systems are already under strain from rising costs and workforce shortages, this reallocation of resources could further hinder the adoption of AI technologies.

At the same time, the recent imposition of trade tariffs by the United States on key technology imports, including semiconductors and advanced medical devices, has exacerbated supply chain vulnerabilities. Many of the components essential for AI-driven health care technologies, such as semiconductors and advanced sensors, are produced in a limited number of countries, making supply chains vulnerable to geopolitical disruptions. For example, tensions between the United States and China over trade and technology could lead to export controls, making AI systems less accessible to health care providers in other countries.

Furthermore, the global competition for AI dominance, often framed as a race between the United States and China, has significant implications for Europe's ability to maintain its technological sovereignty [14]. While the AI Act represents a step forward in terms of ethical AI governance, it may also be seen as a barrier to innovation if it is not balanced with sufficient support for research and development. Europe risks falling behind in the global AI race if its regulatory frameworks are perceived as overly restrictive, potentially leading to a "brain drain" of AI talent to more innovation-friendly regions.

AI, Labor Markets, and Indirect Health Risks

The transformative potential of generative and autonomous AI systems extends beyond clinical applications and into the broader socioeconomic fabric, including labor markets, which are inextricably linked to public health. The automation of diagnostic processes, administrative workflows, and even clinical reasoning threatens to displace certain categories of health care employment. While AI can augment clinical tasks and reduce burden, its large-scale deployment without social protections may contribute to job insecurity, professional deskilling, and psychological stress among health care workers [15]. Drawing from the work of Case and Deaton on "deaths of despair" [16], we recognize that economic precarity and disconnection from meaningful work are major determinants of population health. Policymakers must anticipate these secondary effects when promoting AI adoption and consider protective strategies such as retraining programs, mental health support, and frameworks for meaningful human-machine collaboration in clinical settings.

The Intersection of AI Regulation and Geopolitical Realities

The intersection of AI regulation and geopolitical realities presents both challenges and opportunities for health care. On the one hand, the AI Act provides a framework for ensuring that AI systems in health care are safe, transparent, and accountable. This is particularly important in a field where decisions can have life-or-death consequences. On the other hand, the Act must be implemented in a way that does not hinder the ability of European health care providers to compete globally or to respond to emerging threats, whether they be pandemics, cyberattacks, or the consequences of geopolitical instability.

One area where the AI Act could have a particularly significant impact is in the development of AI-driven diagnostic tools. These tools, which have the potential to revolutionize health care by enabling earlier and more accurate diagnoses, are classified as high-risk under the Act [17]. While this classification is understandable given the potential consequences of diagnostic errors, it also raises questions about how to balance regulation with innovation. For example, how can we ensure that the regulatory burden does not discourage the development of AI tools that could improve access to health care in underserved areas? This is particularly relevant in the context of global health disparities, where AI-driven diagnostics could play a crucial role in bridging gaps in health care access.

Additionally, the geopolitical context adds another layer of complexity to the implementation of the AI Act. For instance, the increasing use of AI in military applications, such as autonomous drones and cyber warfare, raises ethical questions about the dual-use potential of AI technologies. While the AI Act focuses on civilian applications, the broader geopolitical environment may influence how these technologies are developed and deployed. Europe must navigate these challenges carefully to ensure that its regulatory frameworks do not inadvertently weaken its position in the global AI landscape.

Another dimension often overlooked in discussions of AI governance is the environmental impact of AI development and its intersection with health. High-performance computing, data storage, and large-scale model training required for cutting-edge health AI systems consume significant energy and contribute to carbon emissions. These environmental costs carry indirect health consequences, particularly for vulnerable populations already burdened by climate-related disease and resource scarcity. In this light, responsible AI innovation in health care must also be environmentally sustainable [18]. Future iterations of the AI Act and related frameworks could benefit from incorporating sustainability criteria—such as lifecycle assessments, emissions reporting, or green AI standards—to ensure that health innovation does not inadvertently generate new public health risks through environmental degradation.

A Call for Reflection and Action

In light of these challenges, we urge the scientific health care community to take a proactive role in addressing the intersection of AI regulation, health care, and geopolitical uncertainty. The rapid evolution of AI technologies, coupled with increasing global complexity, demands a coordinated and realistic response. While some solutions may face implementation challenges, they can serve as guiding principles or pilot initiatives adaptable to local conditions. To navigate this landscape effectively, we propose the following revised and context-aware actions.

Develop Context-Aware Multidisciplinary Task Forces

While political and institutional fragmentation across the EU poses challenges, the creation of multidisciplinary task forces—initially on a national or regional level—can serve as a pragmatic starting point. These groups, comprising AI experts, clinicians, ethicists, and legal scholars, can work to identify actionable bottlenecks in the implementation of the AI Act. Rather than replacing the EU's legislative role, such task forces would serve in an advisory capacity, promoting dialogue between practitioners and regulators. Initiatives like the European AI Alliance show that inclusive, multistakeholder discussion is possible despite complex politics [19]. One promising approach is the creation of regulatory sandboxes—controlled testing environments where AI technologies can be piloted under temporary regulatory flexibility, with close oversight from authorities. For instance, a hospital could trial an AI diagnostic tool under monitored conditions, with safeguards like mandatory human oversight, real-time bias audits, and strict patient consent protocols. Such sandboxes, already tested in sectors like finance (eg, the UK's Financial Conduct Authority's sandbox for fintech) and digital health (eg, the Food and Drug Administration's precertification program), could accelerate compliance while mitigating risks [20,21]. By adapting these models to health care, task forces could help shape sandbox frameworks that align with the AI Act's high-risk requirements—ensuring innovation thrives without compromising safety or ethical standards.

Invest in AI Literacy and Training

To equip health care professionals with the knowledge and skills needed to understand and work alongside AI systems, investment in AI literacy could be beneficial. This includes training on the ethical use of AI, data governance, and cybersecurity, ensuring that health care providers can confidently integrate AI into their practices while adhering to regulatory requirements [22]. Training programs should also address the geopolitical implications of AI, helping health care professionals understand how global trends may impact their work. Given the linguistic and cultural diversity across Europe, a fully centralized training system is indeed unrealistic. Instead, we advocate for a federated approach by developing modular training curricula that can be localized and adapted by individual Member States or health care institutions. EU agencies such as the European Health and Digital Executive Agency [23] can support these initiatives by setting minimum competency standards and offering open-access multilingual materials. This approach balances regional autonomy with EU-wide quality assurance and can be complemented by peer-exchange platforms and international collaboration.

Advocate for Geopolitically Resilient Supply Chains

It includes working with policymakers and industry leaders to create resilient supply chains for medical devices and AI technologies. This includes diversifying suppliers, investing in local manufacturing capabilities, and developing contingency plans to mitigate the impact of trade tariffs or geopolitical disruptions. However, we recognize that building a completely geopolitically resilient supply chain is not immediately feasible. Instead, we propose diversification and strategic redundancy as realistic steps. This includes identifying critical dependencies (eg, on semiconductors), incentivizing dual-sourcing contracts, and fostering EU-based innovation hubs, such as the European Chips Act initiative [24]. While resilience cannot eliminate risk, it can reduce vulnerability to single points of failure, particularly in high-risk sectors like health care.

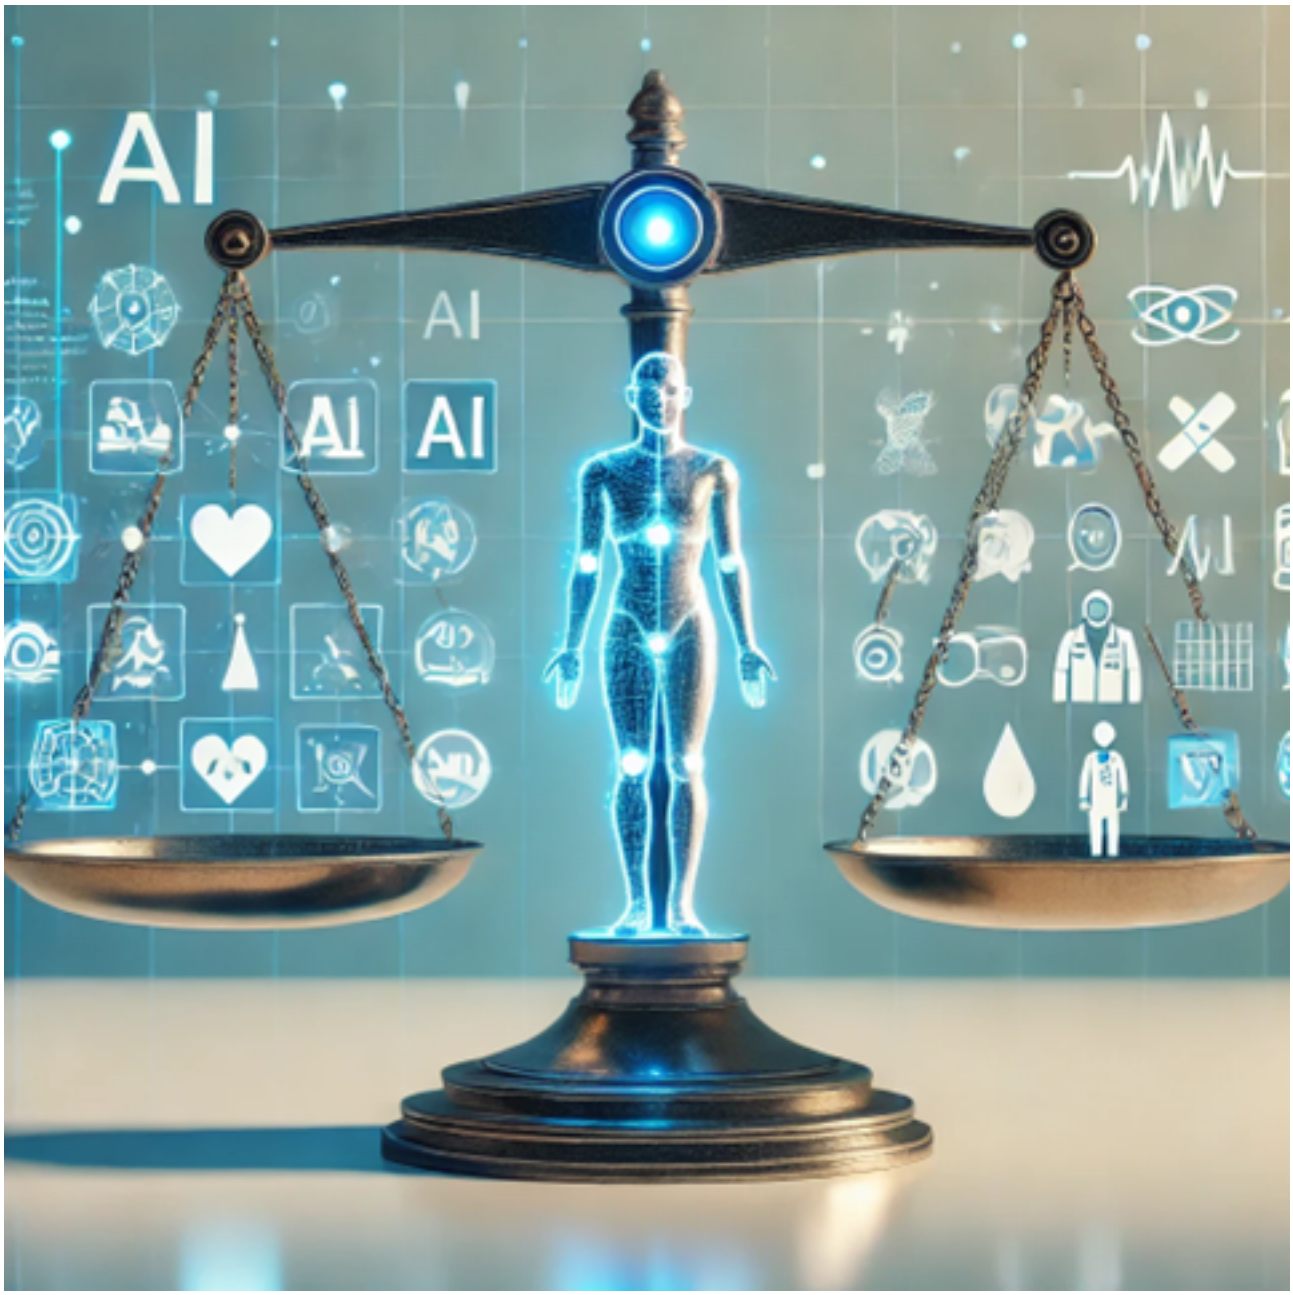
Foster International Collaboration Without Sacrificing Sovereignty

Despite growing techno-nationalism, there remains scope for international collaboration on standards and ethics—especially in health, where global challenges demand collective solutions. Forums such as the World Health Organization, Organisation for Economic Co-operation and Development, and G7/G20 AI initiatives offer platforms for aligning regulatory principles without ceding national control [25-27]. Shared frameworks can lower regulatory friction and support equitable access to AI-driven health care in lower-resource settings.

Implement Human-Augmented AI Systems

Adopting a "human-in-the-loop" approach where AI-generated responses are verified by vetted peer clinician consultants might be . This approach combines the efficiency of AI with the trust and expertise of human clinicians, ensuring more accurate and reliable decision support. The system can be scaled from local institutions to global platforms, with various incentives for peer consultants, such as recognition, continuing medical education credits, or monetary compensation [28]. Of course, it is not always practical or necessary to require human oversight for every AI output. However, for high-stakes clinical applications (eg, diagnosis, triage, treatment decisions), human-in-the-loop systems offer a safeguard against automation bias and unexpected model behavior [29]. We suggest developing risk-tiered guidelines, where human oversight is proportionate to potential patient harm. Enforcement can occur through compliance mechanisms tied to medical device regulation and certification (eg, CE marking), mirroring how pharmacovigilance currently mandates oversight for novel therapies [30].

Prioritize Ethical AI Development



Establishment of clear ethical guidelines for the use of AI in health care, particularly in high-stakes scenarios such as triage during conflicts or pandemics can further development. These guidelines should address issues such as bias, transparency, and accountability, ensuring that AI systems are used in ways that prioritize patient welfare and uphold fundamental rights. Ethical considerations should also extend to the geopolitical implications

XSL•FO
RenderX

of AI, such as the potential for AI technologies to be used in ways that exacerbate global inequalities. Regulating ethical AI development in private industry is undeniably challenging, especially without global harmonization. However, governments and institutions can shape behavior through a mix of regulation, incentives, and transparency requirements. This includes public reporting of algorithmic impact assessments, bias audits, and governance structures—similar to financial disclosures. Procurement policies can also serve as a powerful lever: health care systems can favor vendors that demonstrate ethical compliance, much like environmental or labor standards in other sectors [31]. Furthermore, ethical guidelines co-developed with industry stakeholders can foster shared ownership and practical relevance.

By framing these actions not as universal solutions but as scalable, adaptable strategies, we believe the scientific health care community can meaningfully engage with both the risks and promises of AI. Realistic implementation pathways grounded in the current political, linguistic, and economic landscape are essential for ensuring that AI technologies contribute to safe, equitable, and resilient health care systems across Europe and beyond. (Figure 1)

Figure 1. AI-generated image representing the need for a balanced approach to AI regulation that safeguards patient safety while fostering innovation, even in the face of a rapidly changing geopolitical landscape. AI: artificial intelligence.

Conclusion

The EU AI Act offers a vital framework for ensuring the safe and ethical use of AI in health care but its effectiveness depends on balanced implementation amid geopolitical uncertainty. To avoid stifling innovation, regulatory efforts must be paired with support for adaptation, investment in AI literacy, and resilient infrastructure. To maximize the benefits of the EU AI Act while

XSL•FO
RenderX

mitigating its risks, a broadened perspective is needed—one that recognizes not only direct clinical applications but also the wider socio-economic and environmental contexts in which health care AI operates. This includes addressing market concentration in AI research and development, aligning private innovation with public health needs, anticipating labor market disruptions, and reducing the ecological footprint of digital health. By integrating these factors into future policy and implementation strategies, Europe can foster an AI ecosystem that is not only safe and innovative, but also equitable, sustainable, and socially responsible.

We urge policymakers, health care leaders, and industry to collaborate on practical solutions, such as regulatory sandboxes, ethical oversight, and international alignment to ensure that AI advances benefit patients while reinforcing Europe's role in global health innovation.

Abstract

Properly configuring modern electronic health records (EHRs) has become increasingly challenging for human operators, failing to fully meet the efficiency and cost-saving potential seen with the digitization of other sectors. The integration of artificial intelligence (AI) offers a promising solution, particularly through a comprehensive governance approach that moves beyond front-end enhancements such as user- and patient-facing copilots. These copilots, although useful, are limited by the underlying EHR configuration, leading to inefficiencies and high maintenance costs. To address this, we propose the concept of an "Elastic EHR," which proactively suggests and validates optimal content and configuration changes, significantly reducing governance costs and enhancing user experience, as well as reducing many of the common frustrations including the documentation burden, alert fatigue, system responsiveness, outdated content, and unintuitive design. Our five-tiered model details a structured approach to AI integration within EHRs. Tier I focuses on autonomous database reconfiguration, akin to Oracle Autonomous Database functionalities, to ensure continuous system improvements without direct edits to the production environment. Tier II empowers EHR clients to shape system performance according to predefined strategies and standards, ensuring coordinated and efficient EHR solution builds. Tier III optimizes EHR choice architecture by analyzing user behaviors and suggesting content and configuration changes that minimize clicks and keystrokes, thereby enhancing workflow efficiency. Tier IV maintains the currency of EHR clinical content and decision support by linking content and configuration to updated guidelines and literature, ensuring the EHR remains evidence-based and compliant with evolving standards. Finally, Tier V incorporates context-dependent AI copilots to enhance care efficiency, quality, and user experience. Despite the potential benefits, major limitations exist. The market dominance of a few major EHR vendors—Epic Systems, Oracle Health, and MEDITECH—poses a challenge, as any enhancements require their cooperation and financial motivation. Furthermore, the diverse and complex nature of health care environments demands a flexible yet robust AI system that can adapt to various institutional needs that has not yet been developed, researched, or tested. The Elastic EHR model proposes a five-tiered framework for optimizing EHR systems and user experience with AI. By overcoming the identified limitations through vendor-led, collaborative efforts, AI-enabled EHRs could improve the efficiency, quality, and user experience of health care delivery, fully delivering on the promises of digitization within health care.

Introduction

Properly and proactively configuring modern electronic health records (EHRs) has grown beyond human capabilities. As they are infinitely configurable, embedded potential and capabilities exist; however, properly configuring these capabilities at scale in a timely manner in an increasingly resource-constrained environment is not possible through the manual approaches of today. Fully leveraging this potential will require artificial intelligence (AI)-powered governance. AI integration with EHRs, however, has almost exclusively focused on front-end, user-, and patient-facing "copilots." These copilots enhance navigating, searching, understanding, synthesizing, or

XSL•FO
RenderX

documenting medical information. AI copilots have benefits, but they operate on a manually maintained, costly, and continuously noncurrent EHR content and configurations, ie, their effectiveness is fundamentally limited by flaws in the underlying EHR architecture. These flaws result from the complexity and scale of configurable "solutions" that comprise health record platforms; to solve this issue, we propose the "Elastic EHR". We define this as an EHR that can proactively suggest and, upon validation, perform optimal configuration changes, significantly reducing governance costs and providing better user and patient experience. To specify the areas in which AI should target EHRs, we propose a five-tiered model (please see Table 1), each tier building upon the previous, with an emphasis on Tiers II-IV, as Tiers I and V have already been unofficially defined.

Table . Five tiers of an Elastic electronic health record (EHR).

Level	Tier	Description	Example
Users	Tier V: Copilots and Assistants	Context-dependent functionality designed to enhance care quality, efficiency, or experience for health care professions or patients.	A voice-enabled "copilot" assists clinicians during encounters, suggesting relevant diagnoses, autogenerating draft documentation, and proposed orders.
Configuration	Tier IV: External Knowledge Linkage	Suggested configuration changes based on evolving external evidence, autonomously executed, and communicated upon approval.	After the USPSTF[a] updates its mammogram screening guidelines to start at age 40 years, Tier IV detects this change and proposes new EHR orders, forms, and documentation templates to ensure the organization's screening recommendations and registries match the updated guidelines.
	Tier III: Workflow Optimization	Suggested configuration changes based on user behavior, autonomously executed, and communicated upon approval.	Tier III identifies a subset of clinicians who complete clinic visits more efficiently by using personal order sets, then merges these best-practice sets into a single enterprise-level order set for all physicians in that specialty, automatically queuing it for approval and release.
	Tier II: Internal Configuration Optimization	Suggested configuration changes based on client- and vendor-defined standards and the intended interactions between platform solutions.	An architect updates a patient intake form. Tier II suggests edits to maintain uniform naming conventions, default field values, and interface compatibility. It also highlights downstream solutions (eg, registries, templates) that might be impacted by any change.
Database	Tier I: Autonomous Database Tuning	Automated tuning, patching, and workload balancing, logged for administrator review.	Tier I automatically adjusts database indexes and memory allocations to optimize performance, creating a change log that flags issues such as slow queries or capacity constraints for subsequent human review.

[a]USPSTF: United States Preventive Services Task Force.

Tier I: Autonomous Database Tuning

Tier I consists of autonomous database reconfiguration, operating similarly to the Oracle Autonomous Database with automated tuning, patching, and workload balancing [1]. This tier creates a change log for retroactive review, with examples including component upgrades, system maintenance suggestions, software error detection, cyber security threat detection, and supplemental database backups. To clarify, Tier I does not involve independent editing of the EHR production environment or any create, update, or delete functions.

Tier II: Internal Configuration Optimization

Introduction to Tier II

In Tier II, EHR clients shape the performance based on the desired "solution" strategy, style guides, and standardizations via approval and scheduling of recommended changes. Solutions are defined as a discrete set of functionality, including templated notes, auto text shortcuts (aka "dot phrases"), orders, order sets, and alerts. This tier optimizes connected EHR solution builds. For example, the Oracle Health EHR (formerly known as Cerner Millennium) contains up to 850 content and configuration tools, each with dozens to hundreds of options and subtools. The

XSL•FO
RenderX

output of each of these tools may be connected to one or multiple other solutions. To build a simple form, we may require up to 12 distinct tools and a week of skilled architect time. The proper front-end flow depends on the coordinated build of solutions, but the tools to configure these solutions are siloed, and the solution architect or informaticist may be blind to the full system impacts. Changing the content of this form may negatively impact multiple other solutions, including note templates, orders, interfaces, and discrete data capture. Tier II ensures this hypothetical form is built both to institution-set standards and aligns with these other solutions.

Tier II Scenario

A solution architect needs to update a form, a context-dependent collection of discrete data entry fields. However, multiple other solutions may populate or use these data fields, including results or data review solutions, "smart" documentation or ordering templates, outbound interfaces, logical rules or alerts, or patient registries. Without querying the database or system configurations for each potential impact, the architect is largely unaware of possible downstream ramifications. Tier II addresses this by providing AI-assisted guidance on how these solutions interact, automatically suggesting any necessary edits to keep interrelated components synchronized. In this process, a middleware layer becomes invaluable; it orchestrates data exchange among siloed EHR modules, allowing the AI engine to integrate seamlessly with the relevant system components. By maintaining consistent data structures and communication channels, middleware ensures that the architect's updates are executed safely and comprehensively. Technically, this would include AI-generated queries of relevant database tables and system files, as well as a graphical user interface overlay that helps the architect visualize potential impacts and either approve or deny suggested changes.

Evaluating Tier II

Tier II is designed to streamline how institutions sustain their EHRs, according to enterprise standards, while reducing configuration silos and ensuring that changes to one component do not inadvertently disrupt others. Evaluation metrics may include configuration turnaround time, error rates, compliance with institutional standards, and architect or administrator feedback.

Configuration Turnaround Time

This is the time to implement a specific EHR change—from the initial request to the final deployment. An effective Tier II system should significantly shorten this resolution process.

Error Rates

This is to monitor the frequency of errors or backouts after initial release. Fewer postdeployment fixes indicate that AI-driven guidance is proactively catching conflicts and dependencies.

Compliance with Institutional Standards

This is the alignment of new solutions with established style guides, templates, and regulatory requirements. A high compliance rate suggests that Tier II is helping maintain standardized, high-quality configurations.

Architect or Administrator Feedback

This includes qualitative feedback from solution architects, informaticists, and administrators about the system's ease of use, clarity of recommended changes, and impact on daily workflows.

Tier III: Workflow Optimization

Introduction to Tier III

Tier III proactively suggests configuration changes to optimize EHR choice architecture. Optimal choice architecture in this context entails a configurable design that incentivizes the minimum number of clicks, keystrokes, and mouse miles to achieve an intended, quality outcome. Optimal architecture makes the right, efficient choice path the intuitive option, enhancing EHR usability [2]. With the current complexity of EHR design to account for the high variability within patient care, following the most efficient choice paths is not easy or intuitive. By globally monitoring user behavior and determining pockets of efficient users achieving defined process or outcome metrics, Tier III finds the ideal choice paths and suggests configuration changes to democratize them across all relevant user populations. It makes the easy path, the right path. Examples include identifying missing orders or default selections within order sets; optimizing note template content to reduce the manual insertion of discretely captured information or the unnecessary use of free text; updating default naming conventions and selections to reduce the misrouting of orders, notes, or messages; and consolidating unnecessary user positions, preferences, or roles.

Tier III Scenario

An example scenario involves monitoring the ordering patterns of outpatient primary care physicians treating acute nasopharyngitis (common cold). Across hundreds of outpatient clinics, ordering times for these encounters vary widely, despite similar order volumes and medication classes. Tier III AI identifies a subset of providers who achieve faster, more efficient workflows by using personal order sets. The system consolidates these personal sets into a recommended, enterprise-level order set and queues its integration into the primary care physician's workflow position. Once approved, the AI executes the change. To achieve this level of real-time monitoring and seamless deployment, a robust middleware solution can mediate data traffic, collecting operational metrics from disparate EHR modules, and pushing approved configuration changes into production.

Evaluating Tier III

Tier III aims to optimize user workflows by identifying and disseminating best practices across relevant roles and settings. Key metrics may include user efficiency, clinical process and outcome metrics, adoption and utilization rates, and user satisfaction and burnout scores.

User Efficiency

This is used to quantify the number of clicks, keystrokes, mouse miles, or time spent per task. A Tier III system that democratizes

XSL•FO
RenderX

efficient workflows should reduce these metrics across user populations.

Clinical Process and Outcome Metrics

For instance, we measure whether streamlined order sets improve prescribing accuracy, reduce redundant orders, or decrease overall encounter time. Monitoring patient throughput, wait times, or complication rates can highlight improvements in care quality.

Adoption and Utilization Rates

This is used to track how often recommended workflows, templates, or order sets are actually used by clinicians. High adoption signals that Tier III optimizations align with user needs and clinical realities.

User Satisfaction and Burnout Scores

Survey clinicians gauge whether the system's workflow suggestions reduce frustration, documentation burden, and burnout. Positive shifts in these areas suggest that Tier III is effectively enhancing usability.

Tier IV: External Knowledge Linkage

Introduction to Tier IV

Tier IV proactively maintains the currency of EHR clinical content and decision support through two mechanisms. First, content may be directly linked to its derived source. For instance, registries and their integrated actions (orders, forms, laboratory or radiographic studies) could be linked to the United States Preventive Services Task Force (USPSTF) guidelines [3]. When the guidelines change, Tier IV proactively offers the configurations required to incorporate these updates. These linkages could also extend to nonclinical sources including governmental regulations or issuances, institutional policies, or payer requirements. When the Centers for Medicare and Medicaid Services update the essential elements for clinical note content, Tier IV offers the configurations to add or remove the applicable sections for efficient documentation. Second, Tier IV crawls sources of evidence and peer-reviewed literature and cross-checks these findings with existing EHR configured content. As evidence becomes available, Tier IV suggests its EHR incorporation, either as de novo content or updating existing solutions. If a trusted source of truth publishes a new clinical practice guideline, then Tier IV offers a set of EHR solutions to incorporate this clinical practice guideline across the relevant EHR workflows and positions.

Tier IV Scenario

The USPSTF updates their breast cancer screening recommendation to begin at age 40 years versus age 50 years [3]. Because the USPSTF had been identified as a source of truth as part of Tier IV, a web-crawling, agentic AI identifies the change and suggests the requisite configuration changes to incorporate this update into the corresponding EHR patient registry. With the underlying Tier II AI system in place, changes to other associated solutions can also be performed concurrently, such as any related forms, rules, or clinical documents.

Evaluating Tier IV

Tier IV proactively updates clinical content and decision support based on changing guidelines, regulations, and published evidence. Key metrics include update lag time, completeness of updates, accuracy of incorporated guidelines, and regulatory compliance.

Update Lag Time

This measures how quickly new guidelines or evidence-based recommendations are integrated into EHR workflows after they are published. Shorter lag times indicate that Tier IV is effectively automating the update process.

Completeness of Updates

This is to evaluate how comprehensively the system identifies and applies relevant updates. A high success rate suggests that the AI is accurately mapping external knowledge sources to the EHR's configuration.

Accuracy of Incorporated Guidelines

This is to assess whether the recommended EHR changes align with the authoritative sources, ensuring no contradictory or partial implementations that might compromise clinical care or billing requirements.

Regulatory Compliance

This is to track how often Tier IV updates help ensure compliance with evolving payer, government, and institutional mandates. Fewer compliance violations or missed updates reflect a more robust external linkage mechanism.

This also helps to track how often Tier IV updates help ensure compliance with evolving payer, government, and institutional mandates. Fewer compliance violations or missed updates reflect a more robust external linkage mechanism.

Tier V: Copilots and Assistants

Introduction to Tier V

Finally, Tier V involves context-dependent functions that serve to enhance care efficiency, quality, and user experience for both patients and providers. These are the copilots. This tier is the current, almost exclusive focus of integrating AI within EHRs. Examples are robust, but popular ones include Microsoft's GenAI copilot integration within Epic Systems [4] and the Nuance Dragon Ambient eXperience (DAX) AI copilot [5].

Safeguards

Integrating AI into EHR maintenance and configuration carries inherent risks that require careful mitigation strategies. These safeguards must address proper human oversight, data security, safety testing, legal and regulatory compliance, and data standards.

Tiered Approval

Although AI can autonomously recommend changes to database configurations or workflows, no modifications should be pushed into production without human review and authorization (particularly for Tiers II–IV).

XSL•FO
RenderX

Change Log and Audit Trails

We need to maintain comprehensive records of all AI-generated recommendations and subsequent human-validated changes. This includes versioning, timestamps, rationale for acceptance or rejection, and who approved the changes.

Backout Steps

All AI-recommended changes should come with manual build and backout steps in case manual, direct human architect involvement is required to modify or rollback the change.

Role-Based Access Controls

Authority for approving final changes should be restricted. Only designated administrators, informaticists, or clinicians with appropriate privileges should "sign off" on AI-driven recommendations [6].

Data Security and Privacy

Encryption and Secure Communication

Ensure all data in transit or at rest is encrypted. For Tiers III–IV, where external data sources and registries may be accessed, secure protocols should protect patient and system information.

Regulatory Compliance

Any AI-based solution that handles protected health information must adhere to federal regulations and equivalent international guidelines. This includes thorough documentation of access, role-based permissions, and breach reporting mechanisms [7,8].

Deidentification for Training

If EHR data is used to train AI models, employ robust deidentification or anonymization methods to protect patient privacy.

Safety Testing and Sandbox Environments

Staged Deployments

Deploy AI-generated configuration changes in a nonproduction environment first. Validate for unintended effects, usability impacts, and potential conflicts with existing solutions. Only after thorough testing and clinician feedback should changes move to production.

Automated Regression Testing

Implement continuous and automated testing routines that check clinical workflows, alert systems, and data integrity after each AI-prompted change. This helps identify errors early and prevents adverse impacts on patient care.

Algorithm Transparency and Explainability

Explainable Recommendations

Tiers II–IV rely on AI to suggest or enact configuration changes. Provide clear justifications or "explanations" for each recommendation (eg, how the model determined a particular workflow optimization). Transparency bolsters trust and aids human reviewers' decision-making [9,10].

Ethical and Legal Considerations

Liability and Accountability

Clearly define who bears responsibility if AI-suggested changes negatively impact patient care—whether it is the vendor, the health care institution, or a combination. Incorporate these details into institutional policies and vendor contracts.

Regulatory Approvals

Some aspects of Tiers II–IV that meaningfully affect patient care (eg, advanced clinical decision support) may require regulatory oversight or approval from agencies. Understand and follow applicable guidelines when introducing these features [11].

Interoperability and Third-Party Validation

Standards-Based Implementation

Align AI-driven changes with industry standards (HL7 [Health Level Seven], FHIR [Fast Healthcare Interoperability Resources], SNOMED CT [Systematized Nomenclature of Medicine Clinical Terms], LOINC [Logical Observation Identifiers Names and Codes], etc.) to maintain interoperability.

Independent Audits and Certification

Consider periodic third-party evaluations of AI systems and processes, focusing on data handling, software quality, and patient safety standards.

Challenges

Although nearly every hospital and office-based physician now use a certified EHR [12], the market remains dominated by three vendors—Epic Systems (36%), Oracle Health (25%), and MEDITECH (16%) [13]. This concentration, coupled with the high up-front investment required for AI development and proprietary configuration tools, could stifle the adoption of Tiers II–IV. Overcoming this dynamic requires forging partnerships that incentivize vendors to open their proprietary configuration tools through standardized application programming interfaces and collaborative research and development initiatives. Such measures would allow third-party and in-house AI solutions to integrate, reducing reliance on vendor-specific consulting and expanding client autonomy. By adopting off-the-shelf AI modules—rather than building everything in-house or through a single vendor—small-to-mid-sized health care organizations can gradually implement Tiers II–IV at a lower cost. To make this financially viable for vendors, professional organizations, health care systems, and regulatory bodies should leverage market demand and policy incentives that reward open architectures, building upon the 21st Century Cures Act [14]. In doing so, vendors could reorient their business models—moving from fee-based solution architecture services toward engineering-focused products and support—without sacrificing profitability. This shift would ultimately accelerate innovation, lower costs, and help realize the full potential of the Elastic EHR.

XSL•FO
RenderX

Conclusions

The adoption of the five-tiered Elastic EHR framework represents a structured approach for overcoming some of the major limitations in commercial EHR systems. By leveraging AI to manage and optimize configurations, this model addresses the inefficiencies and high costs, and downstream frustrations, associated with EHR sustainment. However, the realization of this potential faces significant hurdles, particularly due to the dominance of a few major vendors who control the necessary configuration tools and must see financial benefit in adopting such changes. Additionally, the complexity of health care environments, the need for substantial financial investment, and the lack of robust research on this topic also represent significant hurdles. Successful implementation will require collaboration, continuous research, and a balanced approach that augments medical, solution architect, and clinical informatics expertise with AI capabilities. If these challenges can be addressed, the Elastic EHR could substantially improve the efficiency, quality, and user experience of health care delivery, fully delivering on the promises of digitization within health care.

Abstract

With the explosion of innovation driven by generative and traditional artificial intelligence (AI), comes the necessity to understand and regulate products that often defy current regulatory classification. Tradition, and lack of regulatory expediency, imposes the notion of force-fitting novel innovations into pre-existing product classifications or into the essentially unregulated domains of wellness or consumer electronics. Further, regulatory requirements, levels of risk tolerance, and capabilities vary greatly across the spectrum of technology innovators. For example, currently unregulated information and consumer electronic suppliers set their own editorial and communication standards without extensive federal regulation. However, industries like biopharma companies are held to a higher standard in the same space, given current direct-to-consumer regulations like the Sunshine Act (also known as Open Payments), the federal Anti-Kickback Statute, the federal False Claims Act, and others. Clear and well-defined regulations not only reduce ambiguity but facilitate scale, showcasing the importance of regulatory clarity in fostering innovation and growth. To avoid highly regulated industries like health care and biopharma from being discouraged from developing AI to improve patient care, there is a need for a specialized framework to establish regulatory evidence for AI-based medical solutions. In this paper, we review the current regulatory environment considering current innovations but also pre-existing legal and regulatory responsibilities of the biopharma industry and propose a novel, hybridized approach for the assessment of novel AI-based patient solutions. Further, we will elaborate the proposed concepts via case studies. This paper explores the challenges posed by the current regulatory environment, emphasizing the need for a specialized framework for AI medical devices. By reviewing existing regulations and proposing a hybridized approach, we aim to ensure that the potential of AI in biopharmaceutical innovation is not hindered by uneven regulatory landscapes.

artificial intelligence; algorithm; regulatory landscape; predictive model; predictive analytics; predictive system; practical model; machine learning; large language model; natural language processing; deep learning; digital health; regulatory; health technology

Introduction

Background

The convergence of algorithms, artificial intelligence (AI), big data, and digital health technologies (DHTs) is a sea change not seen since the “dot.com” era, which has significantly changed the way we work, play, and learn [1,2]. However, the lack of comprehensive regulatory guidance has led to the force-fitting of novel innovations into existing categories, leading to ambiguous boundaries between medical devices and consumer electronics. This results in added ambiguity for innovators seeking to share valuable product concepts. What is lacking is a comprehensive approach to evaluating medical benefits, risks, and evidence that can be universally applied across different product categories, product types, and regulatory regimes [3]. Such an approach would be flexible, allowing for the distinctions between various products to be properly addressed. Clear regulations play an important role in enabling easier scaling, highlighting the mutually beneficial relationship between regulatory clarity and the acceleration of innovation. Moreover, the pharmaceutical industry’s comprehensive understanding of scaling and marketing extends beyond the confines of drug development, presenting a valuable paradigm for other sectors in the AI landscape. This paper addresses the ambiguity faced by innovators and proposes models for evidence strategies,

XSL•FO
RenderX

particularly focusing on the distinct regulatory challenges faced by the biopharma industry.

At the time of this writing, Gartner [4] has placed the increasingly popular generative AI technology at the peak of inflated expectations for emerging technologies in 2024. Whether the transformation that generative or other forms of AI and DHTs bring to health care occurs gradually or rapidly, there is widespread anticipation of both advancement and potential challenges [5,6]. The many use cases ranging across diagnostics, logistics, clerical improvements, and new treatment modalities in general medicine and across medical subspecialties have been described in detail within the literature [7,8]. Similarly, the use of these technologies holds equally compelling promise within biomedical product development [9,10].

Current Challenges

AI and DHTs represent a wide range of intricate and interconnected technologies, and the vast array of applications are equally diverse and complex. For example, most DHTs rely on proprietary algorithms trained from and across a mixture of private and public data sources. As multiple technologies are integrated into a tool, more information may be shared, and the capabilities and risks aggregate [11]. This additive complexity challenges traditional domain-based regulatory regimes. The US Food and Drug Administration (FDA) regulates medical devices, but not all algorithms and apps meet the regulatory definition of a medical device as defined in Section 201(h) of the Food, Drug, and Cosmetic Act. These apps often access and transmit data across the internet but do not fit neatly into the codified remit of the Federal Communications Commission or the Federal Trade Commission (FTC) [12]. Even within regulatory regimes, there are qualified gaps. The Office for Civil Rights enforces health care privacy, but only for covered entities, leaving a loophole and resulting in gaps in protection that are systematically being exploited [13]. Further, these overlapping, complex, and intricate interregulatory and intraregulatory regimes create confusion and inequities, hindering progress.

Objectives

While there have been efforts to establish standardized approaches to the regulatory assessment of DHT and AI medical products, many of these frameworks take the approach of a single regulator and regulatory regime versus approaches that inform regulatory decision-making across the spectrum of relevant regulators [14-16]. Further, these frameworks incorrectly assume that all innovators are alike. Consumer electronic companies and health technology startups, providing solutions that may overlap or compete with offerings from traditional medical device and pharmaceutical companies, often navigate a regulatory landscape that offers them more adaptability in their operations, which differs from the established health care regulations governing other sectors. The coexistence of unregulated and highly regulated makers in the same market can lead to various challenges, including issues related to safety, quality, and fair competition. Balancing innovation and oversight is crucial in this context. We need solutions that promote fair competition while maintaining a high standard of safety and product effectiveness, without creating a disparity between the heavily and lightly regulated entities. It is also helpful to level set on terminology. Textbox 1 provides definitions for common terms used in this space.

Textbox 1. Key terms and definitions.

Digital health technologies: technologies consisting of hardware (eg, sensors or transmitters) or software (eg, connectivity software, algorithms, or artificial intelligence) components that are used for health care–related purposes.

Medical device software: term primarily used in the European Union to define software with a medical purpose that can be used either alone or in combination with a regulated medical device. This is not interchangeable with software as a medical device [17].

Software as a medical device: software that is used for medical purposes and may do so independently of a hardware medical device as well as not being a required component of a hardware medical device [18].

Mobile medical apps: mobile apps serving as medical devices, which integrate software functionality that aligns with the Food and Drug Administration definition of a device, as outlined in Section 201(h) of the Food, Drug, and Cosmetic Act. These apps may function as accessories to regulated medical devices or convert a mobile platform into a regulated medical device [19].

Digital therapeutics: software-based interventions intended to prevent, manage, or treat medical conditions based on evidence of a demonstrable positive therapeutic impact on a patient's health [20].

Direct to consumer: marketing products or services directly to consumers without the involvement of a health care provider.

Regulatory Regimes and Industries in DHT

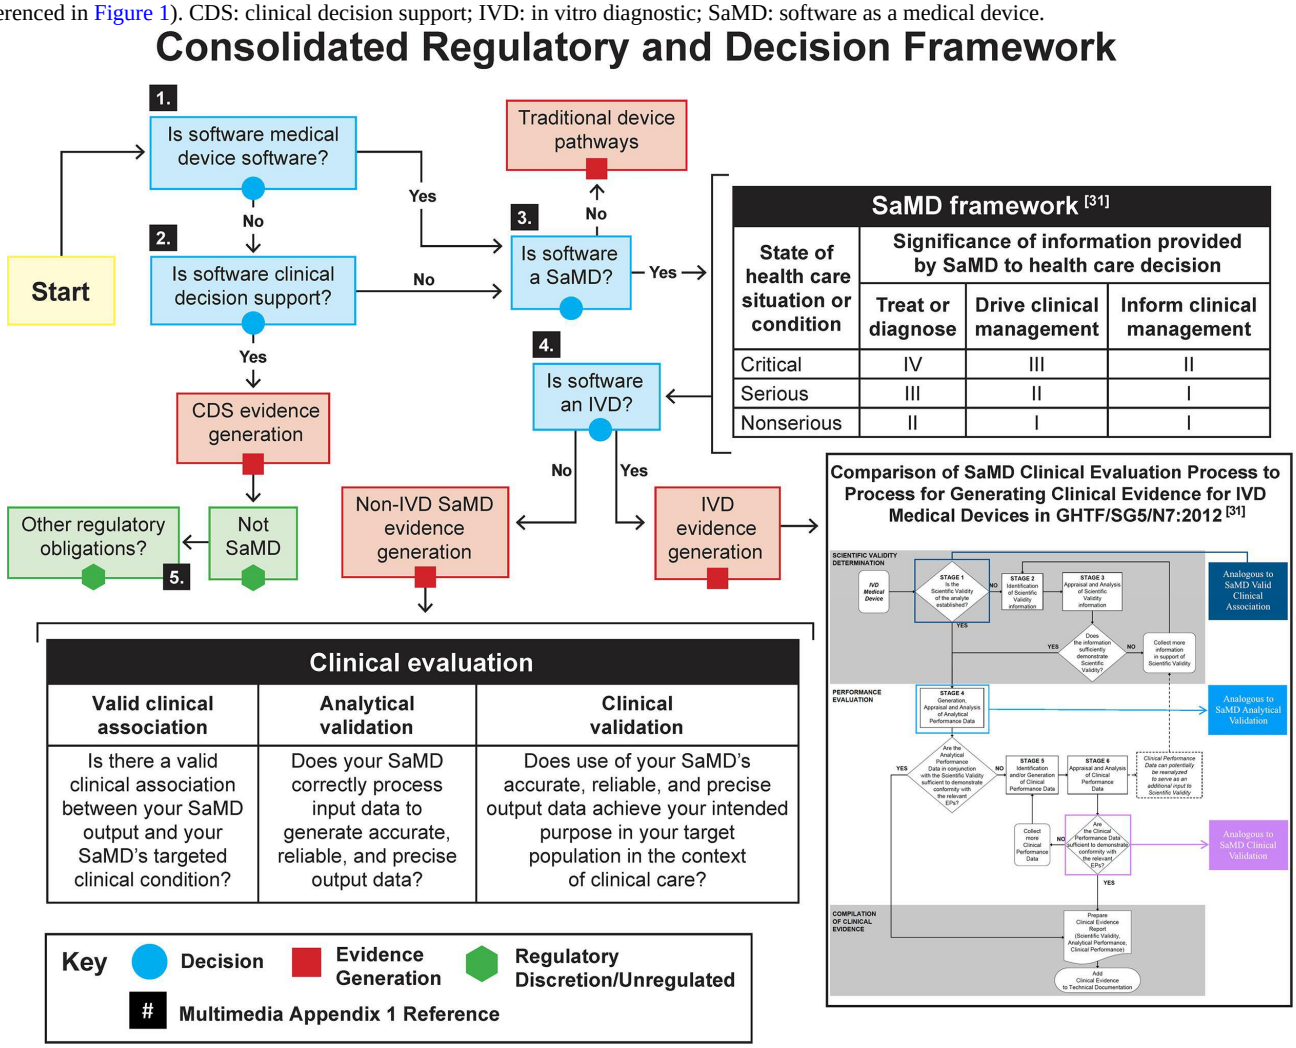
The key is that not all makers are subject to regulations in the same manner nor do they exhibit the same affinity for risk. For example, while direct-to-consumer advertising is highly regulated for pharmaceutical products, the oversight is less consistent for over-the-counter (OTC) "devices," such as some medical tests not regulated by the FDA or FTC [21,22]. This not only results in a less than comprehensive regulatory coverage of AI medical devices and DHTs but also involuntarily creates an ecosystem where makers develop and market their products around the varying gaps in regulatory coverage. Certain products, such as OTC medical device algorithms to detect sleep apnea, may be subject to less regulation and thus have an advantage over established health care products. OTC sleep apnea devices represent a category of products that can fall in the "interstitial spaces" of regulatory oversight, as they are not always subject to the same level of scrutiny as prescription devices. These products often include wearable sensors, smartphone apps, or other consumer-grade devices that purport to detect symptoms of sleep apnea, such as disrupted breathing or low oxygen levels during sleep. Many OTC sleep apnea devices may fall into class I or II and thus may not require

XSL•FO
RenderX

premarket approval, which is the most stringent type of device marketing application required by the FDA. Instead, they may only need to meet the requirements for 510(k) clearance, which is a less rigorous process and does not require clinical trials. However, there are also some OTC sleep apnea devices that do not fall under any FDA regulation because they are marketed as "wellness" or "lifestyle" products rather than medical devices. They do not detect signs of sleep apnea and are not marketed as a medical device but as a sleep improvement system; therefore, they do not fall under FDA regulation.

This lack of consistent regulation can create opportunities for companies to market products with less oversight and potentially greater profit margins, but it can also lead to consumer confusion and potential safety risks if the products do not perform as advertised. It is a clear example of how the existing regulatory framework may struggle to keep up with the rapid pace of innovation in DHT. Clear and well-defined regulations play a pivotal role, especially during the transition from exploratory phases to scaling products, enabling smoother, efficient scaling processes.

In many ways, the opposite situation exists for larger established health care organizations. A highly regulated pharmaceutical company that is already subject to the many previously discussed compliance regimes and other complex corporate regulatory obligations may find it too difficult or risky to attempt digital innovation, as the burden of reporting, evidence, and oversight are all greatly heightened compared to niche innovators. This scenario must be discouraged, as these organizations have deep expertise within the disease areas where they have successfully delivered drugs and devices. This expertise could lend itself to success beyond many health technology startups, which often fail due to a lack of market fit of their products [23]. Encouraging a balance between regulatory clarity and flexibility is paramount to fostering innovation across diverse players in the digital health landscape. Indeed, there is a cost to regulatory compliance, which is more readily absorbed by well-resourced companies. Smaller startups may not have sufficient funding to run the optimal size and scale validation study. They may have funding constrained by the need to showing promise to investors in order to survive to their next round of funding.



Evidence Requirements and Claims

While one side of the matrix is the nature of the products being developed and the types of makers, the evidence supporting these products is equally if not more diverse. Companies with very different sizes and areas of expertise may be competing openly within a range of product categories and evidence strategies with clinical development plans that seem lacking. Much of this may be attributed to the relative lack of maturation of the AI medical device and DHT spaces, which has led to a wide range of interpretation of the guidelines. This can pose challenges for companies with more rigid regulatory boundaries, which wish to participate in this evolving experimental domain and have substantial evidence strategies to support product development but are uncomfortable as the space is not mature. For most, the first step is to determine the type of product being developed. However, when dealing with products designed for medical purposes or functions, it is essential to ensure that it addresses an unmet medical need. In the United States, the product type can vary from a device software or algorithm that may be classified as mobile medical apps, software functions that are not medical devices, clinical decision support software, or software as a medical device (SaMD) [24-26]. Each of these product types needs different types and levels of evidence to support them in the market and may need regulatory approval. While the FDA offers guidance on how to determine the product type, significant judgment is required due to similarities within the categories as well as the severity of the disease indication. This necessitates an iterative thought process, considering multiple regulatory guidance alongside the evidence strategy and clinical development plan [27].

To simplify this process, we developed the graphical consolidated regulatory decision framework shown in Figure 1 [28-30]. This framework builds on the approach in the FDA Guidance, Software as a Medical Device (SAMD): Clinical Evaluation [31]. Additional details supporting this framework are available in Multimedia Appendix 1. A precursor to the workflow is determining whether the clinical association is well-established or novel. This can be nontrivial, as many SaMD products lack clinically established standards due to the novelty of the product. When there is a well-established clinical association, these SaMD have outputs with well-documented association as identified in sources such as clinical guidelines, clinical studies in peer-reviewed journals, consensus for the use of the SaMD, international reference materials, or other similar well-established comparators of previously marketed devices. When the clinical association is novel, these SaMD may involve new inputs, algorithms, outputs, new intended target population, or new intended use. An example may include the combination of nonstandard inputs (eg, mood or pollen count), with standard inputs (eg, blood pressure or other physiological signals), that uses novel algorithms to detect deterioration of health or diagnosis of a disease.

XSL•FO
RenderX

Figure 1. Consolidated regulatory classification decision framework (for the reader's convenience, Multimedia Appendix 1 gives a set of figures referenced in Figure 1). CDS: clinical decision support; IVD: in vitro diagnostic; SaMD: software as a medical device.

The importance of objective consideration of these questions cannot be overstated. Frequently, innovators have embedded biases within their assumptions that cloud judgment in this assessment.

Any one or combination of these biases can threaten or derail the development of novel technology products including product integrity and patient safety. For example, the well-publicized case of the FDA warning letter that caused Owlet to cease selling their Smart Sock and copackaged products includes several of these biases [32]. The FDA determined that the product was a medical device but the maker had not reached the same determination [33]. According to the FDA, the apnea alarms had inadequate clinical evidence, and parents could potentially seek emergency care due to product alarms that had inadequately established clinical association (prestep), specifically dips in oxygen saturation as determined by pulse oximetry in infants during sleep [34]. This incident exemplifies how the misclassification of a product type and inadequate clinical evidence highlight the challenges in navigating ambiguous regulatory guidelines. Clear regulations not only mitigate the risk of inadequate clinical evidence, reducing the likelihood of triggering unnecessary care in this case, but also highlight the significance of aligning evidence strategies with robust clinical development plans to avoid such pitfalls.

In contrast, Apple's approach to irregular heartbeat notification serves as an example that a technology company that operates outside the traditional health care sphere can diligently address product-type classification and evidence. Apple developed these FDA-cleared features via rigorous and traditional approaches using randomized controlled trials [35,36]. The resulting product label is considered FDA-regulated; therefore, the claims made about the product must not exceed the evidence produced, the specifics listed within the clearance letter, or the resulting label [37]. However, Apple is an exception within the technology industry in size, scope, and resourcing. The average medical device maker is much smaller and must build their product strategies around regulatory regimes in order to get their product to market. This is not solely about the avoidance of regulation. Many innovations pass the bar for regulatory clearance but not the bar for reimbursement, which can be a difficult and unprofitable market situation. Alternatively, developing a product that does not meet the bar for FDA regulation can result in a highly profitable "health" or "fitness" application that, while not regulated or reimbursed by health insurance, can be highly profitable by volume of sales even at very low-price points.

If the maker determines that the software product is not a medical device, the next step is to determine whether the product

XSL•FO
RenderX

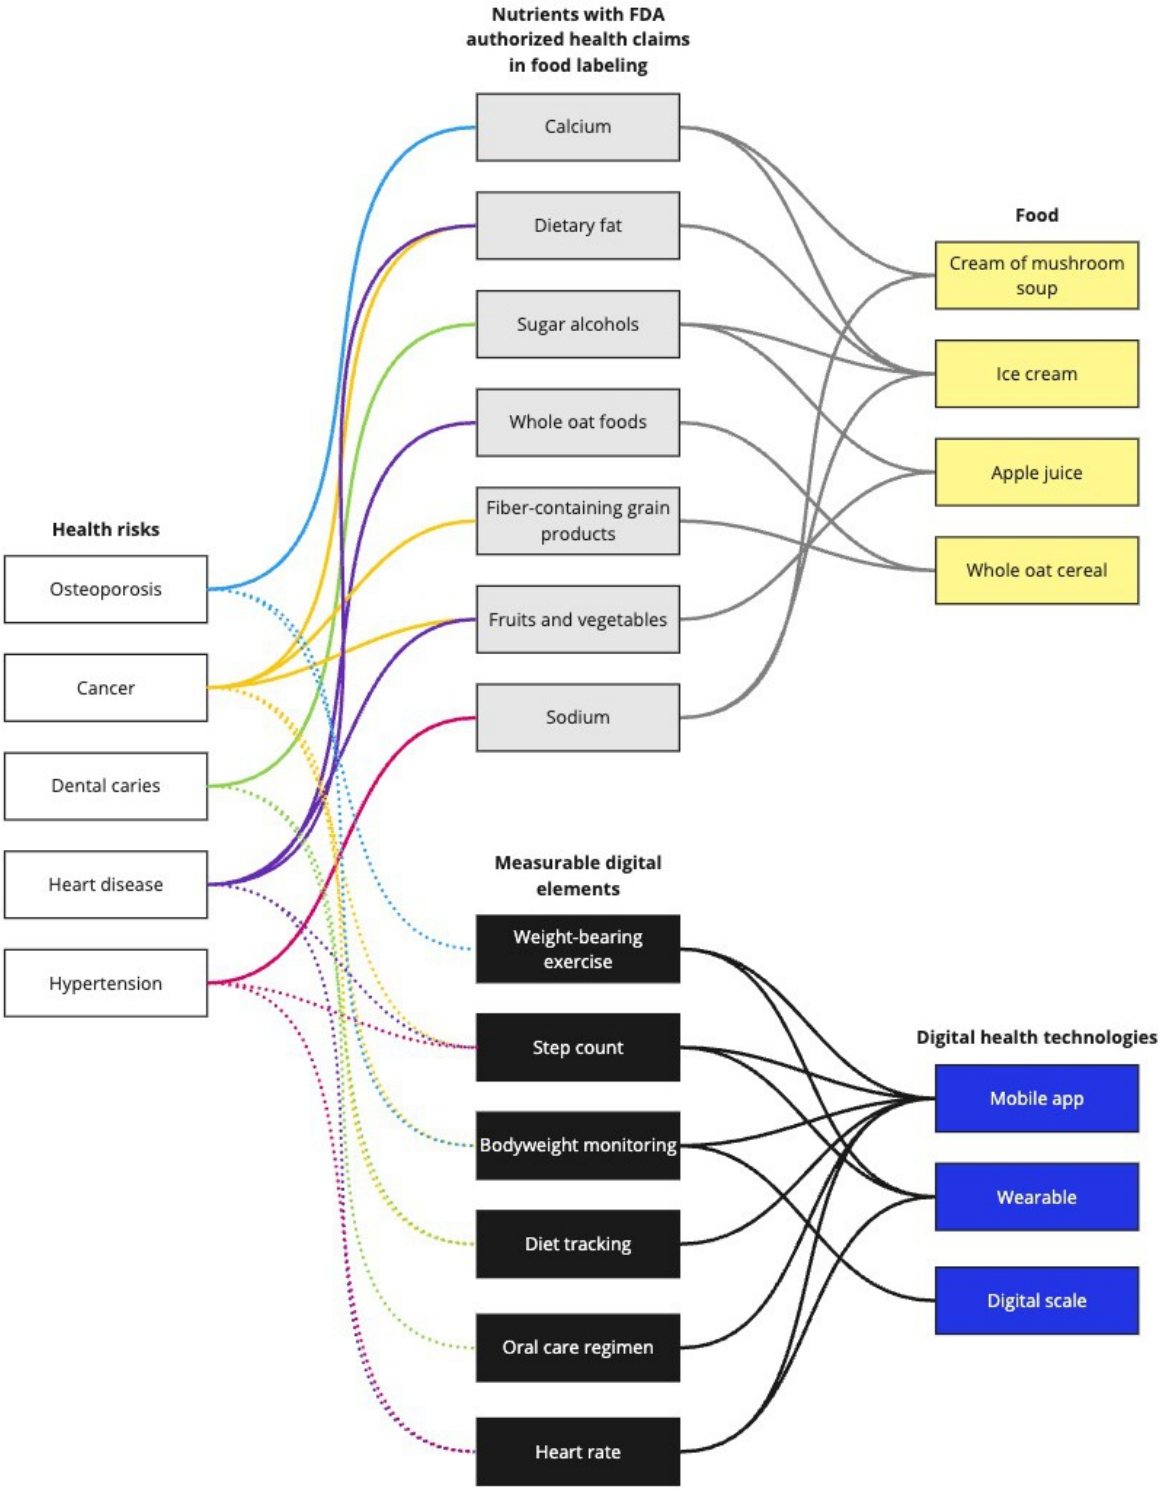
is a decision support tool, and this can be accomplished with the aid of the earlier-referenced FDA guidance document.

Continuing with the framework, if the software is a medical device, the next step is to determine whether the software is a SaMD. If not, the user is directed toward traditional medical device pathways. If so, they are guided through the SaMD categorization process. This is complicated by the requirement for a deep understanding of the medical indication and all possible outcomes from any chosen route. Determining whether a SaMD treats or diagnoses, whether it drives clinical management, or simply informs clinical care yields a level of interpretation that often varies by stakeholders. In addition, it must be simultaneously determined whether these actions occur in a critical, serious, or nonserious medical situation. The FDA has published guidance on when and whether independent review of these decisions should be included.

Once the SaMD is categorized, the next step is to determine whether the product is an in vitro diagnostic (IVD) or non-IVD SaMD. The rubric directs the user toward evidence generation in either case. When the SaMD is non-IVD and novel clinically, the evidence generation process requires the establishment of a valid clinical association, analytical validation, and clinical validation of the product. These steps have been elaborated in detail within the previously referenced work by Goldsack et al [16]. When the SaMD is an IVD, the evidence generation process is analogous to the non-IVD case and can follow the stages of the clinical evidence assessment process as outlined in the Global Harmonization Task Force's Clinical Evidence for IVD Medical Devices [38].

Product Labeling Standards as a Guide

One improbable solution to creating clear and concise regulations would be the reorganization of current regulatory regimes to produce a new agency focused directly on the regulation of health care technologies. However, we can gain some insights from the nutrition industry.



Today, there are 3 agencies responsible for the regulation of food and nutrition information, the FDA, the FTC, and the Food Safety and Inspection Service (FSIS) of the US Department of Agriculture [39]. This may appear logical, assuming that each agency shares part of an overall mission. However, the reality is that handoffs, overlapping, and gray areas decrease the regulatory effectiveness or, at minimum, create confusion of roles and responsibilities. Continuing the example of food labeling, the FTC regulates food advertising, while the other 2 agencies share responsibility for regulating labels: FSIS regulates meat, poultry, and egg labeling and FDA regulates labeling for all other foods and nonspecified red meat (game). The Nutrition Labeling and Education Act addressed FDA-regulated packages and FSIS-issued parallel regulations. As an example of a gap, there are no provisions in the regulatory authorities defined by Congress that allow the FDA to approve dietary supplements for safety before they reach the consumer [40]. This results in fragmented safety data and little ability to forecast or prevent harmful products from reaching consumers [41].

There is a great deal that the digital health space can learn from nutrition and food labeling. Specifically, the FDA or Nutrition Labeling and Education Act and the FSIS oversee 3 elements of food package labeling: nutrient content, nutrient content claims, and "disease" claims. Further, the FDA has restricted health claims to a small number of permitted claims [42]. This type of strategic and comprehensive approach to labeling is a model that if applied to AI medical devices and DHTs would improve transparency and clarify their benefits and risks. Elements are starting to appear in relevant subdomains of digital health such as cybersecurity, computing hardware, clinical decision support, and medical devices [43-45]. Examples extending the nutrition-based health claims into the digital domain are shown in Figure 2. This figure shows health risk areas linked to nutrients having FDA-approved health claims. The figure shows those same health risk areas linked to digital health elements that could also have an impact on risk. Standardized AI medical device and DHT product labeling across prescription and nonprescription products could address the diversity of innovators and makers just as nutrition labeling levels the field between small farms and large, industrial food production corporations, as all are held to the same standards.

Different aspects of the creation, oversight, and enforcement of such labeling regulations would likely fall within the purview of existing regulatory bodies assessing medical devices and algorithm-driven DHTs. As Table 1 suggests, this is a current patchwork of different agencies without necessarily one central authority. The table indicates how the different agencies could each play a role in the oversight of AI medical devices and DHTs and the relevant product development.

Table . Regulatory authority across components of medical devices and algorithm-driven digital health technologies (DHTs).

Federal agency	Relevant aspects of current role	Possible enhanced role
US Food and Drug Administration	Regulation of medical devices, MMAs[a], SaMDs[b]	Develop specific guidelines for labeling AI[c] medical devices, including continuous learning algorithms, and establish a clear pathway for marketing authorizations and DTC[d]
Federal Trade Commission	Enforcement of federal laws that prevent fraud, deception, and unfair business practices (as in advertising)	Regulate use of labels in DTC advertising of AI medical devices and DHTs
Centers for Medicare & Medicaid Services	Administers the Open Payments program, enhancing transparency by collecting and publicly disclosing information about financial relationships between health care providers and pharmaceutical or medical device manufacturers	Outline required transparency elements in the label, capturing health care provider financial interactions with companies in the design, testing, and use of DHTs
US Department of Health and Human Services, Office for Civil Rights	Ensures the privacy and security of protected health information	Ensure that the AI medical device label provides transparency in how AI devices use patient data and enforce penalties for noncompliance
National Institute of Standards and Technology	Develops and maintains technical standards	Establish the benchmarks cited on the label for AI performance, safety, and interoperability with other medical systems
US Consumer Product Safety Commission	Protects the public from the risk of injury or death associated with consumer products	Issue product recalls for all other DHTs or AI-enabled health care devices not under the Food and Drug Administration's purview

[a]MMA: mobile medical app.

[b]SaMD: software as a medical device.

[c]AI: artificial intelligence.

[d]DTC: direct to consumer.

AI-Based DHT Package Labeling

Regardless of the type of maker, a significant unmet need that can inform innovators' strategies is standardized package labeling. Based upon the known potential harms and known potential limitations in AI-based DHTs, the minimum content for analogous product labeling would include the type of algorithm, the framework used for evidence generation, qualification and quantification of reproducibility, the ethical framework used, a description of the data used to train the model including how it was collected and consented, a statement on how bias was minimized or quantified, the risk management framework used to aggregate these various elements, and performance metrics [46-52]. This would enable a DHT packaging label, similar to the example shown in Table 2.

Table . Example of a permitted claims approach to artificial intelligence (AI)–based digital health technologies (DHTs).

DHT or algorithm design element	Permitted health claim	Example
Type of evidence basis	Primary benefit or utility	Randomized controlled trials, real-world evidence, etc
Ethical framework	Population benefit-risk	Inclusion and exclusion criteria as well as interpretability and explainability
Reproducibility	Statistically quantified and qualified claims	Specific indications and efficacy, data lineage, model versioning
Training data description	Applicability and specificity to populations	Rationale for included and excluded populations, training and testing data split
Disclosure of bias	Limitations of use and contraindications	Phenotypic traits such as skin tone
Risk management framework	Product integrity	Cybersecurity resilience, prevention of AI poisoning, measures for protecting user data (such as differential privacy)
Performance	Primary benefit or utility	Sensitivity, specificity, negative predictive value, positive predictive value

Labeling would directly counter the real and perceived black box problem and inform clinicians, researchers, patients, and caregivers in a manner that is equivalent to how they study, learn, and use new prescription and OTC drugs, diagnostics, and medical devices today [53,54].

XSL•FO
RenderX

New regulatory frameworks often face pushback from those they regulate, and labeling regulations are likely no exception. This resistance can be mitigated somewhat with guidance documents that incorporate feedback from various manufacturers, educational initiatives, and avenues for direct interaction between companies and regulatory bodies.

Conclusions

AI medical products and DHTs hold immense promise, but the diverse regulatory constraints among product makers necessitate a standardized approach. This is especially critical for smaller AI developers who operate in a different landscape than health care or larger industries. To create consistency, adopting minimum product labeling requirements, understanding claims, and having substantial evidence plans become essential. As innovation accelerates, ensuring equity in the ecosystem will allow both emerging and mature technology innovators to contribute meaningfully without being hindered by not only regulatory disparities but also ambiguities, such as the uncertain classification of certain AI applications and the lack of clear communication standards. Future research exploring the various reimbursement strategies and ethical implications of AI across product makers would be valuable to providing a more complete picture of this space. The perspectives from a wide range of digital health ecosystem stakeholders should be included to ensure that their diverse needs and expectations are being addressed.

Acknowledgments

This research was a collaboration between Duke University Clinical Research Institute and Pfizer Inc. This research was funded by Pfizer Inc.

Authors' Contributions

EP, KN, EF, and TT contributed to the conceptualization, writing of the original draft, and the reviewing and editing of the manuscript. EP, EF, and TT prepared and finalized all figures. All authors have read and approved the final manuscript.

Conflicts of Interest

KN is an employee and shareholder of Pfizer Inc. EP was affiliated with Duke Clinical Research Institute at the time of this initiative and is currently affiliated with Pluto Health.

Abstract

Shared decision-making is central to patient-centered care but is often hampered by artificial intelligence (AI) systems that focus on technical transparency rather than delivering context-rich, clinically meaningful reasoning. Although AI explainability methods elucidate how decisions are made, they fall short of addressing the "why" that supports effective patient-clinician dialogue. To bridge this gap, we introduce artificial intelligence–supported shared decision-making (AI-SDM), a conceptual framework designed to integrate AI-based reasoning into shared decision-making to enhance care quality while preserving patient autonomy. AI-SDM is a structured, multimodel framework that synthesizes predictive modeling, evidence-based recommendations, and generative AI techniques to produce adaptive, context-sensitive explanations. The framework distinguishes conventional AI explainability from AI reasoning—prioritizing the generation of tailored, narrative justifications that inform shared decisions. A hypothetical clinical scenario in stroke management is used to illustrate how AI-SDM facilitates an iterative, triadic deliberation process between health care providers, patients, and AI outputs. This integration is intended to transform raw algorithmic data into actionable insights that directly support the decision-making process without supplanting human judgment.

(JMIR AI 2025;4:e75866) doi:10.2196/75866

KEYWORDS

artificial intelligence; shared decision-making; AI reasoning; clinical decision support; generative AI; patient-centered care

Introduction

Shared decision-making (SDM) is characterized by collaboration between health care professionals (HCPs) and patients to align with patient values [1]. It has become central to patient-centered care, marking a shift from historical paternalism [2]. Concurrently, artificial intelligence (AI) is increasingly integrated into health care, offering powerful tools for diagnosis, prognostication, and treatment planning [3,4], thereby augmenting clinical capabilities through the analysis of vast datasets [5]. Despite the potential synergies, effectively integrating AI insights into the established SDM process remains a critical challenge.

A key barrier lies in the distinction between artificial intelligence explainability (XAI) and AI reasoning. While XAI focuses on rendering algorithmic processes transparent, primarily for technical validation [6], it often fails to produce justifications that are clinically meaningful and readily communicable within the patient-HCP dialogue. This technical transparency, though important for trust [6], does not equate to the human-centered, contextual reasoning required for SDM. Consequently, there is a disconnect: AI may be explainable technically but not communicable clinically, and traditional SDM frameworks lack mechanisms to incorporate AI-generated reasoning [7].

This paper introduces artificial intelligence-supported shared decision-making (AI-SDM), a conceptual framework designed to bridge this gap. AI-SDM leverages predictive modeling, evidence synthesis, and generative AI to embed AI reasoning, contextual, human-interpretable justifications, directly into the SDM workflow. The framework facilitates collaborative deliberation among HCPs, patients, and AI systems, ensuring AI insights are transparent, contestable, and tailored to individual patient circumstances. By positioning AI as a reasoning facilitator rather than a decision maker, AI-SDM aims to enhance decision quality and evidence-based practice while preserving patient autonomy. Herein, we differentiate AI reasoning from explainability, detail the AI-SDM model and its multimodal AI integration, illustrate its potential application in a clinical scenario, and discuss implementation challenges and future directions.

AI Reasoning Versus Explainability

Integrating AI effectively into SDM demands clarity on key distinctions between AI transparency, XAI, and AI reasoning.

XSL•FO
RenderX

AI transparency provides fundamental visibility into the AI's process and data, aiming for openness and enabling auditability. This primarily serves regulators, developers, and users needing to understand "What did the system do?", often via access to code or data flow [6].

Building on this, XAI focuses specifically on illuminating the internal algorithmic logic. Its goal is primarily technical—model validation, debugging, and fairness checks—targeted at developers, data scientists, and auditors' fairness [6,8]. XAI answers "How did the system produce the output?" using techniques like feature importance scores (Shapley Additive Explanation), heatmaps, or local models (Local Interpretable Model-Agnostic Explanations) [8]. While vital for technical trust and validation [9,10], this technical transparency alone is insufficient for clinical application, as a weight vector or probability score does not equate to a usable explanation for SDM.

AI reasoning, central to the proposed AI-SDM framework, shifts the focus decisively to clinical relevance and justification within the specific patient context. Its goal is to facilitate understanding and deliberation among the key audience: HCPs and patients. It addresses the crucial question, "Why is this output relevant for the patient?" by generating clinically meaningful outputs, such as contextual narratives and risk/benefit summaries, rather than raw algorithmic data [8]. Table 1 summarizes these core distinctions.

Table . Distinctions among artificial intelligence (AI) transparency, artificial intelligence explainability (XAI), and AI reasoning.

Feature	AI transparency	XAI	AI reasoning (for AI-SDM)[a]
Focus	Visibility of process/data	Internal algorithmic logic	Clinical relevance and justification
Goal	Openness and auditability	Model validation, debugging, and fairness check	Facilitate understanding and deliberation
Audience	Regulators, developers, and users	Developers, data scientists, and auditors	HCP[b] and patients
Answers	"What did the system do?"	"How did the system produce the output?"	"Why is this output relevant for the patient?"
Example output	Access to code/data flow	Feature importance (SHAP)[c], heatmaps, LIME[d]	Contextual narrative and risk/benefit summary

[a]AI-SDM: artificial intelligence–supported shared decision-making.

[b]HCP: health care professional.

[c]SHAP: Shapley Additive Explanations.

[d]LIME: Local Interpretable Model-Agnostic Explanations.

The capacity for AI reasoning has evolved significantly. Historically, clinical decision-making relied on human cognition, later supplemented by early rule-based or probabilistic clinical decision support systems offering limited reasoning capabilities [4,11]. The integration of machine learning and, more recently, advanced large language models (LLMs) has transformed AI's potential [12-15]. Modern AI can now perform multistep, domain-specific inference [16,17], moving beyond mere pattern recognition to simulate aspects of human deductive, inductive, abductive, and case-based reasoning [18]. AI systems draw on diverse reasoning approaches—from symbolic logic (transparent but less flexible) and statistical methods (probabilistic and less intuitive causality) to opaque neural networks and hybrid neuro-symbolic or knowledge-infused systems aiming for interpretability and semantic alignment [19-21].

This advanced AI reasoning is crucial for SDM, aligning with principles of evidence-based practice and precision medicine [7,22]. SDM requires more than accurate predictions; it demands justifications grounded in clinical workflows, patient history, and anticipated outcomes, enabling deliberation on values and trade-offs [18,23]. AI reasoning provides this by synthesizing large-scale, heterogeneous data (genomic, clinical, real-world evidence) [24] and articulating not just what is predicted, but why it applies to the individual, considering complex risk-benefit profiles and personal priorities [19,21,24-26]. AI reasoning thus acts as a communicative, human-centered layer built upon, but distinct from XAI's technical foundations [10,23,27]. This distinction reshapes trust: while XAI builds trust via technical validation, AI reasoning fosters interpersonal trust through semantic clarity, contextual relevance, and value alignment within the clinical encounter—prerequisites for meaningful SDM.

The Role of AI Reasoning in SDM

SDM as a Process

SDM is a structured yet flexible process in which HCPs and patients collaboratively determine the best course of action, integrating medical evidence with the patient's values and preferences. Recognizing that many clinical decisions involve multiple valid options, SDM ensures that the chosen path reflects what matters most to an informed patient. The process unfolds in distinct stages [1]. Information exchange serves as the foundation, with HCP presenting viable options, detailing their benefits, risks, and uncertainties. Traditionally, this stage is often supported by static Patient Decision Aids, such as those developed guided by frameworks like the Ottawa Decision Support Framework [28]. The aim is to prepare patients by increasing knowledge and helping clarify values. Deliberation follows, allowing the patient and HCP to explore these options in the context of the patient's goals, concerns, and circumstances. This phase encourages active dialogue, where

XSL•FO
RenderX

patients seek clarification and HCPs ensure comprehension. Decision-making emerges from this discussion, as both parties reach a consensus that aligns clinical expertise with patient priorities. Finally, implementation translates the decision into action, requiring commitment from both patient and HCP. Adherence depends on confidence in the decision, reinforced by clear communication, trust, and continued support through follow-up. While SDM enhances patient engagement and clinical outcomes, its integration into routine practice remains inconsistent. Effective implementation demands a cultural shift in clinical workflows, supported by training, institutional commitment, and tools that facilitate meaningful participation rather than tokenistic involvement.

Challenges in SDM Addressed by AI and Generative AI

Despite the established benefits of SDM, practical implementation faces substantial barriers that AI, particularly generative AI, can effectively address. The contemporary medical environment presents HCPs and patients with increasingly complex information that can impede effective communication. While traditional AI models provide structured risk stratification and evidence-based recommendations, generative AI complements these by transforming clinical data into adaptive, natural language explanations that facilitate interactive engagement.

A significant barrier is varying health literacy, with many adults struggling to comprehend complex medical information. Generative AI addresses this by converting dense medical reasoning into accessible narratives, calibrated to individual literacy levels through techniques like reading-level adaptation, while preserving clinical accuracy. This supports more meaningful engagement across diverse patient populations without sacrificing informational integrity. Furthermore, AI reasoning can synthesize information related to multiple conditions or comorbidities, presenting a holistic view tailored to the patient's overall health status, which is often difficult with standard, single-condition PDAs.

Time constraints consistently limit comprehensive SDM implementation. Generative AI streamlines this process by autonomously producing structured, real-time summaries of clinical options and responding dynamically to patient queries. This capability allows HCPs to allocate consultation time to value-based discussions rather than manual data synthesis, enhancing clinical efficiency without compromising decision quality.

Patient heterogeneity in clinical priorities and outcome preferences necessitates personalized communication. Generative AI enables interactive dialogue that adapts to individual concerns. For example, it can restructure treatment comparisons to emphasize nonsurgical alternatives when patients express concerns about operative interventions or highlight specific risks and benefits relevant to the patient's unique circumstances (eg, comorbidities). This responsive adaptation ensures explanations evolve according to articulated preferences, supporting truly patient-centered communication. To ensure consistency and interoperability, the output generated by AI reasoning systems could be grounded in standardized clinical terminologies, such as Systematized Nomenclature of Medicine Clinical Terms (SNOMED CT). SNOMED CT provides a comprehensive, computer-processable vocabulary for clinical terms used in EHRs globally. Aligning AI-generated explanations with SNOMED CT could help ensure the terminology used is consistent with the patient's record and potentially compatible with existing structured decision support tools or clinical information systems.

AI Reasoning Versus Explainability in SDM

In clinical decision support, AI reasoning aims to deliver tailored rationales specific to a patient's context and values, going beyond technical transparency. Conventional explainability methods, such as feature-importance plots or probability distributions, may reveal how a model arrives at its outputs, yet rarely clarify why a recommendation is meaningful for this patient. By contrast, AI reasoning situates those outputs within clinical logic and patient priorities, generating user-friendly justifications that directly facilitate SDM conversations. In this way, generative AI can transform raw model outputs into narrative explanations relevant to each patient's unique goals, thus enabling a richer, more interactive exchange than code-level transparency can provide.

The value of AI in SDM lies not in technical transparency but in delivering clear, relevant, and actionable explanations that support informed decision-making. Generative AI enhances this process by enabling real-time refinement of reasoning based on HCP modifications and patient queries. This dynamic responsiveness allows the system to restructure explanations according to evolving priorities, for instance, shifting focus when patients express preferences regarding quality versus length of life, or adjusting the complexity based on literacy needs. Human-level AI reasoning, augmented by generative AI's capacity to produce adaptive, context-aware explanations, surpasses abstract explainability in clinical relevance and utility, directly supporting the fundamental objectives of SDM in contemporary health care practice.

The Intersection of AI Reasoning and SDM

Overlapping Elements of AI Reasoning and SDM

For AI to effectively support SDM, its reasoning processes must align with the communicative and deliberative nature of HCP-patient interactions. Both AI reasoning and SDM inherently demand clarity, transparency, justification, and personalization. For instance, when an AI provides clinically aligned logic, it directly supports the information exchange step by framing recommendations in medical terms that HCPs can relay and discuss with patients. Transparent recommendations facilitate the deliberation phase by clearly presenting options alongside their respective pros and cons. Similarly, a clear justification for AI-generated outputs bolsters the decision-making step, providing concrete, evidence-based rationales. Additionally, AI adaptability to individual patient contexts, values, and literacy levels emulates the tailored communication essential for effective SDM. An AI system capable of communicating through clinical reasoning can

XSL•FO
RenderX

seamlessly integrate into the SDM dialogue. In contrast, an AI that provides only raw recommendations without explanations offers limited value in collaborative clinical interactions (Table 2).

Table . Overlap between artificial intelligence (AI) reasoning components and shared decision-making (SDM) process steps.

AI reasoning component	SDM component	Overlap
Clinically aligned logic	Information exchange	AI must explain decisions in terms of medical reasoning HCPs[a] can share with patients.
Transparent recommendations	Deliberation	AI reasoning should present options openly, helping patients and doctors compare choices.
Justification of AI outputs	Decision-making	AI should provide clear rationale ("why") to support the chosen option.
Adaptability to patient context	Tailored communication	AI should adjust its explanations to the individual patient's needs and values.

[a]HCP: health care professional.

What SDM Lacks Without AI Reasoning

When AI reasoning is absent, HCPs and patients are left with raw scores or black-box outputs that fail to address individual preferences and concerns. Moreover, merely disclosing the technical details of a system's predictions does not sufficiently enable patients to evaluate personal trade-offs. Similarly, it does not help them understand how a recommendation aligns with their health objectives. Consequently, lacking coherent, patient-centered logic, these AI suggestions may appear arbitrary, eroding trust and undermining SDM's commitment to collaborative, value-sensitive decision-making. Ultimately, advice that lacks contextual reasoning, which both the HCP and patient can discuss meaningfully, turns into top-down instructions. Thus, this approach limits the opportunity for a shared dialogue.

Bridging AI Reasoning and SDM: Toward AI-SDM

Bridging the gap between AI capabilities and SDM needs requires a shift toward a new paradigm: AI-SDM. This model emphasizes practical integration and technical feasibility in real-world care. AI-generated explanations must be tailored to the clinical context [29,30]. Just as experienced HCPs adjust communication to different scenarios and patient profiles, AI systems should generate context-sensitive justifications. These must reflect clinical reasoning and align with patient values. For example, in chemotherapy decisions, AI reasoning should emphasize expected efficacy based on tumor type, potential side effects, and survival projections—framed according to the patient's values, such as prioritizing quality of life over longevity. In chronic disease management, such as lifestyle interventions, explanations may instead highlight long-term risk reduction and adherence support. Tailoring AI reasoning to clinical context ensures its explanations are both relevant and usable [30].

Integrating AI-SDM into clinical practice requires alignment with existing health IT infrastructure. A feasible workflow might involve the AI-SDM system being triggered within the electronic health record (EHR) during a patient encounter. The system could leverage modern interoperability standards, such as Health Level Seven International Fast Health care Interoperability Resources application programming interfaces, to interface with the EHR [31]. These standards enable secure retrieval of up-to-date patient data, including diagnoses, medications, lab results, and problem lists coded using SNOMED CT [32]. Predictive AI components would then analyze this data to generate context-specific risk assessments, outcome probabilities, or treatment comparisons based on established models and guidelines. Subsequently, a generative AI component would synthesize these complex outputs into patient-friendly language, creating tailored explanations, summaries, and potentially visual aids. These can be presented directly within the EHR interface for the HCP and patient to review and discuss together.

Successful adoption hinges not only on technical integration but also on stakeholder readiness. Key hurdles include ensuring robust IT infrastructure and establishing privacy-compliant data governance protocols. Providing adequate training for HCPs is also key. This helps them effectively use and critically appraise AI outputs within the SDM context. Strong leadership and organizational commitment are essential to address these challenges, supporting integration and promoting AI as a collaborative tool. This tool enhances, rather than replaces, clinical judgment and patient partnership. Such a standards-based foundation is a prerequisite for reliable data retrieval, consistent interpretation, and effective AI-SDM deployment across diverse clinical settings and platforms.

Defining AI-SDM: A New Conceptual Model

Theoretical Foundations of AI-SDM

Dual-process theory of clinical cognition proposes that clinicians alternate between fast, intuitive pattern recognition (system 1) and slower, analytical reasoning (system 2) when diagnosing and selecting treatments [33]. AI-SDM mirrors this architecture by pairing predictive and recommendation models, which emulate System 2's probabilistic deliberation, with a generative reasoning layer that approximates System 1's narrative synthesis. This pairing enables the framework to deliver quantitative risk estimates while simultaneously providing context-sensitive justifications that fuel real-time dialogue. The model is further anchored in the Ottawa Decision Support Framework, which conceptualizes SDM as a sequence of need identification, values clarification, and decision support [34].

XSL•FO
RenderX

By embedding adaptive values-clarification prompts within the generative layer, AI-SDM operationalizes these stages and ensures that explanations evolve in response to patient priorities. Principles of patient-centered communication likewise inform system design: explanations are calibrated to individual literacy, emotional state, and cultural context to preserve relational autonomy and encourage bidirectional questioning [35]. Empirical evidence shows that decision aids incorporating tailored narratives and explicit values clarification improve decisional quality and patient trust, particularly when powered by AI-driven reasoning engines that maintain transparency and contestability [36,37]. Synthesizing these theoretical strands positions AI-SDM not merely as a technological overlay but as a cognitive and communicative scaffold that aligns algorithmic inference with the epistemic norms of evidence-based, patient-centered care.

What Is AI-SDM?

AI-SDM is a comprehensive, multimodel conceptual framework developed to incorporate AI-driven reasoning into clinical decision-making. It explicitly ensures HCP oversight and preserves patient autonomy. Unlike conventional AI-based decision-support tools that often focus solely on algorithmic outputs or technical explainability, AI-SDM introduces a collaborative reasoning approach. It enables real-time interaction and deliberation among HCPs, patients, and AI-generated insights. AI-SDM is built upon a multilayered AI system where different AI models contribute distinct functionalities: predictive AI performs risk stratification and outcome modeling; recommendation AI retrieves evidence-based guidelines and treatment options; natural language processing (NLP) AI extracts relevant data from clinical records; and generative AI functions as the crucial reasoning facilitator, transforming complex, structured AI outputs into interactive, patient-specific explanations. Through this synergistic integration, AI-SDM ensures that AI remains an adaptive and justifiable tool. It allows HCPs and patients to engage in structured deliberation while preserving the core principles of SDM.

AI-SDM builds on advances from sophisticated clinical decision support systems and incorporates Human-Computer Interaction principles for usability. It distinguishes itself fundamentally by its primary goal. That is to generate adaptive, narrative clinical reasoning specifically designed to facilitate the triadic deliberation (HCP-patient-AI) inherent in the SDM process. It shifts the focus from mere prediction or transparency toward context-rich, personalized justifications that clinicians can explore, modify, and communicate in natural language. While Table 1 compared technical forms of AI interpretation, Table 3 expands the comparison to full clinical decision frameworks, contrasting how SDM, XAI, and AI-SDM function at the bedside.

Table . Comparison of traditional shared decision-making (SDM), artificial intelligence explainability (XAI), and artificial intelligence–supported shared decision-making (AI-SDM) framework.

Dimension	Traditional SDM	XAI	AI-SDM framework (proposed)
Purpose	Aligning decisions with patient values	Explain algorithm outputs	Generate contextual and patient-specific reasoning
Output format	Human dialogue and evidence summaries	SHAP[a] values, LIME[b], and saliency maps	Adaptive narrative, visual, and verbal reasoning
Workflow integration	Manual and time-intensive	External to workflow	Embedded within clinical encounter workflow
Personalization	Based on clinician skill/time	Minimal; generalized models	High; tailored to clinical context and patient data
Patient role	Dialogue partner	Passive receiver	Active participant in AI-driven[c] deliberation
Clinician role	Central guide	Interpreter of AI outputs	Deliberation lead, with modifiable AI input
Use of AI	None	Explanatory only	Multimodel: predictive, generative, NLP[d], and recommendation
Transparency	Human-led discussion	Technical interpretability	Justifiable clinical reasoning in natural language
Limitations	Time, consistency, and cognitive load	Low usability in clinical conversations	Dependent on quality of AI design and integration
Example scenario	Stroke decision made via verbal counseling	Feature weights for “recommend thrombectomy”	Narrative of options, risks, and priorities generated in-session

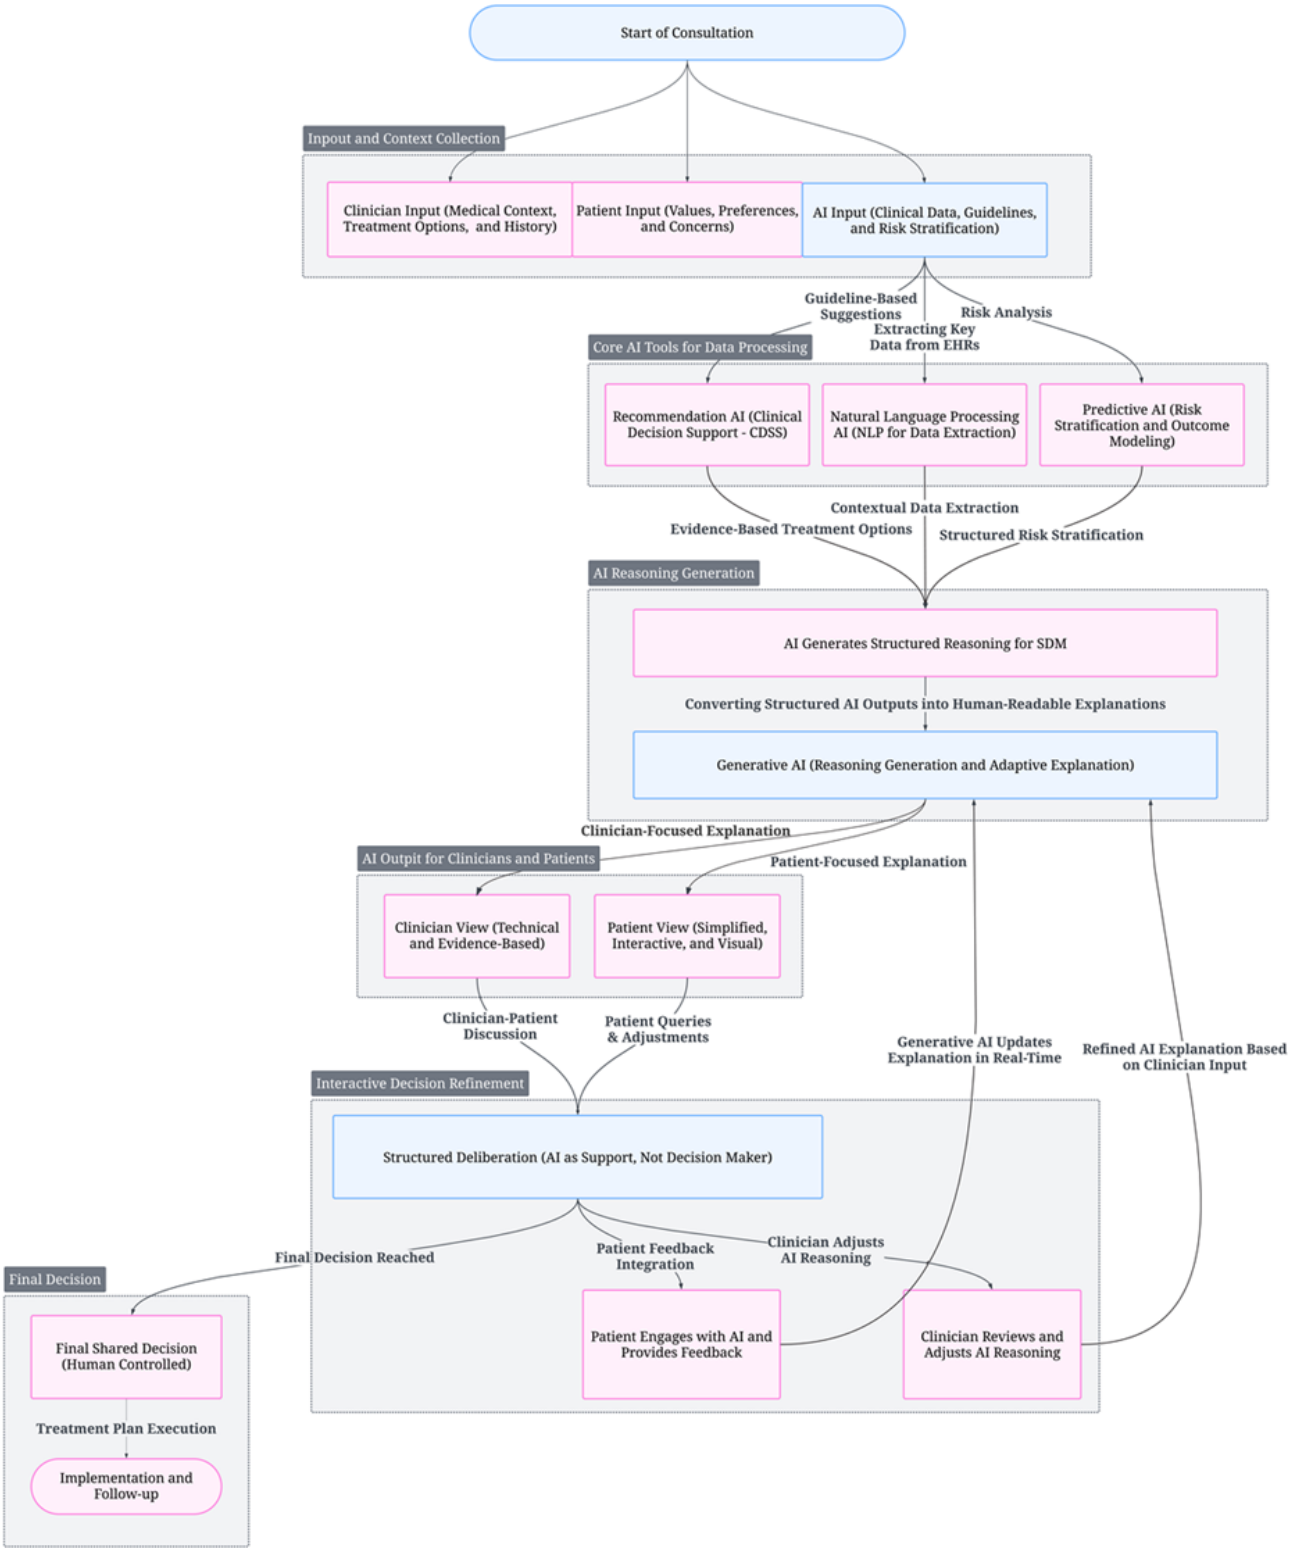
AI-SDM Workflow and Multimodel AI Integration

AI-SDM operates through 4 integrated phases. Each phase leverages specialized AI models while preserving HCP oversight and patient autonomy (Figure 1).

The decision process begins with structured data acquisition. This involves gathering information from 3 essential sources: HCP-provided medical history and diagnostic considerations; patient-articulated values, goals, and risk preferences; and AI-derived evidence from clinical guidelines and research findings. During this phase, 3 specific AI functions are used. Predictive AI performs personalized risk assessment and outcomes analysis. Recommendation AI determines evidence-based treatment paths. Additionally, NLP with LLMs extracts unstructured data from health records and literature.

Following data integration, AI-SDM synthesizes statistical models, clinical best practices, and individual patient characteristics into a structured decision model. This model then generates 2 distinct outputs. First, HCPs receive a comprehensive, evidence-based report detailing risk-adjusted treatment pathways, complete with probability estimates and confidence intervals. Second, patients receive an interactive explanation, which may include visual aids, tailored to their understanding. Generative AI plays a crucial role by transforming these structured outputs into context-specific explanations. These explanations are adaptable to user engagement, thereby surpassing the limitations of static AI summaries.

An important conceptual consideration in this multimodel integration is the potential for conflicting or inconsistent outputs. Such conflicts can arise between the predictive, recommendation, and NLP components. For example, a high predicted risk from the predictive model might conflict with a standard guideline recommendation from the recommendation module. To address these conflicts, the AI-SDM framework incorporates a dedicated reconciliation layer. This layer automatically applies a clinically prioritized weighting mechanism. If a conflict occurs, the system assigns greater weight to validated risk factors while flagging any unresolved discrepancies for HCP review. This process ensures full transparency regarding potential ambiguities within the underlying data. Moreover, it maintains a robust foundation that supports subsequent generative AI reasoning. This ensures both transparency and audibility of any data ambiguities.



A central innovation in the AI-SDM workflow involves converting structured algorithmic output into adaptive, human-centered reasoning. Instead of static recommendations, generative AI produces dynamic, context-sensitive explanations that evolve based on HCP and patient interaction. These explanations are explicitly grounded in the underlying evidence and are safeguarded against potential biases or hallucinations (details of this implementation are beyond the scope of this paper). The AI component is designed for adaptability in both content and timing. It can, for instance, provide concise, rapid summaries for acute scenarios or more detailed rationales for planned consultations. The AI delivers reasoning, rather than merely outcomes, through dual channels tailored specifically to HCP and patient needs. This transforms the AI from a data synthesizer into a deliberation partner, supporting more justifiable clinical decisions.

The AI-SDM model facilitates real-time modification of AI-generated reasoning through continuous HCP evaluation and patient engagement. HCPs can adjust recommendations based on their expertise and contextual factors that extend beyond algorithmic reach. Simultaneously, patients can interrogate specific risks and refine their preferences. In response to these inputs, generative AI dynamically updates explanations. This iterative adaptation process ensures continuous alignment with both clinical judgment and evolving patient priorities.

The culmination of this process is a human-controlled, AI-assisted decision that aligns clinical evidence with patient values. AI-enhanced documentation captures the deliberative process, preserving transparency and accountability in medical records. The system can then generate personalized educational materials to support treatment adherence and follow-up strategies, ensuring continuity of care beyond the initial decision point.

RenderX

Figure 1. AI-supported SDM conceptual model: a structured, multiphase workflow for integrating AI-generated reasoning into SDM. The model begins with input collection from health care professionals (HCPs; medical context), patients (values, preferences), and AI-derived sources (clinical data and guidelines). Core AI functions, predictive modeling, clinical recommendation, and NLP support contextual risk stratification and evidence synthesis. Generative AI then produces adaptive, human-centered explanations tailored separately for HCPs and patients. The system supports real-time refinement of reasoning through HCP adjustments and patient queries, culminating in a human-controlled shared decision and follow-up planning. Color key: blue boxes within the diagram indicate processes or stages that generate multiple distinct outputs or lead to multiple subsequent steps in the workflow; pink boxes represent processes or outputs that are directly driven or generated by AI components. AI: artificial intelligence; CDSS: clinical decision support system; EHR: electronic health record; NLP: natural language processing; SDM: shared decision-making.

Hypothetical Application: AI-SDM in Stroke Management

Overview

The decision to perform mechanical thrombectomy or pursue medical therapy in elderly patients with acute ischemic stroke presents a complex, high-risk clinical scenario requiring rapid yet nuanced deliberation. While thrombectomy significantly improves functional outcomes in patients with large-vessel occlusion, older adults face unique challenges such as increased procedural risks, pre-existing comorbidities, and varied rehabilitation potential [38]. AI-SDM enhances this decision-making process by integrating predictive modeling, evidence-based recommendations, NLP for context extraction, and generative AI to facilitate structured, adaptive reasoning.

Scenario

A patient, aged 82 years, presents with an acute ischemic stroke due to an occlusion of the middle cerebral artery. Neuroimaging confirms a substantial penumbral salvageable region with a small infarct core, indicating potential eligibility for thrombectomy based on current criteria [39]. However, the patient has a history of hypertension, mild cognitive impairment, and prior minor strokes, all of which influence the potential for meaningful neurological recovery and postprocedure rehabilitation. The AI-SDM workflow guides the decision-making process by structuring the evaluation into distinct phases, ensuring that clinicians and patients engage in a transparent and data-driven discussion.

Phase 1: Input and Context Collection

This phase initiates the process by consolidating patient, clinician, and AI-derived inputs. The clinician provides an assessment of the patient's neurological status, prestroke function, and imaging results, while the patient and family articulate treatment priorities (eg, maximizing independence) and risk tolerance. AI synthesizes these inputs through distinct subcomponents: predictive AI generates probability-adjusted functional outcome estimates (eg, modified Rankin Scale scores) based on real-world stroke registries and thrombectomy trials [40]; recommendation AI retrieves current stroke management guidelines. Additionally, NLP integrated with LLM extracts relevant historical data from the patient's records, such as identifying and categorizing symptoms, diagnoses, and treatment plans, which helps clinicians make informed decisions [41]. This comprehensive dataset serves as the foundation for AI-generated reasoning.

Phase 2: AI Reasoning Generation

Here, AI-SDM integrates structured insights into a clinical model. It facilitates individualized decision support. The AI synthesizes statistical models predicting outcomes with or without thrombectomy. It incorporates clinical best practices based on guideline recommendations. It also includes patient-specific variables such as age, comorbidities, and imaging findings. These are combined into a structured analysis adapted for clinicians and patient needs. Drawing from studies such as DAWN and DEFUSE-3, the system provides outcome and risk projections [42,43]. It may show based on such studies that thrombectomy increases independence, for example, from 25% to 50%. It may also show a 10% chance of symptomatic intracerebral hemorrhage. The clinician's view presents a quantitative comparison of 90-day functional outcomes. For patients, generative AI transforms these insights into a simplified, interactive format. It presents recovery trajectories and risks using visual aids and clear language.

Phase 3: Interactive Clinician-Patient Deliberation

This phase enables real-time clinician-patient engagement with the AI-generated insights via a dedicated interface supporting both voice and text-based interactions. The patient might query the AI about expected recovery timelines or independence, prompting generative AI to adjust explanations using refined predictive models. The interface simultaneously displays the original and updated outputs side by side, enabling the clinician to review, modify, and discuss these results with the patient. By recalibrating the risk-benefit summary in response to each query, the system keeps every explanation grounded in evidence-based data. This process occurs within a structured deliberation framework where AI is a support, not a decision maker. Because these updates happen in near real time, clinicians and patients remain actively involved in refining the decision until they reach a fully informed consensus. Patient feedback is integrated, and clinicians may review and adjust AI reasoning accordingly. This iterative loop allows both parties to deepen their understanding before reaching a decision.

Phase 4: Shared Decision Implementation and Documentation

The process concludes with the clinician and patient reaching a shared decision informed by the AI-assisted deliberation. In this scenario, the patient, having engaged with the structured reasoning, opts for mechanical thrombectomy after weighing the potential benefits against the articulated risks. AI then facilitates implementation by generating structured documentation of the decision rationale for the medical record, ensuring transparency. The shared decision is fully clinician- and patient-controlled, with AI strictly supporting the process. Generative AI can also assist in drafting personalized postprocedure care recommendations, outlining rehabilitation expectations, and follow-up plans. The system continues to support follow-up planning and adaptation, ensuring the implementation remains aligned with patient needs. Throughout, the AI acts as a facilitator, ensuring the decision is guided by evidence and patient values under clinician oversight. Table 4 summarizes these 4 phases using the acute ischemic stroke scenario.

XSL•FO
RenderX

Table . Summary of artificial intelligence–supported shared decision-making (AI-SDM) phases in the stroke scenario.

AI-SDM phase	Application in acute stroke scenario example
Input and context collection	Patient aged 82 years with MCA[a] occlusion. Imaging shows salvageable penumbra and small infarct core. Clinician assesses neurological status, prestroke function, and imaging. Patient/family expresses independence goals and risk tolerance. Predictive AI[b] generates probability-adjusted functional outcome estimates from stroke registries and thrombectomy trials. Recommendation AI retrieves current stroke management guidelines. NLP[c]+LLM[d] extracts relevant historical data, including symptoms, diagnoses, and treatment plans.
AI reasoning generation	AI integrates predictions, guidelines, and patient variables into structured analysis. Based on DAWN/DEFUSE-3, it estimates outcomes (eg, 25% - 50% independence, 10% hemorrhage risk). Clinician's view presents a quantitative comparison of 90-day outcomes. Generative AI presents simplified, interactive patient explanations using visual aids and clear language.
Interactive decision refinement	Patient queries recovery timelines or independence. Clinician adjusts AI outputs based on rehab and support. Occurs within a structured deliberation framework where AI is a support tool. Generative AI updates reasoning dynamically. Patient feedback is integrated. Clinicians may review and adjust AI reasoning.
Final decision and implementation	Shared decision made after AI-assisted deliberation. Patient selects thrombectomy. AI documents rationale and generates personalized post-procedure recommendations, including rehab expectations and follow-up. System supports ongoing adaptation. The decision is fully clinician- and patient-controlled.

[a]MCA: middle cerebral artery.

[b]AI: artificial intelligence.

[c]NLP: natural language processing.

[d]LLM: large language model.

Through this structured AI-SDM approach, complex stroke treatment decisions can remain data-driven, transparent, and patient-centered, leveraging advanced analytics and adaptive explanations within a collaborative framework.

While the stroke scenario illustrates AI-SDM in an acute, time-sensitive setting, the framework's principles also apply to complex, preference-sensitive decisions in chronic disease management. In advanced chronic kidney disease, particularly among older adults, patients often face substantial burdens and uncertain benefits from dialysis and may remain uninformed about conservative kidney management as a treatment choice [44,45]. Likewise, in cardiology, decisions such as whether to pursue left atrial appendage occlusion instead of long-term anticoagulation for atrial fibrillation, or how to manage advanced heart failure in line with patient goals, frequently require nuanced SDM discussions [46]. AI-SDM can help address these challenges by integrating longitudinal data, evidence-based predictions, and patient-reported outcomes, thus facilitating more individualized deliberation around what matters most to each patient over the course of their illness trajectory.

Ensuring AI-SDM Preserves Patient Autonomy

A fundamental requirement for AI-SDM is that it must safeguard patient autonomy and uphold the ethos of SDM at every step. To this end, the model is designed such that the AI's outputs are always transparent, open to question, and subordinate to human input. Both the HCP and the patient should be empowered to challenge or adjust the AI's suggestions freely. For example, if the AI's analysis seems to favor a particular treatment strongly, the patient can ask for clarification or express discomfort, and the HCP can probe the AI's reasoning for validity—in both cases, the AI must accommodate these challenges by explaining its rationale or recalibrating its advice. This contestability is deliberate: the AI is not a black box oracle handing down decisions, but a tool that invites scrutiny. Transparency is crucial here; the AI-SDM system should clearly communicate why it is highlighting certain options (eg, "Option A is supported by X study for patients with your profile") so that the human participants can critically evaluate the reasoning. By avoiding opaque or one-sided recommendations, the AI prevents any undue influence or bias that could pressure the patient. In practice, this means AI-SDM will present multiple options with evidence rather than a singular "do this" directive, and it will explicitly incorporate the patient's own goals into its analysis. The HCP retains ultimate responsibility to interpret and, if necessary, correct the AI's output before any action. In sum, AI-SDM is constructed as a facilitator, not a decision maker: it expands the information and reasoning available to the patient and HCP, but it never replaces their agency. The patient's values and the HCP's professional judgment remain at the center of every decision, thereby preserving the autonomy and individualized nature of care.

Challenges and Future Directions

The successful integration of AI into SDM requires proactively addressing critical implementation barriers to ensure clinical uptake, effectiveness, and ethical deployment.

HCP Adoption and Trust

Adoption hinges on transparent, interpretable AI systems that avoid "black box" functionality. In AI-SDM, generative AI transforms complex algorithmic outputs into verifiable explanations with clear references to clinical guidelines and explicit confidence levels. Implementation requires structured reasoning pathways that allow HCPs to interrogate AI-derived conclusions and understand their evidentiary basis, particularly when recommendations diverge from conventional practice.

Regulatory Landscape and Liability

Navigating the evolving regulatory frameworks for AI-assisted clinical decision-making is crucial. AI-SDM systems, particularly those providing diagnostic or therapeutic recommendations, would likely be considered software as a medical device and need to align with guidelines from regulatory bodies like the US Food and Drug Administration or equivalent authorities globally. Key considerations include rigorous validation, demonstrating safety and effectiveness, ensuring transparency (allowing HCPs to independently review the basis for recommendations), and implementing robust quality management systems, including postmarket surveillance. While AI-SDM preserves human oversight by positioning AI as decision support rather than the ultimate decision maker, clear governance policies are needed to delineate responsibility among developers, HCPs, and health care institutions, especially concerning liability if AI suggestions deviate from the standard of care.

Ethical Considerations and Equity

AI-SDM must be implemented ethically, safeguarding patient rights and promoting equity. This includes strict adherence to data privacy regulations pertinent to health information, such as the principles outlined in the Health Insurance Portability and Accountability Act in the United States or the General Data Protection Regulation in Europe, as well as relevant national or local regulations (eg, in Saudi Arabia). Systems must be designed to accommodate diverse health literacy levels, cultural contexts, and cognitive abilities, and generative AI interfaces should dynamically adjust explanation complexity based on individual needs while preserving clinical accuracy. Furthermore, proactive measures are essential to address potential algorithmic biases, which could arise from training data used in the predictive or recommendation models. To prevent AI hallucinations and preserve clinical integrity, each generative output is anchored to explicit citations from validated guidelines or peer-reviewed studies. An automated audit protocol continuously monitors real-time outputs for discrepancies, flagging any deviations from established evidence standards so that HCPs can rapidly override or adjust the AI's recommendations. This includes rigorous auditing of the underlying predictive and recommendation models for fairness across demographic groups and designing the generative AI reasoning layer to explicitly surface significant uncertainties or conflicting evidence that might stem from data limitations or potential biases.

Building on these safeguards, future deployments will institute a 4-layer governance loop for continuous bias mitigation. First, training pipelines will use fairness-aware algorithms—such as reweighting and equalized-odds postprocessing—to correct calibration disparities before clinical deployment, an approach recommended by Rajkomar et al [47] for advancing health equity in machine-learning systems. Second, the production environment will stream model outputs into a real-time dashboard that audits performance by age, sex, ethnicity, and socioeconomic status; similar bias-auditing infrastructures have been shown to reveal hidden performance gaps in widely used clinical algorithms [48]. Third, quarterly ethical-compliance reviews will examine data provenance, feature attribution, and workflow impact to maintain regulatory alignment, and finally, all bias metrics and remediation actions will be logged in a version-controlled registry to support external audit and public transparency. Together, these stages create an auditable feedback loop that limits drift, documents remediation, and embeds fairness governance directly into routine system maintenance.

The sociotechnical impact of AI-SDM also depends on how clinicians and patients adopt, negotiate, and contest its recommendations. Rogers' Diffusion of Innovations theory explains variability in uptake by highlighting perceived complexity, relative advantage, and trialability, whereas technological-determinist perspectives warn that overly authoritative AI may erode clinician agency, and social-constructivist analyses emphasize that users actively reshape technology through practice [49]. To preserve balanced doctor-patient dynamics, AI-SDM therefore labels the scope and limitations of every recommendation, requires explicit clinician confirmation before any automated action, and provides a "why-question" interface so both parties can interrogate underlying evidence or override suggestions. Empirical work on person-centered AI indicates that transparent, assistive designs strengthen trust when clinicians retain control, while unmoderated reliance can attenuate empathy and SDM [50]. Embedding these sociological insights into interface rules and governance policies anchors AI-SDM in relational autonomy and guards against power imbalances.

Technical Integration and Workflow

The clinical utility of AI-SDM depends on seamless integration with existing EHR systems and clinical workflows. Implementation requires user-friendly interfaces that generate concise, contextually relevant insights without increasing cognitive burden or documentation requirements for HCPs. However, seamlessly embedding this potentially complex, multistep interaction, particularly the deliberative refinement phase, into time-constrained and varied clinical workflows represents a significant practical and design hurdle. Achieving this without disrupting clinical practice or unduly lengthening consultations will be critical for successful adoption. As discussed earlier (in section "Bridging AI Reasoning and SDM: Toward AI-SDM"), leveraging interoperability standards like Fast Health care Interoperability Resources and terminologies

XSL•FO
RenderX

like SNOMED CT is vital. Ultimately, AI-SDM must demonstrate measurable improvements in decision quality, patient experience, or efficiency to justify the technological investment and workflow adjustments required for widespread adoption.

Addressing these multifaceted challenges necessitates an iterative implementation approach, combining continuous HCP and patient feedback with rigorous validation. Validating the efficacy and safety of the AI-SDM framework itself would require a phased approach, progressing from algorithmic validation of individual AI components and rigorous usability testing of the interface and explanation formats, through simulation studies assessing decision quality, to eventual pilot clinical trials evaluating real-world impacts on patient engagement, decision concordance, and outcomes. Successful deployment will ultimately depend on collaborative governance structures that balance technological innovation with clinical pragmatism, ethical principles, patient safety, and regulatory compliance.

Future Directions

Realizing the potential of AI-SDM necessitates substantial future research and development. Key priorities include the rigorous development and refinement of the generative reasoning component, incorporating robust mechanisms for clinical validity, grounding, and bias mitigation, alongside effective strategies for reconciling outputs from disparate AI models. While this paper introduces AI-SDM as a conceptual framework, future work could explore empirical validation, such as usability studies, workflow simulations, or clinical implementation pilots, to assess its impact on decision quality, patient engagement, and workflow integration. Further research grounded in HCI principles may also inform how the model could integrate seamlessly into clinical environments without increasing HCP burden. Finally, ongoing investigation into dynamic fairness auditing, evolving regulatory pathways for AI-driven SDM tools, and establishing clear governance structures will be crucial for responsible and equitable deployment.

Building on the dual-process and patient-centered theories outlined above, future iterations of AI-SDM will deepen its affective intelligence by coupling multimodal emotion‐recognition pipelines with the existing generative explanation layer. Recent work demonstrates that equipping decision-support systems with emotional capabilities can reduce affective bias and improve user trust when complex trade-offs are discussed [51]. To operationalize this insight, we plan to integrate a multimodal deep learning model that fuses facial microexpressions, vocal prosody, and lexical sentiment—an approach shown to outperform unimodal affect detectors in health care contexts and to strengthen access trust between patients and clinicians [52]. Continuous emotion streams will inform dynamic values-clarification prompts generated by the narrative engine, ensuring that explanations adapt when signs of confusion, anxiety, or decisional conflict emerge. A recent systematic review of emotion-recognition AI identifies transparent feature attribution and dataset diversity as prerequisites for reliable affective computing in clinical environments; these requirements will guide our data-governance and model-validation strategy [52]. Finally, evidence from a randomized trial of an AI-enabled decision aid shows that personalized, empathetic narratives significantly improve decisional quality and shared-decision metrics compared with static educational material. By embedding such adaptive affective feedback into AI-SDM, we not only enhance the emotional-computing module but also further align the framework with the Ottawa Decision Support and patient-centered communication theories that underpin its interdisciplinary foundation.

Conclusions

Integrating AI into clinical practice requires more than predictive accuracy; it demands alignment with patient-centered care principles like SDM. This paper introduces AI-SDM, a conceptual framework designed to bridge this gap. AI-SDM leverages predictive modeling, evidence synthesis, and generative AI to embed AI reasoning, contextual, human-interpretable justifications, directly into the SDM workflow, facilitating collaborative deliberation among HCPs, patients, and AI, ensuring insights are tailored. However, several limitations warrant attention, including the need for pilot studies to test real-world feasibility, clear protocols for reconciling conflicting model outputs, and safeguards against AI hallucinations. Immediate next steps will involve simulation-based validation and user-centered design iterations to refine how AI-SDM integrates with existing clinical workflows. While significant implementation challenges remain, including ethical considerations, regulatory alignment, and workflow integration, AI-SDM offers a promising pathway. By synergizing AI's analytical power with the personalized approach of SDM, this model can potentially enhance decision quality, foster patient autonomy, and advance evidence-based, patient-centered care in the era of intelligent health systems.

Authors' Contributions

The study was conceptualized by MA (lead), with support from NF and HJ. The methodology and visualization were led by MA. MA also took the lead in writing the original draft of the manuscript. The review and editing of the manuscript were carried out by MA (lead), with contributions from NF and HJ. Project administration was also led by MA.

Abstract

Digital health interventions often use machine learning (ML) models to make predictions of repeated adverse health events. For example, models may be used to analyze patient data to identify patterns that can anticipate the likelihood of disease exacerbations, enabling timely interventions and personalized treatment plans. However, many digital health applications require the prediction of highly heterogeneous and nuanced health events. The cross-subject variability of these events makes traditional ML approaches, where a single generalized model is trained to classify a particular condition, unlikely to generalize to patients outside of the training set. A natural solution is to train a separate model for each individual or subgroup, essentially overfitting the model to the unique characteristics of the individual without negatively overfitting in terms of the desired prediction task. Such an approach has traditionally required extensive data labels from each individual, a reality that has rendered personalized ML infeasible for precision health care. The recent popularization of self-supervised learning, however, provides a solution to this issue: by pretraining deep learning models on the vast array of unlabeled data streams arising from patient-generated health data, personalized models can be fine-tuned to predict the health outcome of interest with fewer labels than purely supervised approaches, making personalization of deep learning models much more achievable from a practical perspective. This perspective describes the current state-of-the-art in both self-supervised learning and ML personalization for health care as well as growing efforts to combine these two ideas by conducting self-supervised pretraining on an individual's data. However, there are practical challenges that must be addressed in order to fully realize this potential, such as human-computer interaction innovations to ensure consistent labeling practices within a single participant.

Introduction

In recent years, the intersection of consumer digital health and machine learning (ML) has emerged to enable ML-powered digital therapeutics, which have been developed in areas such as interventions for substance use [1-4]; technologies for managing mental health conditions such as anxiety, stress, and depression [5-8]; and autism therapeutics using Google Glass [9,10]. The models powering these digital therapies typically analyze large streams of an individual patient's data in order to anticipate adverse health events or actionable patient-reported outcomes. However, a significant computational challenge arises when dealing with the prediction of nuanced and subjective health events that are typically self-reported by participants in the form of patient-reported outcomes, such as mental health states like stress and anxiety. For such prediction targets, the cross-subject variability poses an obstacle for traditional ML approaches, as one participant's label of "moderately stressed" might be another participant's "lightly stressed".

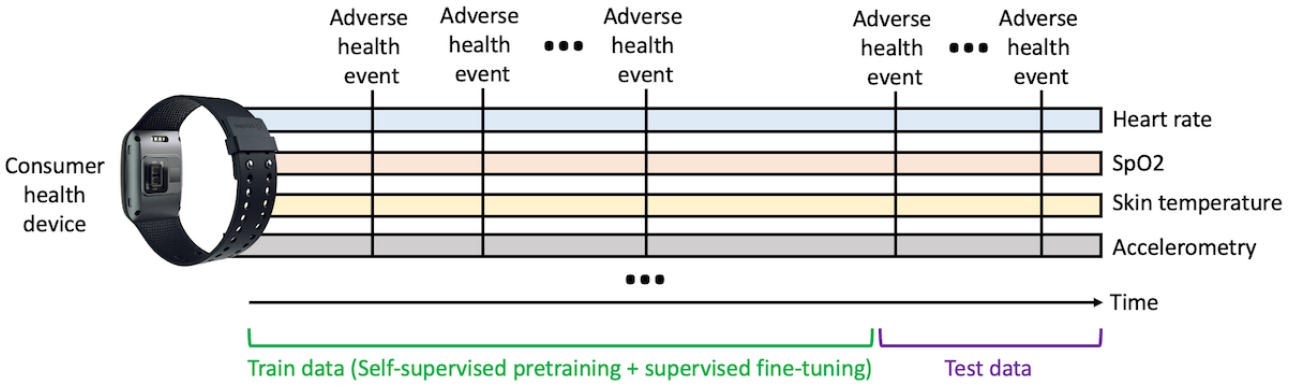
XSL•FO
RenderX

Conventional ML methodologies typically involve training a single generalized model to classify a specific condition [11], such as for diagnostic or screening purposes. However, attempting to apply a universal model often leads to poor generalization to individuals and health systems that were not represented in the training data. An alternative solution involves training separate models for each individual or subgroup, tailoring the model to the unique characteristics of the patient. However, this approach would traditionally demand extensive labeled data from each participant, a requirement that has historically hindered the feasibility of personalized ML applications in precision health care.

The relatively recent advent of self-supervised learning (SSL), made popular in the context of pretraining large language models like ChatGPT (OpenAI), has enabled a transformative solution to address the challenges associated with personalized ML in health care [12-14]. SSL is a machine learning paradigm in which a model is trained to understand and represent the underlying structure of its input data without relying on externally provided labels. By pretraining deep learning models on vast amounts of unlabeled data streams derived from patient-generated health data to understand the baseline temporal dynamics of the data stream without a single label, SSL provides a means to fine-tune personalized models with significantly fewer labeled data points than when using traditionally supervised learning. This relatively new paradigm opens new avenues for making ML personalization in health care more practical, thereby overcoming one of the major hurdles that has historically impeded progress in this area.

This perspective explores the integration of SSL and personalization in scenarios where there are large unlabeled data streams generated per patient, focusing in particular on the potential of personalized SSL to improve the performance of digital therapeutics that provide some sort of digital therapy or digital intervention when a prediction about the participant in question is made by an ML model.

Personalized Models in Health Care



Traditional ML methodologies, which often rely on a one-size-fits-all model, face substantial challenges when confronted with the diverse and nuanced nature of health outcomes. The need for personalized models that cater to individual characteristics has led to a paradigm where a single ML model is trained on data streams coming from a single user and evaluated on future data coming from that same user (Figure 1).

Several examples of personalized ML models for health care have been published in the past decade. Zhang et al [15] developed Patient2Vec, a representation learning approach for longitudinal electronic health record data used to predict clinical events into the future. Luu et al [16] trained a generalized model that was then fine-tuned to predict step count in a personalized manner, achieving 98%-99% accuracy in the personalized case and 96%-99% accuracy with the generalized models. Li et al [17] compared a personalized model for stress prediction against 2 baselines, subject-inclusive and subject-exclusive generalized models, finding that the personalized models significantly outperformed both sets of generalized models. This finding indicates that personalization using only an individual's data outperforms personalization when combining the personal data with data from other users, at least for highly heterogeneous outcomes such as affective computing.

Federated learning, where distributed local models are trained and sent to a central global server for weight aggregation, is naturally connected to the idea of personalized ML. Each "local" model is, by definition, a personalized model. Federated learning has been successfully applied to certain health care settings. For example, Rudovic et al [18] developed a personalized federated learning approach for pain estimation from face images where clients train models using local data, aggregate the model weights in a central server, and then send the global model back to the clients for fine-tuning. This federated learning approach enables the classification of a traditionally difficult classification task due to its inherent subjectivity and heterogeneity between individuals, namely, pain estimation using computer vision.

Traditional applications of personalized ML apply to scenarios where there are vast amounts of data labels per patient. Unfortunately, this situation is often unattainable. In contexts where the data labels pertain to patient-generated health data, it is especially infeasible to collect many labels. To address this practical issue with traditional personalized ML, this perspective explores the idea of performing SSL on an individual's unlabeled data streams to create a personalized foundation model.

Figure 1. In many biomedical domains, there exist massive unlabeled data streams with sparse annotations of the health event of interest. In personalized self-supervised learning, we can pretrain on data coming earlier from the participant and then fine-tune on an ideally small number of patient-provided labels. Evaluation then occurs later temporally. HR: heart rate; SpO2: oxygen saturation.

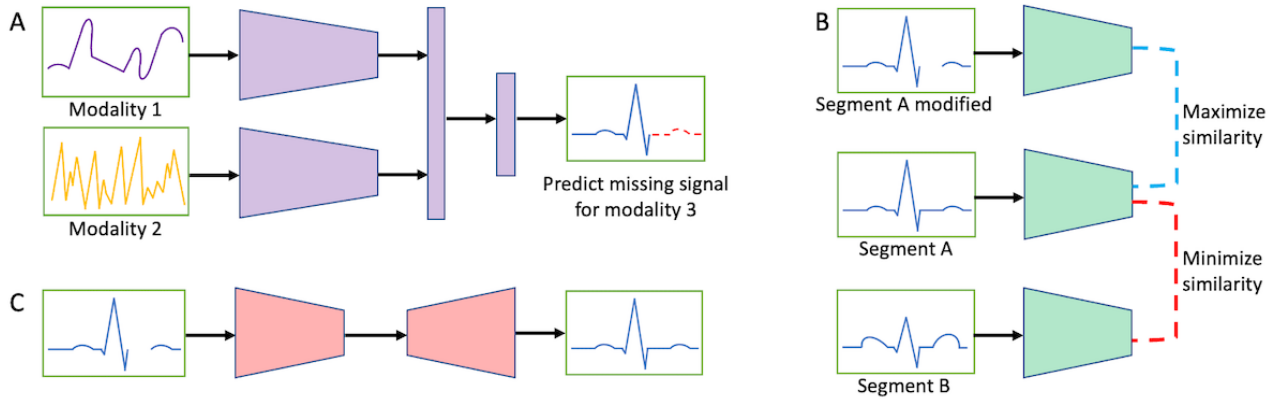
Personalized Foundation Models: Combining Personalization With Self-Supervised Learning

SSL holds great promise to improve the performance of ML models in health care [19], broadly speaking. SSL involves leveraging the inherent information within the data itself to create supervisory signals for training. SSL has been traditionally applied to large datasets containing data from a broad array of patients. In passive data generation contexts, however, such as when patients wear a monitor that continuously collects biosignals, it can be productive to run SSL separately for each patient, as each patient has a large amount of data sampled several times a second. These separate pretraining procedures per patient can result in a "personal foundation model." Because foundation models can learn using much less data than would have been required if no SSL took place, the personal foundation models can enable learning of complex health outcomes where the supervisory signal drastically varies across patients.



SSL for personalization of longitudinal time series data for health care can be achieved through a variety of adaptations of popular SSL pretraining strategies (Figure 2). An inherently multimodal approach is to predict the missing portion of a signal given the values of signals from separate data modalities (Figure 2A) [20], treating the prediction as a multiple-output regression task [21]. Another approach is to perform contrastive learning algorithms such as SimCLR [22] on the signals to maximize representational similarity between augmented versions of the same time period while minimizing similarity between 2 distinct time windows (Figure 2B) [23,24]. More sophisticated generative approaches, such as masked autoencoders [25] and latent masking [26], can also be used to predict masked portions of input signals (Figure 2C), including in a multimodal manner [27].

Personalized modeling combined with SSL has recently enabled the successful prediction of traditionally heterogeneous and subjective health outcomes. For example, Li and Sano [28] used unsupervised representation learning to predict outcomes related to wellbeing, such as mood and stress. Li et al [29] computed personalized brain function networks from functional magnetic resonance imaging using SSL. Spathis et al [30] used SSL to learn user-specific representations of wearable data streams and demonstrated that these personalized representations can be fine-tuned to a variety of downstream tasks.

One important consideration is that increases in model performance might be due to either the personalization aspect or the SSL aspect. SSL without personalization has been repeatedly documented to improve ML model performance [31-34]. Thus, it is important to systematically isolate both conditions in isolation as baselines to determine the true contribution of each component.

Another caveat to personalized SSL is that within-subject consistency in labeling is crucial, and initial studies have found that improvement gains observed using personalized SSL require consistency in data labeling within a user. For example, Islam and Washington [35,36] applied personalized multimodal SSL to the Wearable Stress and Affect Detection dataset [37], observing significant improvements in model performance when compared to a baseline model using identical data without self-supervised pretraining. By contrast, Eom et al [38] evaluated a multimodal dataset collected by Hosseini et al [39] consisting of wearable biosensors measured from nurses working during the COVID-19 outbreak. Eom et al [38] did not observe increased performance on average when using personalized models pretrained on each individual's data compared to baseline models, likely due to particularly noisy and irregular data collection procedures arising from nurses providing data during a stressful event. This highlights the importance of using datasets that have consistent labeling within a participant in order to make personalized SSL actually work.

Figure 2. Examples of self-supervised learning approaches for longitudinal time series data. (A) An inherently multimodal approach is to predict the missing portion of a signal given the values of signals from separate data modalities. (B) Another approach is to perform contrastive learning on the signals by training a network to maximize similarity between a data point and an augmented version of that data point while minimizing similarity between that data point and a separate data point. (C) A third possible strategy is to predict the missing portion of a signal using a masked autoencoder or similar model.

Future Opportunities

Applications of personalized SSL to recurrent health predictions have been successful thus far under clean data scenarios. By harnessing the power of SSL, these applications have demonstrated the ability to glean intricate patterns and dependencies within longitudinal health data. As advancements continue in this burgeoning field, the promise of enhanced precision, early intervention, and improved overall health outcomes appear increasingly attainable for health domains and datasets that are traditionally "challenging" due to their inherent subjectivity, heterogeneity, and complexity.

Despite the initial successes described here, there are likely myriad digital health applications that have yet to be realized because they were not previously feasible prior to the advent of SSL. For example, recent advances in personalized SSL for emotion recognition [40] have the potential to improve the efficiency of the personalization of artificial intelligence–powered digital therapeutics for children with autism [41,42]. While the state-of-the-art of emotion recognition models hovers around 70% accuracy [43], previous emotion personalization efforts without self-supervision were able to achieve strong performances [44]. It is likely that further improvements with fewer labels will be possible with personalized SSL. This approach has yet to be applied to digital therapeutics more broadly, and this gap suggests the possibility of more precise digital therapeutics in the coming years.

Ongoing Challenges

Personalized SSL studies can often be framed as several independent N=1 studies, where each study and corresponding model consists of training, validation, and testing data that all come from a single user. Such studies must be careful about overfitting across 2 dimensions: within subjects and between subjects. While between-subject overfitting, or overfitting to some patients while failing to generalize to other patients, is often discussed, discussions and evaluations of overfitting within a subject appear relatively sparse in the literature. Future work should explore overfitting in this temporal dimension more thoroughly.

Another ill-studied area is the intersection of performance discrepancies and personalization. Personalization of models should, in theory, lead to a reduction in ML performance discrepancies across groups. The capability of model personalization to reduce these discrepancies has yet to be thoroughly studied. However, it is plausible that personalized models could still propagate existing performance gaps across groups if the underlying data remains skewed or if the personalization process disproportionately benefits certain groups [45]. A thorough understanding of this will require rigorous evaluation across a wide range of populations.

Another key challenge of personalized foundation models is that individuals change over time. As an extreme example to illustrate the point, a personalized model that was trained on an individual during their youth may be irrelevant during their 30s. The paradigm of continual (or online) learning, or the continual retraining of models as new data become available, can offer a solution. By allowing models to adapt incrementally, continuous learning can ensure that they evolve alongside the user, capturing shifts in behavior, preferences, and needs over time. Possible approaches can include incremental fine-tuning [46-48], where the model is periodically retrained on newly available data while retaining previously learned weights; experience replay [49,50], where a subset of past data is stored and combined with new data during model updates; and meta-learning [51,52], where the model learns how to quickly adapt to new data by leveraging prior knowledge, making it efficient in learning new tasks from fewer examples.

A final critical challenge is addressing human factors that influence the quality, consistency, and usability of patient-generated data in personalized SSL pipelines. As Slade et al [53,54] highlight, participants often encounter both technical and behavioral barriers during data collection, including device discomfort, app usability issues, and low perceived relevance of labeling tasks. These factors can lead to sporadic participant engagement, mislabeled or missing data, and dropout, ultimately undermining the effectiveness of models that rely on temporal consistency and high-volume personal data streams. Designing for human factors through mechanisms such as clearer feedback loops, improved incentives, and user-centered data collection interfaces will be essential to support robust protocol adherence leading to successful personalization.

Conclusion

The training of personalized foundation models by learning from the vast unlabeled time series data that are often generated from patients can lead to ML applications in health care that expand beyond the traditional realm of diagnostics, such as adaptive and customized digital therapeutics. This area of research is relatively understudied in comparison to other aspects of ML-powered digital health, though it is likely that the advent and increasingly widespread application of SSL will lead to a proliferation of such applications.

Acknowledgments

Abstract

Generative artificial intelligence (GenAI) is increasingly being integrated into health care, offering a wide array of benefits. Currently, GenAI applications are useful in disease risk prediction and preventive care, diagnostics via imaging, artificial intelligence (AI)–assisted devices and point-of-care tools, drug discovery and design, patient and disease monitoring, remote monitoring and wearables, integration of multimodal data and personalized medicine, on-site and remote patient and disease monitoring and device integration, robotic surgery, and health system efficiency and workflow optimization, among other aspects of disease prevention, control, diagnosis, and treatment. Recent breakthroughs have led to the development of reliable and safer GenAI systems capable of handling the complexity of health care data. The potential of GenAI to optimize resource use and enhance productivity underscores its critical role in patient care. However, the use of AI in health is not without critical gaps and challenges, including (but not limited to) AI-related environmental concerns, transparency and explainability, hallucinations, inclusiveness and inconsistencies, cost and clinical workflow integration, and safety and security of data (ETHICS). In addition, the governance and regulatory issues surrounding GenAI applications in health care highlight the importance of addressing these aspects for responsible and appropriate GenAI integration. Building on AI's promising start necessitates striking a balance between technical advancements and ethical, equity, and environmental concerns. Here, we highlight several ways in which the transformative power of GenAI is revolutionizing public health practice and patient care, acknowledge gaps and challenges, and indicate future directions for AI adoption and deployment.

Introduction

Artificial intelligence (AI), also referred to as augmented intelligence, currently plays multiple critical roles in public health and medical practice, the rapid implementation and profound impact of which were unforeseen just a few years ago [1-5]. The emergence of generative AI (GenAI) through the release of a popular large language model in late 2022 made AI readily accessible to the general population and brought transformational shifts in several sectors, including health care [6,7]. GenAI has changed how people interact with each other—how they communicate, exercise, work, do business, relate, and lead. As part of this societal seismic shift, GenAI is revolutionizing global health care systems.

Digital technology is fast becoming an integral part of public health and medical practices, providing validated tools for detecting, screening, diagnosing, caring for patients, and monitoring health-related parameters. GenAI has measurably improved patient care and enabled individuals to self-identify issues, thereby leading to better management of their health and well-being [8]. According to a 2025 survey of senior health care leaders, 95% of respondents believed that GenAI will transform the industry, with 85% of health care providers and 83% of "payer leaders" stating that it will "reshape clinical decision-making within three to five years" [9]. In total, 54% of all respondents reported that they were already seeing a meaningful return on investment in their organization after the first year of GenAI adoption.

The introduction of GenAI into public health and medical ecosystems offers enormous opportunities for training, research, patient care, and resource management [10]. Nevertheless, the potential benefits of AI are accompanied by profound ethical considerations and substantial implementation challenges. In this viewpoint, we contend that the effective adoption of AI within health care contexts is contingent upon systematically addressing these concerns. We further delineate recommendations intended to inform stakeholders seeking to foster the responsible development and deployment of innovative AI systems.

Current Trends in Health Care

GenAI is currently used as a powerful tool to provide diverse services to health care and public health providers. This includes the delivery of personalized services to patients and accurate information to health care leaders, enabling them to improve the quality of services, efficiency, and effectiveness of care and to combat the increasingly widespread online dissemination of health misinformation and disinformation (Table 1).

XSL•FO
RenderX

Table 1. Common applications of artificial intelligence (AI) in public health and clinical medicine.

Application area	Role of AI	Current or expected benefits
Disease risk prediction and preventive care [11-13]	Predicts future susceptibility to many diseases using health records, lifestyle factors, and other data sources (eg, Delphi-2M and BlueDot).	Helps public health professionals plan. Has the potential to inform early interventions and long-term personalized risk estimates.
Diagnostics via imaging [14-16]	Supports automated detection of anomalies in medical imaging (x-ray, CT[a], and MRI[b]) for tuberculosis, cancer, and other diagnoses.	Supports faster triage to reduce radiologist workload and ensures earlier detection with fewer missed cases.
AI-assisted devices and point-of-care tools [17,18]	Enables faster diagnosis by providing diagnostic insights in real time for cardiomyopathies and other abnormalities.	Supports faster diagnosis with potential use in nonspecialist settings, freeing specialists' time and reducing delays.
Drug discovery and design [19-21]	Helps in identifying or designing new drug molecules, predicting toxicity, optimizing clinical trials, and repurposing existing drugs, thereby accelerating the drug development process.	Reduces time and cost of drug development compared to the traditional drug discovery process, potentially compressing decades into months and saving billions of dollars.
Remote monitoring [22,23]	Helps with continuous collection and analysis of physiological and behavioral data for chronic disease management and early detection of signs and symptoms (eg, wearables for PGHD[c]).	Supports early detection of complications, reduces hospitalizations, promotes better disease management, and provides more proactive care.
Integrating multimodal data and personalized medicine [15,23]	Combines genomics, imaging, and EHRs[d] to tailor treatments to patients' specific needs.	Allows more precise treatments with the potential to reduce adverse reactions and achieve better patient outcomes.
Patient and disease monitoring [24]	Provides tools and devices that help track disease progression to detect early disease symptoms.	Supports care in nonclinical settings to improve patients' quality of life through early detection and diagnosis.
Robotic surgery [23,25]	Uses GenAI[e]-based algorithms to improve precision and control during surgical procedures.	Improves the effectiveness and efficiency of surgical procedures by enhancing precision, reducing surgeon fatigue, and improving safety.
Health system efficiency and workflow optimization [15,23,26]	Automates administrative tasks, prioritization, and resource allocation.	Reduces delays in administrative tasks by improving allocation of resources, leading to cost savings and fewer preventable complications.

Current Gaps in GenAI in Health Care and Mitigation Strategies

AI is expected to improve health care outcomes by facilitating early diagnosis, reducing the medical administrative burden, aiding drug development, personalizing medical and oncological management, and monitoring health care parameters on an individual basis, thereby allowing clinicians to spend more time with their patients [27]. Although the integration of AI into health care has the potential to transform the industry, it also raises ethical, regulatory, and safety concerns [28]. AI can rapidly analyze large and complex datasets; extract tailored recommendations; support decision-making; and improve the efficiency of many tasks that involve processing data, text, or images [29]. As the operability of GenAI in public health and medicine advances, significant gaps remain. AI systems risk perpetuating or amplifying existing health disparities when trained on current available data, which are largely nonrepresentative and noninclusive in nature [30,31]. AI tools and resources also lack explainability and transparency, which undermines clinician trust and introduces legal and ethical issues in safety-critical care [32,33]. Data silos, poor data quality, and limited interoperability remain major technical and organizational barriers to AI integration and use across the health care sector [34]. Regulatory, governance, and evaluation frameworks for safe clinical deployment are often incomplete or inconsistent across jurisdictions. Furthermore, models can degrade in new settings (dataset shift), and routine monitoring and maintenance of deployed models are frequently inadequate [35-38]. Other challenges include environmental concerns, hallucinations, inconsistent outputs, and various forms of cultural insensitivities across models in health. Table 2 summarizes some of the current gaps in AI adoption in health care.

XSL•FO
RenderX

Table 2. Common gaps in artificial intelligence (AI) adoption in health care and possible mitigation strategies.

Gap in AI technologies	Clinical and public health implications	Mitigation strategies
Bias and fairness [30,31]	• Unequal performance across race, sex, and socioeconomic groups may lead to harm and widened disparities. • For example, pulse oximeters and some AI tools perform worse for individuals with darker skin tones, and biased AI models can reduce clinician accuracy.	• Use only diverse, inclusive, and representative datasets. • Apply fairness-aware ML[a] techniques (eg, reweighting and adversarial debiasing). • Ensure routine equity audits during deployment.
Explainability and transparency [32,39]	• "Black box" models are difficult to interpret, making legal and ethical accountability unclear. • The lack of explainability and transparency has been linked to adoption failure.	• Develop interpretable models or integrate XAI[b] methods. • Implement regulatory requirements that make explainability in safety-critical systems a requirement. • Co-design model explanations with clinicians and patients.
Data access, quality, and interoperability [34]	• Poor data quality, fragmented EHRs[c], and governance issues reduce model utility and transferability. • To date, many institutions are unwilling or unable to share data, while legacy systems and nonstandard formats impede seamless integration.	• Implement common data standards across systems. • Establish secure health data–sharing frameworks protected from cyberattacks and misuse. • Improve data curation pipelines and maintain audit trails.
Generalizability and reproducibility [36,40]	• Models validated on narrow cohorts fail in new hospitals or populations, producing unsafe predictions (overfitting). • When models move across sites, performance drops and reproducibility issues arise even in published models.	• Ensure multisite validation across demographics. • Establish open-source benchmarks and reproducible pipelines. • Implement stress testing for the dataset shift.
Regulation, governance, and evaluation standards [35,37]	• Inadequate regulatory frameworks delay safe adoption or allow the use of poorly validated tools in practice, as there are no consistent premarket or postmarket standards.	• Update and operationalize AI-specific regulatory pathways. • Require premarket validation and postmarket monitoring. • Establish independent ethics boards to ensure objective oversight.
Continuous monitoring and model predictive maintenance [36,38]	• As some deployed models degrade over time (drift) and clinical workflows change, continuous monitoring is necessary to detect safety issues early.	• Establish continuous monitoring pipelines for model drift. • Implement active learning and regular model retraining. • Operationalize clear sunset policies for unsafe models.
Evidence-based clinical evaluation [27,28]	• A lack of prospective clinical trials or robust impact evaluations exists for most published models, as most studies were retrospective.	• Fund and conduct prospective clinical trials and RCTs[d]. • Apply implementation science frameworks. • Report findings following approved AI and scientific guidelines.
Data privacy, security, and governance [35,41]	• Consent models for secondary AI data use are unclear, and several large health datasets are at risk of breaches.	• Use privacy-preserving ML techniques. • Implement strong cybersecurity frameworks in hospitals. • Ensure transparent consent and governance systems.
Clinical workflow integration and usability [42]	• Poorly integrated tools disrupt patient care, increase workload, and provide outputs that are not actionable.	• Adopt human-centered design approaches. • Conduct pilot testing in real-world clinical workflows. • Integrate workflow with EHR systems to reduce burden.

XSL•FO
RenderX

Gap in AI technologies	Clinical and public health implications	Mitigation strategies
Workforce skills and trust [42,43]	• Clinicians and the public currently lack adequate AI literacy, amplifying distrust. • Inadequate training and limited AI competency impede responsible and appropriate use.	• Operationalize AI literacy programs for clinicians. • Ensure transparent communication with patients. • Clarify liability and responsibility guidelines.
Equity in public health contexts [29,30]	• Current AI models may underrepresent populations considered marginalized and neglect social determinants of health, leading to misallocation of resources.	• Use diverse, inclusive, and representative datasets. • Proactively include populations considered marginalized in model development and training. • Ensure routine equity audits during deployment.
Conflicts of interest and transparency [27]	• Vendor opacity, commercial incentives, and limited independent validation bias evidence and deployment decisions.	• Ensure commercial interests do not override patient and public safety. • Ensure developers sign a conflict of interest declaration form.
Computational cost and environmental impact, including carbon footprint [44-46]	• Training and operating large AI models consume substantial energy and water resources, contributing to climate change and straining sustainability goals in the health sector.	• Develop better energy-efficient architectures. • Use carbon accounting and offsetting in model classification. • Optimize hardware efficiency across models.
Hallucination with fabricated outputs [47-49]	• AI systems may generate incorrect or entirely false but convincing outputs, posing patient safety risks if used for diagnosis, clinical advice, or health communication.	• Use RAG[e] and grounding in trusted medical databases. • Ensure use of human-in-the-loop verification. • Build uncertainty estimation into outputs.
Inconsistent outputs (stochasticity and reproducibility) [50-52]	• LLMs[f] may produce different answers to the same query depending on prompt wording or repetition, undermining reliability in clinical decision-making.	• Understand the limitations of AI in the patient care spectrum. • Ensure use of human-in-the-loop verification. • Ensure health care service providers such as physicians and nurses take full responsibility for patient safety regardless of the use of AI tools.
Cultural insensitivity and lack of contextual grounding [53]	• AI models trained primarily on Western or English datasets may overlook cultural beliefs, practices, idioms, and health priorities of diverse populations, leading to alienation, mistrust, or unsafe advice.	• Include culturally diverse datasets and annotations. • Partner with local communities to ensure context-aware AI design. • Train multilingual and multicultural AI systems.

[a]ML: machine learning.

[b]XAI: explainable artificial intelligence.

[c]EHR: electronic health record.

[d]RCT: randomized controlled trial.

[e]RAG: retrieval-augmented generation.

[f]LLM: large language model.

To address these gaps, it is essential to be deliberate and proactive in the design, development, and deployment of new AI models by ensuring representative data, appropriate validation, transparency, and prospective clinical evaluation before deployment; implementing continuous monitoring for dataset shifts, retraining policies, and incident reporting after deployment; and encouraging stakeholders to invest in interoperable data infrastructure, clinician training, clear regulation, and system-level equity assessments. This underscores the ethical imperative to integrate ethics into all stages of AI design, development, training, and deployment.

Although AI has tremendous potential in public and clinical health care, there is an urgent need to mitigate these challenges to effectively harness these benefits for more effective and efficient health care delivery systems. Leaders and health care providers must address all or most of the issues identified in Table 2. This is achievable, as there are documented steps for the design, development, and deployment of AI models that are largely free (or relatively free) of these challenges.

Maximizing AI Opportunities in Health Care

To maximize the opportunities that AI provides, health care leaders, public health specialists, and providers must work with biomedical engineers, computer scientists, and AI experts to develop interoperable data solutions, address biases, and ensure equity and fairness. In developing and deploying the next generation of health care AI tools, they must build transparency and ensure the development of explainable GenAI tools that enhance health care providers' trust in AI, thus improving its

XSL•FO
RenderX

use and subsequent better patient-related decision-making. These modifications will promote responsible, appropriate, and ethical practices in health care. For example, GenAI-driven tools such as Woebot (Woebot Health) [54], AI-powered mental health chatbots [55], and wearable electrocardiogram (ECG) apps such as the Apple Watch (Apple Inc) ECG feature [56] demonstrate how AI is already transforming health care by improving accessibility, decision-making, and transparency in patient care and data delivery. AI-powered chatbots and virtual health assistants, such as Babylon Health (eMed), provide patients with 24/7 access to health care advice, symptom checks, and appointment scheduling [57]. Imagine what could happen if these tools were trained with inclusive datasets that greatly minimize or eliminate bias, improve generalizability, and are open to providers. Such unbiased tools will accelerate adoption and use, saving providers' time, enabling opportunity for better provider-patient interactions, and enhancing the accuracy of diagnosis and treatment, as well as the safety of hospital procedures.

Creating platforms that ensure high-quality, interoperable data can significantly enhance GenAI applications in health care. This will facilitate seamless data integration across different systems. Currently, GenAI-powered wearable health monitoring devices such as Apple Watch (Apple Inc), Fitbit (Google Inc), and Garmin (Google Inc) include pedometers, blood oxygen sensors, pulse oximeters, and electrodermal activity sensors to monitor skin temperature and stress. These personally generated health data, when analyzed, can be used to predict potential health risks and encourage preventive measures. Most of these devices are stand-alone products. However, system interoperability can bridge the gap between real-time monitoring and clinical decision-making. For instance, the ECG feature of a smartwatch that leverages GenAI to detect heart health anomalies can enable remote patient monitoring and provide explainable alerts to both lay users and health care professionals. Such alerts will help the wearer and the physician make timely, informed decisions [58].

Ensuring tools are trained using representative datasets is essential to ensure that GenAI model outputs appropriately reflect the entire population. Standardizing data collection protocols can enable consistency to be achieved across sources. Developing tools that detect and measure levels of bias in AI models and incorporating fairness constraints during the development process may help reduce biases [59].

Focusing on developing explainable GenAI models can help build trust among clinicians and patients because such models enable users to trust and understand how decisions are made, thereby fostering transparency and accountability. Integrating GenAI into clinical decision support systems that assist health care providers at the point of care can improve decision-making and patient outcomes. For example, the AI-driven Woebot mental health chatbot provides users with clear explanations for its therapeutic recommendations [54]. When suggesting cognitive behavioral therapy exercises, it explains their evidence-based benefits, such as reducing anxiety by addressing unhelpful thought patterns [37]. Similarly, the Apple Watch's ECG feature builds user confidence and empowers individuals by providing instantaneous, actionable information, while stored data offer clinicians detailed insights into detected irregularities [59]. These applications demonstrate the value of transparent AI in improving user engagement and trust.

Making AI tools more user centered and integrated into health system workflows is essential to ensure a good user experience. Such tools will also be able to provide real-time monitoring and early warnings for health challenges, such as cardiac issues, thereby facilitating early professional evaluation and reducing morbidity and mortality [58,60]. In addition, updating and streamlining ethical guidelines and regulatory frameworks for AI in health care that prioritize data privacy, inclusivity, and transparency will facilitate appropriate, responsible, and equitable use of AI technology [56,57]. To achieve this, health leaders and biomedical engineers must collaborate with policymakers and other dominant stakeholders [61].

Moreover, early exposure of future health care professionals to GenAI at secondary and tertiary levels of education is critical to producing an AI-astute health workforce for primary, secondary, and tertiary care. Therefore, it is imperative to incorporate hands-on training and practical application sessions into both graduate and undergraduate curricula so that future health care professionals can work seamlessly with GenAI tools and datasets. Simulation exercises, case studies, and project-based learning are pedagogical approaches that can be tailored to enhance practical understanding. To improve engagement and effectiveness, learning pathways should be customizable to meet the needs of individual users, thereby promoting AI literacy among the emerging health care workforce. Some companies currently offer excellent case studies for health care students to learn about GenAI applications. Similarly, several colleges and institutions have created new courses on AI at the graduate level. However, more courses should be created at the undergraduate level, especially in historically minority-serving institutions. Each program should consider the diverse backgrounds, expertise levels, and specialties of participants [61,62].

Fostering interdisciplinary collaboration through joint programs and projects will enhance stakeholders' awareness of the potential and limitations of GenAI technologies and thus identify their most appropriate use. Interdisciplinary knowledge sharing between health care professionals, data scientists, biomedical engineers, policymakers, and computer scientists can accelerate the discovery of more innovative, appropriate, user-friendly, inclusive, and applicable solutions [61,62].

Bridging Equity Gaps in AI Adoption and Use

The future of GenAI in health care is poised to be transformative, fundamentally altering the landscape of public health and clinical practice. Similar to wielding a hammer, GenAI in the hands of trained and experienced health care providers will augment, rather than replace, skilled and experienced operators. It is a force for positive change when appropriately developed, modeled, and used properly. Making GenAI available to all individuals, irrespective of ethnicity, race, gender, or socioeconomic status, will reduce inequity and

XSL•FO
RenderX

improve health outcomes. However, the current adoption and use of GenAI is not equitable across the health care industry, as large systems in high-income countries have unhindered access, while small organizations struggle to afford the tools they need most. Similarly, AI penetration in low- and middle-income countries remains limited due to inadequate infrastructure and insufficient financial resources. First-generation scholars and students from populations considered historically marginalized are also behind in AI adoption and use.

Health care systems adopting GenAI must prioritize people over profits to prevent inequity and its associated adverse outcomes, as the integration of advanced machine learning algorithms and big data analytics is not merely a trend but a paradigm shift that promises to enhance public health, improve clinical decision-making and patient experiences, and address systemic inefficiencies in resource allocation. To leverage these technological advances equitably and effectively, several key issues must be considered.

First, limited engagement by key stakeholders on how best to embed GenAI into health care provision poses a significant risk [63]. This challenge is exacerbated when medical, nursing, and allied professions are excluded from conversations that potentially impact health care services and professional practices. Establishing formal GenAI leadership roles will help ensure ethical and equitable use [51]. Health care leaders must drive the ethical and equitable integration of GenAI into health care services and ensure proper oversight to promote holistic, patient-centered, and professional care [64]. They can achieve this through a deliberate proactive leadership approach that thinks, plans, provides, processes, and communicates ahead to ensure seamless and timely transition of health care systems from a pre-GenAI era to one that is fully GenAI integrated [65,66].

Second, as the success of GenAI in health care depends on acceptance by both patients and providers, transparent communication about the benefits and limitations of GenAI, as well as demonstrations of its value, is essential for building trust. Our recent studies have revealed that very few employees are aware of the process, cost, and implications of GenAI adoption in their organizations [67,68]. This is worse for minority populations and underserved communities. Thus, proper and timely communication systems must be developed, adopted, and operationalized in accordance with the deliberate proactive leadership approach [66].

Third, to translate AI research into clinical practice across all populations, there is an urgent need for system-wide AI education, including a professional development component tailored to local contexts, with emphasis on underserved communities. Limited access to resources, including skilled and equipped AI trainers and the required infrastructure, hinders such on-the-job training. Therefore, there is a need to develop and popularize both accredited instructor-led and self-directed learning courses that provide introductory content on AI [69], as its opacity limits widespread adoption. Furthermore, as the complexities of GenAI and its implementation can negatively impact its use in health care practice [70], identifying discrepancies in priorities between health care managers and GenAI developers will lead to better collaboration. For instance, the development of GenAI applications with inclusive data that focus on health care leadership and management priorities should be a unified goal for all stakeholders [71]. These innovations must incorporate both the in-out (from providers to industry) and out-in (from industry to providers) approaches, placing providers and industry at the center of innovation, development, and deployment of new GenAI tools [61].

Finally, as much of the early adoption of GenAI has been concentrated in better-resourced provider settings, such as hospitals, academic medical centers, and large health system networks, deliberate steps must be taken to overcome barriers such as data infrastructure, technical capacity, investment, governance, and risk management, which tend to disproportionately impact resource-limited settings [72-74]. In the United States, for example, this gap is especially apparent in resource-limited settings, such as essential community providers, including federally qualified health centers, tribal or urban Indian clinics, and community or free clinics, which serve underserved populations in medically disadvantaged areas. Essential community providers face well-established challenges, including limited resources and health information technologies, and they exhibit lower rates of deployment of advanced digital tools compared to private systems [75]. The adoption of GenAI by community clinics and hospital departments should be supported financially and otherwise by governments and relevant foundations. Some countries, such as Vietnam, are ahead of the curve in this regard, illustrating how GenAI could enhance service efficiency, improve outcomes of interventions, and raise the quality of care provided by the health care industry [76,77]. Efforts to expand the availability of GenAI applications to underserved health care units across regions should be intensified, and the global health care community should also collaborate to ensure that further GenAI developments are tailored to address identified needs.

Conclusions

GenAI technologies have the potential to transform health care by improving public health practices, enhancing diagnostic accuracy, personalizing treatments, automating services, and increasing administrative efficiency. Future developments in GenAI should be guided by the need to address health care's most pressing AI-related challenges, especially environmental concerns, transparency and explainability, hallucinations, inclusiveness and inconsistencies, cost and clinical workflow integration, and safety and security of data (ETHICS). Similarly, AI regulation, governance, and clinical validation processes should be streamlined and strengthened to ensure the responsible and effective integration of AI in health care settings. Priority should also be given to establishing appropriate leadership and management structures and developing interoperability of data systems. By ensuring fairness, ethical practices, and appropriate educational and infrastructural initiatives, the global health community can strengthen the positive impact of GenAI, driving more efficient health care delivery systems and leading to improved patient outcomes.

Abstract

Background: Cisplatin resistance remains a significant obstacle in cancer therapy, frequently driven by translesion DNA synthesis mechanisms that use specialized polymerases such as human DNA polymerase η (hpol η). Although small-molecule inhibitors such as PNR-7-02 have demonstrated potential in disrupting hpol η activity, current compounds often lack sufficient potency and specificity to effectively combat chemoresistance. The vastness of chemical space further limits traditional drug discovery approaches, underscoring the need for advanced computational strategies such as machine learning (ML)–enhanced quantitative structure-activity relationship (QSAR) modeling.

Objective: This study aimed to develop and validate ML-augmented QSAR models to accurately predict hpol η inhibition by indole thio-barbituric acid analogs, with the goal of accelerating the discovery of potent and selective inhibitors that could overcome cisplatin resistance.

Methods: A curated library of 85 indole thio-barbituric acid analogs with validated hpol η inhibition data was used, excluding outliers to ensure data integrity. Molecular descriptors spanning 1D to 4D were computed in MAESTRO, resulting in 220 features. In total, 17 ML algorithms, including random forest, extreme gradient boosting (XGBoost), and neural networks, were trained using 80% of the data for training and evaluated with 14 performance metrics. Robustness was ensured through hyperparameter optimization and 5-fold cross-validation.

Results: Ensemble methods outperformed other algorithms, with random forest achieving near-perfect predictive performance (training mean square error=0.0002; R^2=0.9999 and testing mean square error=0.0003; R^2=0.9998). Shapley additive explanations analysis revealed that electronic properties, lipophilicity, and topological atomic distances were the most important predictors of hpol η inhibition. Linear models exhibited higher error rates, highlighting the nonlinear relationship between molecular descriptors and inhibitory activity.

Conclusions: Integrating ML with QSAR modeling provides a robust framework for optimizing hpol η inhibition, offering both high predictive accuracy and biochemical interpretability. This approach accelerates the identification of potent selective inhibitors and represents a promising strategy for overcoming cisplatin resistance, thereby advancing precision oncology.

Introduction

Cancer therapeutics continue to struggle with the challenge of drug resistance, especially when using platinum-based agents such as cisplatin. These drugs induce cytotoxicity by creating DNA cross-links that interfere with DNA replication and transcription, ultimately leading to apoptosis [1-6]. However, resistance often develops through enhanced DNA repair mechanisms, particularly translesion DNA synthesis (TLS) [7-9]. TLS allows cancer cells to bypass cisplatin-induced DNA damage by using specialized DNA polymerases—most notably human DNA polymerase η (hpol η)—which can accurately replicate damaged DNA. Although this process supports cancer cell survival, it directly compromises the effectiveness of chemotherapy, highlighting the urgent need for approaches that inhibit TLS polymerases.

Targeting hpol η has emerged as a promising approach to counteract resistance [10-13]. Small-molecule inhibitors such as PNR-7-02, as demonstrated by Zafar et al [14], selectively disrupt hpol η's TLS activity by binding to its "little finger" domain, misorienting the DNA template and stalling lesion bypass. This compound exhibits specificity for hpol η (IC =8 μM), sparing replicative polymerases and minimizing off-target effects [14]. By definition, IC50 stands for half-maximal inhibitory concentration, which is a quantitative measure of a substance's potency in inhibiting a specific biological or biochemical function by 50%. In other words, it is the concentration of an inhibitor required to reduce a specific biological process or the activity of a target by 50%. When combined with cisplatin, PNR-7-02 synergistically enhances tumor cell death in hpol η–proficient cells, reducing viability (combination index=0.4 - 0.6) and amplifying DNA damage markers such as γH2AX [14]. Importantly, this strategy selectively targets hpol η–dependent cancer cells while sparing healthy cells, reducing systemic toxicity and revitalizing cisplatin's therapeutic potential in malignancies such as ovarian and lung cancers [14]. Despite this initial progress, no existing inhibitor achieves complete DNA polymerase η inhibition, underscoring the critical need for novel small molecules with improved potency and specificity [15-21].

The search for such inhibitors is complicated by challenges related to target specificity, resistance evolution, and off-target effects. Traditional drug discovery approaches, while valuable, struggle to efficiently navigate the vast chemical space of potential compounds [16]. This limitation has spurred interest in computational strategies, particularly machine learning (ML)–enhanced quantitative structure-activity relationship (QSAR) modeling, which predicts biological activity based on molecular descriptors that quantitatively represent physicochemical, structural, and electronic properties [15-21]. ML has provided the computational power and strength needed to tackle critical questions across diverse fields [22-24], ranging from drug discovery to precision medicine. Conventional QSAR methods, though instrumental in early drug discovery, often lack accuracy and scalability when applied to complex datasets [25-27].

In this study, we present a systematic framework to optimize the identification of DNA polymerase inhibitors through artificial intelligence (AI)–driven QSAR modeling. By leveraging a curated database of 220 molecular descriptors with known activity against DNA polymerases, we trained 17 distinct ML models (eg, random forests, gradient boosting machines, support vector machines, and deep neural networks) and evaluated them across 14 performance metrics (refer to Table 1 for a summary of ML algorithms used in this study).

Table . Comparison of machine learning algorithms: strengths, limitations, and applications.

Algorithm	Brief summary
Linear regression	Models a proportional relationship between dependent and independent variables using a linear equation; simple, efficient, and interpretable but assumes linearity, is sensitive to outliers, and struggles with multicollinearity in QSAR[a] [28,29].
Ridge regression	Adds an L2 regularization term to prevent overfitting, handles multicollinearity well, and improves stability but does not perform feature selection [30,31].
Lasso regression	Uses L1 regularization to shrink coefficients to zero, thus performing feature selection and reducing complexity; however, because it arbitrarily selects 1 variable among correlated predictors, it may be misleading for causal inference [32-35].
Isotonic regression	Fits a free-form line ensuring monotonicity; it is robust to outliers but computationally intensive and may not generalize well outside the training range [36,37].
Partial least squares regression	“Identifies fundamental relationships between matrices, effectively handling multicollinearity and reducing dimensionality, though often at the cost of interpretability [38-40].
Support vector regression	Finds a function approximating input-output relationships, effective in high-dimensional spaces, and robust against overfitting but sensitive to kernel choice and computationally intensive [41,42].
ElasticNet	Combines L1 and L2 penalties, balancing the strengths of lasso and ridge regression; suitable for high-dimensional data with multicollinearity but requires tuning of 2 hyperparameters [43-45].
Decision tree	Nonparametric method for classification or regression, easy to interpret, handles categorical and numerical data, and captures nonlinear relationships but prone to overfitting and may not generalize well [46-48].
Random forest	Constructs multiple decision trees to reduce overfitting, handles large datasets, and assesses feature importance but is computationally expensive and less interpretable [49-51].
Gradient boosting	Builds an ensemble of weak learners sequentially for high predictive power and complex modeling but can overfit if not properly tuned [52-54].
Extreme gradient boosting (XGBoost)	Optimized gradient boosting library offers high accuracy, efficient computation, and handling of missing data but is complex to tune and less interpretable [55-58].
AdaBoost	Combines weak classifiers by focusing on misclassified instances for improved performance but is sensitive to noisy data and outliers [59,60].
CatBoost	Uses ordered boosting to efficiently handle categorical features while reducing overfitting with high accuracy but can be slower and less interpretable [61,62].
K-nearest neighbors	A nonparametric method capturing complex relationships without assuming a specific model; computationally intensive for large datasets and sensitive to data scaling [63-66].
Neural network	Mimics the human brain to capture complex nonlinear relationships; highly adaptable but requires large datasets, is computationally intensive, and is prone to overfitting [67-71].
Gaussian process regression	Provides a probabilistic approach with uncertainty estimates while modeling complex functions; computationally intensive for large datasets and difficult to interpret [72-74].

[a]QSAR: quantitative structure-activity relationship.

AI-driven QSAR modeling enables the prediction of inhibitor efficacy and identifies critical molecular features for second-generation optimization. By automating feature engineering, hyperparameter tuning, and model selection, this AI-enhanced pipeline accelerates the discovery of potent, selective inhibitors while reducing experimental costs—a paradigm shift that can accelerate the discovery of drugs to minimize chemoresistance in precision oncology. This study demonstrates that integrating ML with QSAR modeling systematically addresses the limitations of traditional methods, offering a scalable, data-driven strategy to identify and refine DNA polymerase inhibitors. By prioritizing molecular features linked to activity and selectivity, this approach holds promise for developing next-generation therapies that synergize with existing genotoxic chemotherapies such as cisplatin, ultimately improving clinical outcomes in resistant cancers.

Methods

The study used a curated library of 85 indole thio-barbituric acid (ITBA) analogs with experimentally validated inhibition of hpol η activity, expressed as the mean percent reduction in activity [14]. In total, 6 compounds (PNR-7-02, PNR-7-01, PN9-66B, PNR-6-92, PNR-6-89, and PNR-6-97) were excluded due to absence of reported hpol η activity, and 3 outliers (PNR-5-88, PNR-3-50, and PNR-3-64) were identified via scatter plots and IQR analysis and removed to ensure dataset integrity. Chemical structures, initially drafted in ChemDraw (Revvity Signals) [75], were converted to Simplified Molecular Input Line Entry System (SMILES) format and then to SYBYL Mol2 files using MAESTRO (version 12.5; Schrödinger, Inc) [76] for 3D visualization. Ligand preprocessing involved energy minimization to optimize molecular geometries and structural

XSL•FO
RenderX

alignment of conserved ITBA cores, thus standardizing the presentation of side-chain modifications and ensuring consistent descriptor computation [16].

Molecular descriptors, which encompass a wide range of molecular properties, were calculated using MAESTRO software [76]. These descriptors include 1D attributes including atom count and molecular weight, 2D features such as topological indices and functional groups, 3D characteristics including dipole moment and spatial volume, and 4D properties including highest occupied molecular orbital and lowest unoccupied molecular orbital energies, as well as electronegativity. These descriptors provide insights into the electronic behavior of molecules during interactions, facilitating a comprehensive analysis of molecular structure and properties [76]. Such descriptors allowed quantitative comparisons of physicochemical attributes (eg, hydration energy and polarizability) and quantum chemical behavior critical for DNA polymerase interactions [16]. The resulting database integrated 220 descriptors with experimental inhibition data, forming the basis for QSAR modeling (refer to Multimedia Appendix 1 for molecular descriptors computed in MAESTRO software [76]).

Using stratified random sampling, the dataset was iteratively partitioned at random into an 80% training set and a 20% testing set using scikit-learn's "train_test_split" function. This split ensures a robust training dataset for learning and a significant test dataset for accurate performance evaluation, while also maintaining the distribution of activity classes to overcome bias [77]. Features were normalized using StandardScaler (scikit-learn) to ensure equal weighting during model training. A total of 17 ML algorithms were evaluated (Table 1), spanning linear models (linear regression, ridge, lasso, and ElasticNet), tree-based ensembles (decision trees, random forest, gradient boosting, and AdaBoost), kernel methods (support vector regression), instance-based learning (K-nearest neighbors), neural networks (multilayer perceptron), probabilistic approaches (Gaussian process regression), dimensionality reduction (partial least squares regression), nonparametric models (isotonic regression), and advanced gradient-boosting frameworks (XGBoost, light gradient boosting machines [LightGBM], and CatBoost) [78,79]. Hyperparameters were optimized via grid or random search with 5-fold cross-validation, prioritizing minimization of mean square error (MSE) and maximization of coefficient of determination (R^2) and adjusted coefficient of determination (adjusted R^2) metrics.

Model performance was rigorously assessed using 14 metrics: mean squared error (MSE), coefficient of determination (R^2), mean absolute error (MAE), root mean squared error (RMSE), adjusted coefficient of determination (adjusted R^2), mean absolute percentage error (MAPE), predictive squared correlation (Q^2), concordance correlation coefficient (CCC), root mean squared logarithmic error (RMSLE), normalized mean squared error (NMSE), normalized root mean squared error (NRMSE), symmetric mean absolute percentage error (SMAPE), median absolute error (MedAE), and Pearson correlation coefficient (PCC) [80].

MSE quantifies the average squared difference between predictions and observations and is calculated as follows:

$$(1)\ MSE=\frac{1}{n}\sum_{i=1}^{n}(y_i-\hat{y}_i)^2$$

where y_i is the observed value and $\hat{y}_i$ is the predicted value. MSE is critical for identifying models prone to severe inaccuracies.

RMSE provides error magnitude in the same units as the response variable, enhancing interpretability and sensitivity to outliers. It is calculated as follows:

$$(2)\ RMSE=\sqrt{MSE}$$

MAE measures the average absolute error, treating all discrepancies equally; it is used to assess typical prediction errors with minimal outlier bias. It is calculated as follows:

$$(3)\ MAE=\frac{1}{n}\sum_{i=1}^{n}|y_i-\hat{y}_i|$$

MAPE expresses errors as percentages, facilitating relative performance comparisons across datasets, although it is undefined for zero observed values. It is calculated as follows:

$$(4)\ MAPE=\frac{100\%}{n}\sum_{i=1}^{n}\left|\frac{y_i-\hat{y}_i}{y_i}\right|$$

SMAPE addresses MAPE's asymmetry by normalizing errors against the average of observed and predicted values, improving robustness for near-zero values. It is calculated as follows:

$$(5)\ SMAPE=\frac{100\%}{n}\sum_{i=1}^{n}\frac{2|y_i-\hat{y}_i|}{|y_i|+|\hat{y}_i|}$$

MedAE is resistant to outliers and is calculated as follows:

$$(6)\ MedAE=\text{median}(|y_1-\hat{y}_1|,\ldots,|y_n-\hat{y}_n|)$$

R2 represents the proportion of variance explained by the model, with values closer to 1 indicating better fit. It is calculated as follows:

$$(7)\ R2=1-\frac{\sum_{i=1}^{n}(y_i-\hat{y}_i)^2}{\sum_{i=1}^{n}(y_i-\bar{y})^2}$$

where $\bar{y}$ is the mean of observed values and $\hat{y}_i$ represents the predicted or fitted value of the dependent variable (y) for the i-th observation.

Adjusted R^2 adjusts for model complexity, preventing overfitting by penalizing unnecessary predictors. It is calculated as follows:

$$(8)\ \text{Adjusted } R2=1-(1-R2)\times\frac{n-1}{n-k-1}$$

where R^2=R-squared of the model

n=number of observations (data points)

k=number of predictors (independent variables) in the model.

CCC evaluates agreement between predictions and observations, combining precision (correlation) and accuracy (mean shift). It is calculated as follows:

$$(9)\ CCC=\frac{2\rho\sigma_x\sigma_y}{\sigma_x^2+\sigma_y^2+(\mu_x-\mu_y)^2}$$

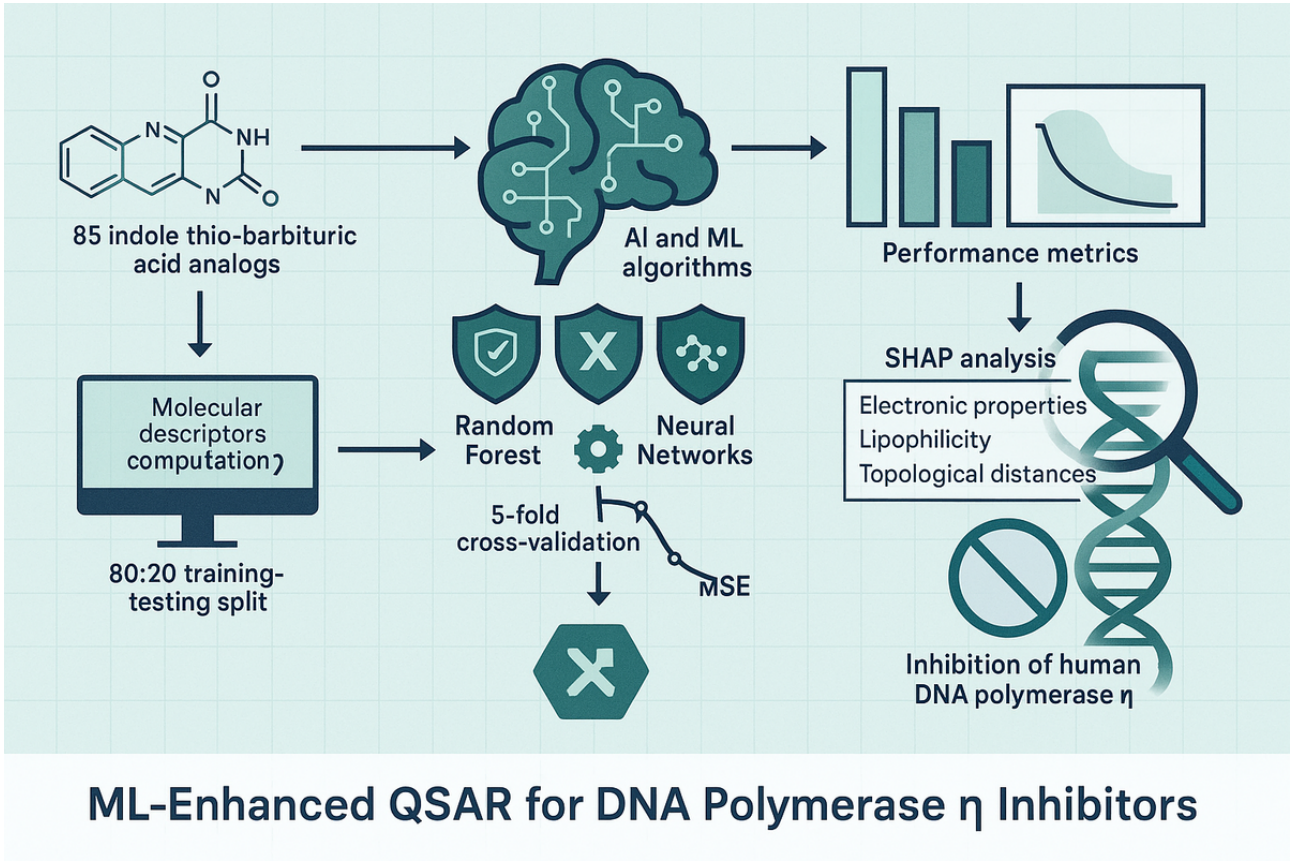
where ρ is Pearson correlation, μ_x and σ_x are mean and SD of observed values, and μ_y and σ_y are mean and SD of the predicted values, respectively.

NMSE scales MSE by dataset variance, enabling cross-study comparisons. It is calculated as follows:

$$(10)\ NMSE=\frac{MSE}{Var(y)}$$

NRMSE provides a scale-free error metric, which is useful for comparing models across different units. It is calculated as follows:

XSL•FO
RenderX



(11)NRMSE=RMSERange(y)=1n∑i=1n(yi−y^i)2ymax−ymin

Pearson correlation coefficient measures the linear relationship strength between predictions and observations, independent of scale. It is calculated as follows:

(12)r=∑i=1n (yi−y¯)(y^i−y^¯)∑i=1n (yi−y¯)2∑i=1n (y^i−y^¯)2

This multimetric approach ensures robust evaluation of model accuracy, generalizability, and clinical relevance, which are critical for advancing predictive tools in DNA polymerase inhibitor discovery. Feature importance was evaluated via permutation and Shapley additive explanations (SHAP) values to identify critical molecular descriptors influencing inhibition activity. The computational pipeline, implemented in Python (version 3.8; Python Software Foundation) [81], combined pandas for data manipulation, scikit-learn for model building, XGBoost, LightGBM, and CatBoost for gradient boosting, and SHAP for interpretability. Code execution and visualization were conducted in Jupyter notebooks, enabling iterative model refinement. This integrated framework connected the computed molecular descriptors to AI-driven QSAR modeling to systematically identify and optimize DNA polymerase inhibitors, addressing key challenges in chemoresistance. Figure 1 displays a graphical abstract for the methodology adopted for this study.

Figure 1. Graphical abstract of DNA polymerase inhibitor discovery using machine learning (ML)–enhanced quantitative structure-activity relationship (QSAR) modeling. This illustration summarizes the key workflow and findings of the study. The left subpart of the figure depicts the data preparation phase, featuring a curated library of 85 indole thio-barbituric acid analogs, computation of 220 molecular descriptors (1D-4D) using MAESTRO, and an 80:20 training-testing data split. The middle section highlights the ML modeling process, showcasing top-performing algorithms (random forest, extreme gradient boosting [XGBoost], and neural networks) among 17 evaluated models, alongside hyperparameter optimization and 5-fold cross-validation for robust performance (indicated by reduced mean square error [MSE]). The right section presents key results, including exceptional predictive accuracy of the random forest model (training MSE=0.0002; R^2=0.9999 and testing MSE=0.0003; R^2=0.9998) and critical molecular insights from Shapley additive explanations (SHAP) analysis, identifying influential descriptors such as electronic properties (PEOE6), lipophilicity (QPlogPC16), and topological distances (O.Cl). The workflow culminates in the goal of inhibiting human DNA polymerase η (hpol η) to address cisplatin resistance in cancer therapy, symbolized by a DNA strand. Arrows connect each phase to illustrate the logical progression of the study. AI: artificial intelligence.

Results

Overview of ML Performance Evaluation

The 17 ML models all led to robust predictions of compounds' specific inhibition of hpol η, as evidenced by their training and testing performance metrics across all algorithms. Table 2 presents validation results for the training dataset, highlighting the models' ability to learn from the data, while Table 3 displays results for the test datasets, providing insights into their generalization capabilities. Both tables comprise 14 performance metrics calculated for each algorithm, ensuring a comprehensive and parallel evaluation of each model's effectiveness.

Model Performance Evaluation

In total, 17 ML models demonstrated robust predictive capabilities for DNA polymerase η (hpol η) inhibition activities, validated through comprehensive performance metrics (Table 2 and Table 3). Ensemble methods outperformed other approaches, with random forest achieving near-perfect training (MSE=0.0002; R^2=0.9999) and testing performance (MSE=0.0003; R^2=0.9998). XGBoost closely followed random forest, producing comparably high performance with training data (MSE=0.0001; R^2 = 0.9999) and testing data (MSE=0.0002; R^2=0.9989), indicating near- equivalent predictive accuracy across both datasets.

Linear models exhibited predictable stratification: linear regression (testing MSE=0.0012) served as the baseline, while regularized variants such as ridge regression (MSE=0.0022) and lasso regression (MSE=0.0032) improved multicollinearity handling at the expense of accuracy. Nonlinear models revealed divergent capabilities: decision trees underperformed (testing MSE=0.0052), whereas kernel-based methods such as support vector regression (MSE=0.0006) surpassed neural networks (MSE=0.0008). Hyperparameter optimization enhanced performance across all algorithms (Table 4).

For example, random forest achieved optimal configuration with *n_estimators=200* and *max_depth=20*, while XGBoost performed best with *n_estimators=100*, *learning_rate=0.1*, and *max_depth=3*. Model robustness was confirmed through CCC (CCC>0.9988) and low error ranges (MAE=0.0088 - 0.051; RMSE=0.0141 - 0.0721).

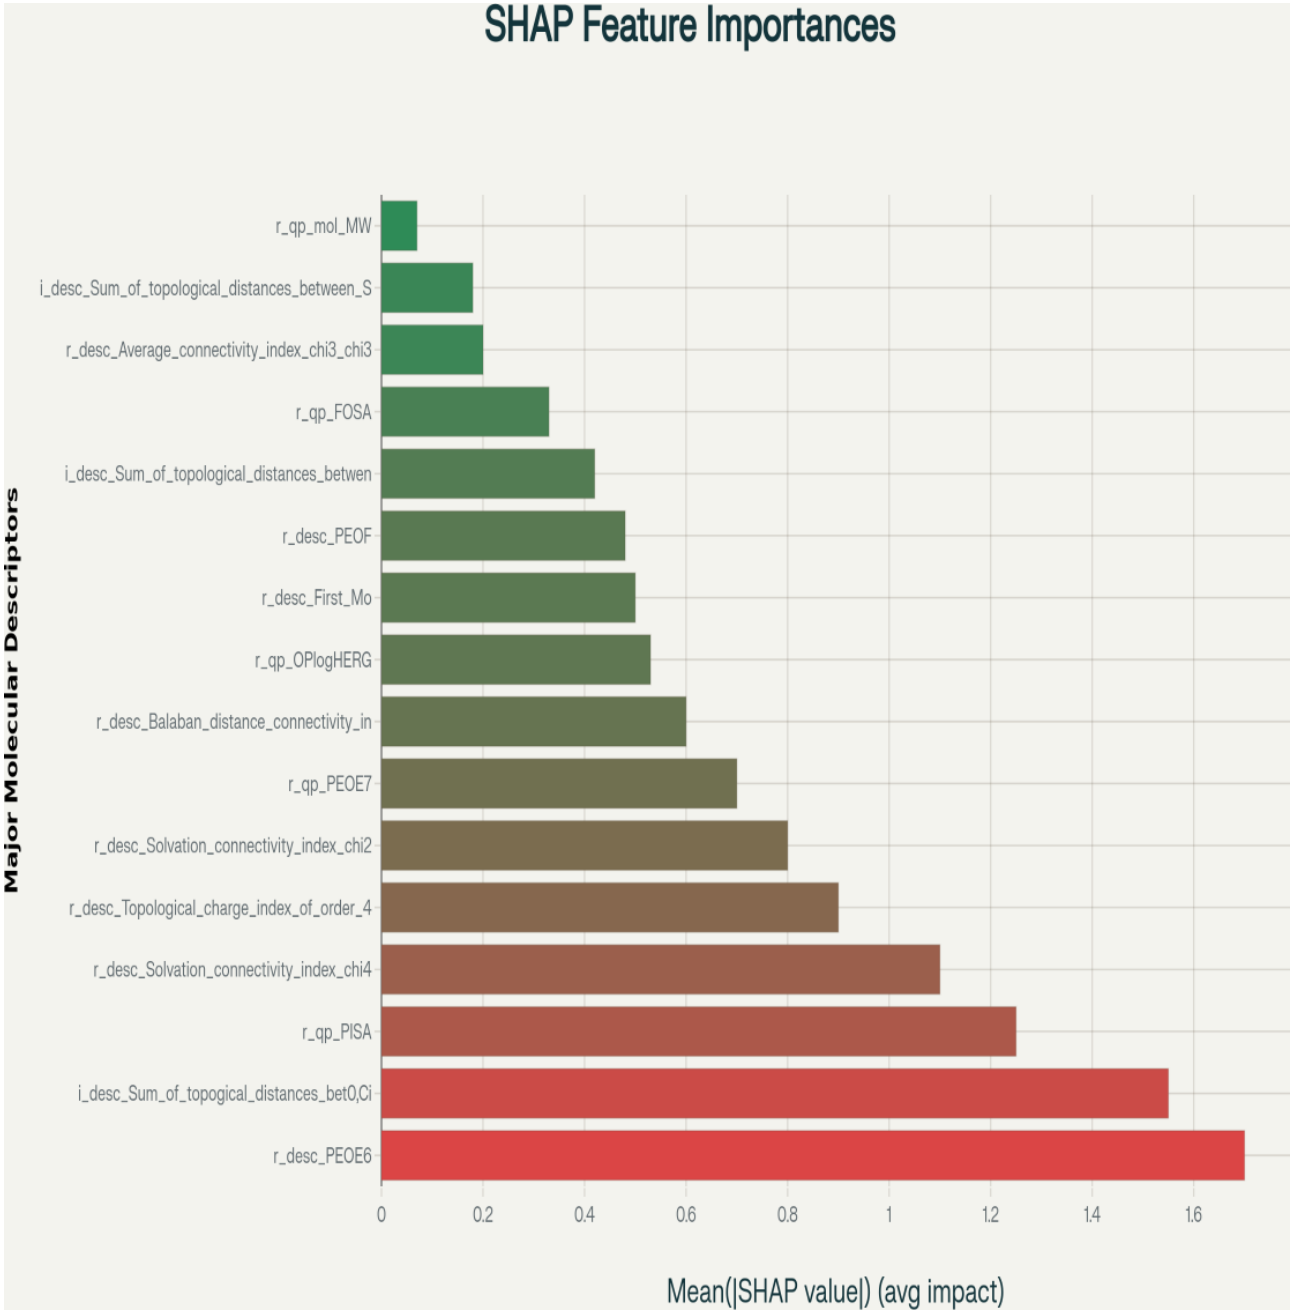
Table . Machine learning algorithms and best parameters.

Machine learning algorithms	Best parameters
Ridge regression	alpha=1.0
Lasso regression	alpha=0.1
ElasticNet	alpha=0.5 and l1_ratio=0.5
Decision tree	max_depth=10, min_samples_split=2, and min_samples_leaf=1
Random forest	n_estimators =200, max_depth=20, min_samples_split=2, and min_samples_leaf=1
Gradient boosting	n_estimators=100, learning_rate=0.1, and max_depth=3
AdaBoost	n_estimators=50 and learning_rate=1.0
SVR[a]	C=1.0, kernel="rbf," and gamma="scale"
K-nearest neighbors	n_neighbors=5 and weights="uniform"
Neural network	hidden_layer_sizes=(100), activation="relu," solver="adam," alpha=0.0001, and learning rate=0.001
Gaussian process regression	kernel=RBF() and alpha=$1e^{-10}$
PLS[b] regression	n_components=2
Isotonic regression	y_min=none, y_max=none, increasing=true, and out_of_bounds="nan"
Extreme gradient boosting	n_estimators=100, learning_rate=0.1, and max_depth=3

[a]SVR: support vector regression.

[b]PLS: partial least squares.



Feature Importance via SHAP Analysis

The SHAP summary plot identified r_desc_PEOE6 (electronic properties) as the most influential descriptor, with a mean absolute SHAP value 23% higher than the next best feature (Figure 2).

The second and third top-ranked features were *r_qp_QPlogPC16* (partition coefficients) and *i_desc_Sum_of_topological_distances_between_O.Cl* (atom spacing), respectively. Secondary contributors included r_qp_PISA (polar surface area) and solvation indices such as *r_desc_Solvation_connectivity_index_chi-4*, which stabilized interactions within the polymerase active site. Lower-impact descriptors such as *r_qp_FOSA* (hydrophobic surface area) and *r_qp_mol_MW* (molecular weight) provided structural insights but contributed minimally to predictive reliability.

XSL•FO
RenderX

Figure 2. Shapley additive explanations (SHAP) summary plot showing the mean absolute SHAP values of molecular descriptors and their average impact on model predictions for inhibition of DNA polymerase η activity. Higher SHAP values indicate greater importance in predicting compound activity. The most influential descriptors include *r_desc_PEOE6* (electronic properties), *r_qp_QPlogPC16* (partition coefficients), and *i_desc_Sum_of_topological_distances_between_O.Cl* (topological distances between oxygen and chlorine atoms). Secondary features such as *r_qp_PISA* (polar surface area) and solvation-related descriptors also contribute significantly to the model's predictions. Lower-ranked descriptors, such as *r_qp_FOSA* (hydrophobic surface area) and r_qp_mol_MW (molecular weight), provide additional structural insights but have less impact on activity than the top-ranked features.

Discussion

Principal Findings

The exceptional predictive performance of ensemble methods, particularly random forest and XGBoost, underscores their suitability for modeling the complex, nonlinear relationships inherent in hpol η inhibition [82-92]. Random forest achieved near-perfect testing metrics (MSE=0.0003; R^2=0.9998), demonstrating robust generalization through feature space partitioning and aggregation of decision trees. This finding aligns with prior studies in which ensemble methods excelled for biological datasets, such as cancer transcriptome prediction of cell survival, due to their capacity to handle high-dimensional, sparse molecular descriptors [83,85-87]. The minimal performance gap between training and testing (ΔMSE=0.0001 [%]²) highlights effective overfitting mitigation, a critical advantage given the multicollinearity observed in QSAR datasets. XGBoost's superior performance over neural networks (testing MSE=0.0002 vs 0.0008) further emphasizes gradient-boosted trees' adaptability to sparse feature spaces, a finding consistent with their success in predicting protein-DNA binding affinity [23,84,92-96]. In contrast, linear models such

XSL•FO
RenderX

as lasso regression (testing MSE=0.0032) revealed the necessity of regularization to manage sparsity, although at the cost of predictive accuracy—a trade-off well documented in drug discovery applications [84-93].

SHAP analysis identified electronic properties (r_desc_PEOE6) as the most critical determinant of inhibition activity, with a mean absolute SHAP value 23% higher than the second-ranked descriptor. This aligns with crystallographic evidence showing that charge distribution governs ligand binding stabilization in polymerase active sites [80,97]. The prominence of partition coefficients (r_qp_QPlogPC16) underscores lipophilicity's dual role in cellular permeability and target engagement, a principle central to antiviral drug design [98,99]. Structural descriptors such as *i_desc_Sum_of_topological_distances_between_O.Cl* further emphasize steric complementarity requirements, mirroring findings in DNA polymerase β inhibition studies where atomic spacing dictated binding specificity [82,100-102]. Secondary features, including polar surface area (*r_qp_PISA*) and solvation indices (*r_desc_Solvation_connectivity_index_chi-4*) [83], elucidate how compounds stabilize aqueous-phase interactions, consistent with enzyme-substrate kinetic models [103-105]. While lower-impact descriptors (*r_qp_FOSA*, *r_qp_mol_MW*) provided auxiliary structural insights, their minimal contributions suggest prioritization of electronic and topological optimization in rational drug design [106,107].

The models' consistent error distribution (MAPE: 0.89% - 5.1%) across activity ranges indicates reliability for moderate-activity compounds but exposes limitations in predicting extreme potencies. This mirrors similar challenges observed in solubility modeling, where outlier compounds often defy linear or ensemble-based predictions [108,109]. The clustering of MedAE around 0.01 suggests that while the models capture general trends, they struggle with highly potent inhibitors—a critical gap in drug discovery pipelines. This limitation likely stems from insufficient representation of extreme-activity compounds in training data, a common issue for biochemical datasets. Future work can address this limitation through synthetic minority oversampling or adversarial training techniques.

Methodologically, the integration of SHAP values bridges the interpretability-accuracy divide. While simpler models such as linear regression underperformed by 2 orders of magnitude, SHAP's ability to deconvolute feature contributions enables actionable insights without sacrificing predictive power [82,83,110]. For instance, the identification of *r_desc_PEOE6* as a top predictor provides a direct optimization target for medicinal chemists: tuning electronic properties to enhance binding affinity. Similarly, *r_qp_QPlogPC16*'s influence offers a pathway to balancing lipophilicity and solubility—a strategy validated in recent hpol η inhibitor development [83]. Integrating molecular-dynamic simulations may enhance predictive accuracy for structurally flexible compounds.

While our models emphasize solvation indices, Salgado et al [111] prioritized hydrogen-bonding descriptors in their polymerase inhibition studies. Discrepancies between these approaches may reflect hpol η's uniquely hydrophobic active site, suggesting the need for crystallographic validation of descriptor-activity relationships. Conversely, consistency with the solvation models by Gupta et al [112] emphasizes the importance of aqueous-interaction stabilization in enzyme kinetics [104,113-115]. Such contrasts highlight the critical role of target-specific descriptor selection in QSAR workflows.

Translating these findings into drug discovery requires balancing multiparameter optimization. For example, improving *r_desc_PEOE6* (electronic distribution) might conflict with *r_qp_QPlogPC16* (lipophilicity) adjustments, necessitating Pareto front analysis to identify optimal compound profiles. Additionally, the moderate impact of *r_qp_QPlogHERG* (cardiac toxicity risk) implies the necessity for parallel absorption, distribution, metabolism, excretion, and toxicity profiling during lead optimization—a practice increasingly adopted in computational drug design.

This study establishes a predictive framework for hpol η inhibitors by combining ensemble methods (for accuracy) and SHAP analysis (for interpretability). The models prioritize electronic distribution, topological alignment, and solvation properties as critical descriptors, directly guiding rational drug design. The integration of these features underscores the need for multidimensional optimization in QSAR workflows, aligning with modern computational approaches.

Limitations and Future Directions

This study faced challenges in accurately predicting extreme values, highlighting the need for improved methodologies to address outlier prediction. Additionally, the absence of 3D conformational data limits the ability to model dynamic molecular interactions, which is crucial for capturing the full spectrum of polymerase-targeted binding events. Incorporating such structural information in future models will enhance the realism and predictive power of dynamic interaction analyses.

While SHAP analysis effectively identifies key molecular features, mechanistic interpretations, such as the role of r_desc_PEOE6 in binding pocket interactions, require validation through molecular dynamics simulations. This integration will strengthen the biological relevance of feature importance findings [1-5].

Furthermore, the current model's applicability domain does not extend to metalloenzyme inhibitors, despite structural similarities among DNA polymerases. Expanding the training set to include these compounds could improve model generalizability and utility across a broader range of enzyme targets. Finally, future studies should explore hybrid modeling architectures that combine ensemble learning methods with graph neural networks. Such approaches may better capture both topological and electronic molecular effects, thereby refining QSAR methodologies for diverse enzyme systems. A key limitation of this study is the relatively small sample size compared to the large number of descriptors, which can increase the risk of overfitting despite the application of robust feature selection, regularization, and algorithmic strategies. Although our SHAP analysis identifies key molecular features, this study does not systematically assess pairs of structurally similar compounds with divergent activities, which is essential for fully

XSL•FO
RenderX

evaluating model reliability and understanding potential activity cliffs. Addressing this limitation through focused analyses and validation in future studies will enhance the robustness and interpretability of our QSAR models. While our study claims superiority over linear models, it does not include direct comparisons with recent ML–based QSAR (MLQSAR) approaches, such as deep learning–based models. This limits our ability to fully contextualize our results within the broader scope of state-of-the-art MLQSAR studies. Although the high performance across our algorithms suggests model trustworthiness, future work will address this gap by benchmarking our models against advanced MLQSAR and deep learning methodologies. Additionally, this study evaluated model performance using only an internal 20% test split and did not include external validation with independent datasets or prospective testing. This limits the ability to fully assess the generalizability and real-world applicability of the models. Future work will incorporate validation using independent external datasets and prospective testing to rigorously evaluate model robustness, confirm generalizability, and strengthen confidence in their predictive performance in practical applications. Finally, critical toxicity descriptors (eg, r_qp_QPlogHERG) were identified but not optimized in this study. Future work will optimize these key toxicity descriptors to strengthen absorption, distribution, metabolism, excretion, and toxicity profiling and predictive safety. The current models show reduced performance for outliers and extreme inhibition values, which may impact predictive reliability. Future work will explore strategies such as data augmentation, robust loss functions, and uncertainty estimation to improve the models' resilience to extreme values and enhance prediction accuracy across the full activity range. While this study achieves strong predictive performance, there is a lack of explicit analysis of the model's applicability domain and chemical space coverage for novel ITBA analogs. Without thorough assessment of the regions in descriptor space where the model is most reliable, the generalizability to structurally diverse or previously unseen compounds remains uncertain. To address this, future work will incorporate formal applicability domain evaluation, such as leverage and distance-based techniques, to more precisely define the confidence boundaries of predictions and ensure robust extrapolation to new ITBA scaffolds and analogs. This will strengthen the practical utility of the model for prospective inhibitor discovery and design.

Conclusions

The ML-driven QSAR framework presented in this study overcomes cisplatin resistance challenges by identifying hpol η inhibitors with unprecedented precision. Ensemble methods (random forest and XGBoost) outperformed traditional models, capturing nonlinear relationships between molecular features and activity. SHAP analysis prioritized electronic distribution (*r_desc_PEOE6*), lipophilicity (*r_qp_QPlogPC16*), and structural topology (*i_desc_Sum_of_topological_distances_between_O.Cl*) as critical for efficacy, consistent with biochemical binding principles. While limitations persist in predicting extreme-potency compounds, the study provides actionable strategies to optimize inhibitor design. Future integration of dynamic 4D descriptors, experimental validation, and generative AI could accelerate development of next-generation therapies, revitalizing cisplatin-based treatments for resistant cancers through computationally guided precision.

Acknowledgments

The authors thank Prof Wilma Sue T Griffin, Prof Steven W Barger, and Prof Peter A Crooks from the University of Arkansas for Medical Sciences for their training and funding support. The authors also thank President Michael A Fitts, Provost Robin Forman, and Dean Thomas LaVeist of the Celia Scott Weatherhead School of Public Health and Tropical Medicine at Tulane University for their exceptional support to SK for the article processing fee, made possible through start-up funds. This work was supported by grants (VA Merit 2 I01 BX001655 and Senior Research Career Scientist Award) awarded to RJSR from the United States Department of Veterans Affairs and by Program Project Grant 2P01AG012411-17A1 (Wilma Sue Tilton Griffin, PI) from the National Institute on Aging (NIA/NIH). The authors also acknowledge the Windgate Foundation and the Philip R. Jonsson Foundation for additional support. Support to SK was provided by the Arkansas INBRE program, funded by grant P20 GM103429 from the National Institute of General Medical Sciences, National Institutes of Health.

Data Availability

The datasets generated and analyzed during this study are not publicly available due to ongoing intellectual property applications but are available from the corresponding author on reasonable request. The molecular database used for quantitative structure-activity relationship modeling is included in the supplementary material.

Authors' Contributions

SK, RJSR, and CMC designed the study. SK designed and implemented the machine learning–driven quantitative structure-activity relationship workflow presented in the study. SK performed all statistical and machine learning analysis with input from RJSR. The manuscript was written by SK, with additional contributions from SA, CMC, RJSR, AYC, and KEA.

Multimedia Appendix 1
Molecular database: molecular database of molecular descriptors representing structural, physicochemical, and quantum properties were calculated using Schrödinger MAESTRO 12.5 software [76]. These included 1D attributes (atom count, molecular weight), 2D features (topological indices, functional groups), 3D characteristics (dipole moment, spatial volume), and 4D properties (HOMO-LUMO energies, electronegativity). A total of 220 descriptors were integrated with experimental inhibition data to enable QSAR modeling.

Abstract

Background: Accurately assigning *ICD-10* (*International Statistical Classification of Diseases, Tenth Revision*) codes is critical for clinical documentation, reimbursement processes, epidemiological studies, and health care planning. Manual coding is time-consuming, labor-intensive, and prone to errors, underscoring the need for automated solutions within the Norwegian health care system. Recent advances in natural language processing (NLP) and transformer-based language models have shown promising results in automating *ICD* (*International Classification of Diseases*) coding in several languages. However, prior work has focused primarily on English and other high-resource languages, leaving a gap in Norwegian-specific clinical NLP research.

Objective: This study introduces 2 versions of NorDeClin-BERT (NorDeClin Bidirectional Encoder Representations from Transformers), domain-specific Norwegian BERT-based models pretrained on a large corpus of Norwegian clinical text to enhance their understanding of medical language. Both models were subsequently fine-tuned to predict ICD-10 diagnosis codes. We aimed to evaluate the impact of domain-specific pretraining and model size on classification performance and to compare NorDeClin-BERT with general-purpose and cross-lingual BERT models in the context of Norwegian ICD-10 coding.

Methods: Two versions of NorDeClin-BERT were pretrained on the ClinCode Gastro Corpus, a large-scale dataset comprising 8.8 million deidentified Norwegian clinical notes, to enhance domain-specific language modeling. The base model builds upon NorBERT3-base and was pretrained on a large, relevant subset of the corpus, while the large model builds upon NorBERT3-large and was trained on the full dataset. Both models were benchmarked against SweDeClin-BERT, ScandiBERT, NorBERT3-base, and NorBERT3-large, using standard evaluation metrics: accuracy, precision, recall, and F_1-score.

Results: The results show that both versions of NorDeClin-BERT outperformed general-purpose Norwegian BERT models and Swedish clinical BERT models in classifying both prevalent and less common *ICD-10* codes. Notably, NorDeClin-BERT-large achieved the highest overall performance across evaluation metrics, demonstrating the impact of domain-specific clinical pretraining in Norwegian. These results highlight that domain-specific pretraining on Norwegian clinical text, combined with model capacity, improves *ICD-10* classification accuracy compared with general-domain Norwegian models and Swedish models pretrained on clinical text. Furthermore, while Swedish clinical models demonstrated some transferability to Norwegian, their performance remained suboptimal, emphasizing the necessity of Norwegian-specific clinical pretraining.

Conclusions: This study highlights the potential of NorDeClin-BERT to improve *ICD-10* code classification for the gastroenterology domain in Norway, ultimately streamlining clinical documentation, reporting processes, reducing administrative burden, and enhancing coding accuracy in Norwegian health care institutions. The benchmarking evaluation establishes NorDeClin-BERT as a state-of-the-art model for processing Norwegian clinical text and predicting *ICD-10* coding, establishing a new baseline for future research in Norwegian medical NLP. Future work may explore further domain adaptation techniques,

XSL•FO
RenderX

external knowledge integration, and cross-hospital generalizability to enhance *ICD* coding performance across broader clinical settings.

Introduction

The transition to digital health records and the automation of clinical documentation processes represent significant milestones in modern health care management. Central to these advancements is the accurate assignment of the *ICD-10* (*International Statistical Classification of Diseases, Tenth Revision*) codes to patient records [1]. These codes serve multiple critical functions: they streamline billing and insurance claims, play a pivotal role in epidemiological studies, facilitate health care planning, and aid in the management of public health resources. In addition, they serve as a measure of both the quantity and quality of health care provided [2].

In Norway, all hospitals record their activity by summarizing patient encounters into *ICD-10* codes. Despite its importance, manually assigning *ICD-10* codes is time-consuming and prone to errors, highlighting the need for an automatic solution [3,4]. Several Norwegian studies have highlighted the issues associated with clinical coding [5-7], and similar findings from other countries support this nonsatisfactory quality of the manually assigned codes [8-11].

Recent advances in natural language processing (NLP), particularly the development of Bidirectional Encoder Representations from Transformers (BERT) models [12], have facilitated novel methodologies for automating complex text data processing. Specifically, the architecture of the BERT transformer facilitates a good understanding of contextual linguistic nuances, making it highly applicable for various clinical tasks, including deidentification [13,14] and the prediction of *ICD-10* codes from clinical notes [15]. Building on these advancements, NorBERT3-base, developed by the Language Technology Group [16] at the University of Oslo and available on Hugging Face [17], is an advanced, state-of-the-art Norwegian BERT model tailored to understand the complexities of the Norwegian language. It was trained as part of the NorBench initiative, which benchmarks Norwegian language models across various NLP tasks to ensure high performance and robustness. NorBERT3-base is a powerful tool for NLP tasks such as text classification and named entity recognition [18].

Regarding the state-of-the-art automatic *ICD* (*International Classification of Diseases*) coding or computer-assisted coding (CAC) tools, Yan et al [19] provided an overview of different approaches to predict *ICD-10* diagnosis codes, describing training datasets in various languages and highlighting issues such as dataset imbalance and explainability. Studies from China [20] and Taiwan [21] have demonstrated the potential of these tools to improve coding speed and quality.

In the study by Zhou et al [20], a set of regular expressions was written to encode the diagnosis of *ICD-10* automatically. The CAC tool was used for 16 months in 2017 - 2018 and compared with manual diagnosis coding. During this period, 160,000 codes were automatically assigned by the CAC tool and then compared with the manual coding. One of the main findings was that the CAC tool was 100 times faster than manual coding, and the CAC tool could maintain high coding quality. The F_1-score of the CAC tool is around 0.6086. In another study by Chen et al [21], the authors implemented a CAC tool using the BERT model. They trained on patient records from one hospital. A total of 14,602 labels were distributed in the training material that comprised discharge summaries. Note that Chinese and Taiwanese use the same dialect but have different character sets, which are simplified and traditional. The Taiwanese *ICD-10* CAC tool predicts *ICD-10* codes with the best results of F_1-score of 0.715 and 0.618, respectively. The tool was also used in a user study that did not decrease coding time; however, the coding quality increased significantly from a median F_1-score of 0.832 to 0.922. Ponthongmak et al [22] used NLP and discharge summary texts to develop a CAC tool for Thai, achieving an F_1-score of 0.7239 using a pretrained language model for automatic *ICD* coding. A systematic literature review of artificial intelligence (AI)–based *ICD* coding and classification approaches using discharge summaries can be found in [23].

Several studies have also explored pretraining on clinical text for automatic *ICD* coding, leveraging transformer-based architectures. One such approach is GPsoap, developed by Yang et al [24], which transforms *ICD* coding into an autoregressive text generation task. Instead of directly predicting *ICD* codes, GPsoap first generates natural language code descriptions, which are then mapped to *ICD* codes. This approach has shown advantages in few-shot learning and rare code prediction. Other studies, such as López-García et al [25], focused on Spanish oncology clinical texts, where a BERT-based model was pretrained on Spanish biomedical literature and further fine-tuned on ICD-O-3 (International Classification of Diseases for Oncology) coding. Similarly, Gao et al [26] proposed BNMF, a BERT and Named Entity Recognition-based model for Chinese *ICD* coding, integrating semantic features from clinical text and structured information from *ICD* taxonomies. These studies highlight the importance of domain-specific adaptation when applying language models to clinical coding.

In contrast, our approach focuses on pretraining a domain-specific clinical BERT model, NorDeClin-BERT, directly on Norwegian clinical text, enabling robust *ICD-10* classification in a multilabel setting. Unlike GPsoap, which generates free-text descriptions, our model directly assigns *ICD-10* codes, aligning more closely with real-world coding

XSL•FO
RenderX

workflows. Additionally, our work explores cross-linguistic transfer, evaluating models pretrained on Swedish clinical text for Norwegian *ICD* coding. By fine-tuning various general-domain and domain-specific Scandinavian BERT models, we systematically assess the impact of domain adaptation, model size, and linguistic generalization on *ICD* coding performance.

Furthermore, our approach provides a comprehensive evaluation of model performance across both domain-adapted and general-purpose pretraining approaches, offering insights into the effectiveness of Norwegian-specific pretraining compared with multilingual and cross-lingual alternatives. By investigating how domain-specific pretraining influences *ICD-10* coding accuracy, our study contributes to advancing automatic clinical coding for Norwegian, a language with limited prior research in this area. While model performance is crucial, interpretability is equally important, especially in health care settings where understanding the reasoning behind predictions can impact patient care and trust in the system. Various approaches to model interpretability have been explored in the context of automated *ICD-10* coding. For example, Dolk et al [27] evaluated 2 popular interpretability methods, LIME (Local Interpretable Model-agnostic Explanations) and SHAP (Shapley additive explanations), to explain automatic *ICD-10* classifications of Swedish gastrointestinal discharge summaries, where SHAP was considered better than LIME. In our study, we opted for an attention-based analysis instead of LIME or SHAP. This choice is motivated by several factors. Attention mechanisms are inherent to BERT and other Transformer-based models, providing a direct window into the model's decision-making process without requiring post hoc explanations. Furthermore, attention-based interpretability can be extracted during inference, making it more computationally efficient than methods like LIME and SHAP. Attention weights offer fine-grained, token-level insights into which parts of the input text the model focuses on when making predictions, aligning well with the nature of the clinical text and *ICD-10* coding tasks.

Our research group has previously explored the application of NLP techniques to improve the accuracy and efficiency of *ICD-10* diagnosis coding. In a recent study, we developed a BERT-based language model, SweDeClin-BERT, trained on a large open clinical corpus of Swedish discharge summaries, particularly in the gastrointestinal surgery domain [13]. This model demonstrated significant potential in assigning *ICD-10* codes to discharge summaries written in Swedish [15]. Building on the insights gained from this work, we have extended our focus to the Norwegian clinical context, aiming to develop a specialized language model tailored to the nuances of Norwegian medical texts.

This study introduces 2 versions of NorDeClin-BERT, BERT-based models specifically developed and fine-tuned for processing Norwegian clinical texts and predicting *ICD-10* codes. We detail the continuous pretraining process of NorDeClin-BERT-base from NorBERT3-base using a large, relevant subset of Norwegian gastroenterological clinical notes, and NorDeClin-BERT-large from NorBERT3-large using the full clinical corpus. By leveraging domain-specific pretraining on Norwegian clinical texts, both models capture the unique linguistic features and domain-specific terminology in Norwegian medical documentation. To assess their effectiveness, we compared the performance of NorDeClin-BERT with other BERT variants, including ScandiBERT [28] and NorBERT [29]. This comparative analysis aims to provide insight into the advantages of a domain-specific, language-tailored model for Norwegian clinical text processing.

To guide our study, we defined the following research questions (RQs):

- RQ1: Does domain-specific pretraining on Norwegian clinical text improve *ICD-10* code classification performance compared with general-domain and cross-lingual models?
- RQ2: How does model size impact performance in *ICD-10* coding tasks when combined with clinical domain adaptation?
- RQ3: Can a domain-specific base-size model match or outperform larger general-purpose models in a practical clinical classification task?

Methods

Overview

This study adopts a structured approach to the continuous pretraining and evaluation of 2 NorDeClin-BERT, new clinical BERT-based models developed for predicting *ICD-10* codes from Norwegian clinical notes, specifically focusing on the gastroenterology domain. This section covers ethical considerations related to data use, the process of data collection and preparation, selection of model architecture and continuous pretraining, fine-tuning, evaluation, and interpretability analysis.

Ethical Considerations

This research was approved by the Norwegian Regional Committees for Medical and Health Research Ethics North, decision number 260972. This study is based on a retrospective analysis of deidentified clinical text. The ethics committee granted a waiver of informed consent in accordance with Norwegian regulations for secondary use of health data in research. All data used in this study were fully deidentified prior to analysis. No personal identifiers were included in the dataset. Access to the data was restricted to authorized personnel, and all analyses were conducted in secure computing environments. No compensation was provided to individuals, as the study did not involve direct participation and was conducted on retrospective clinical data. The manuscript does not contain any images or materials in which individual participants or users can be identified. All data used in this study were fully deidentified prior to analysis. No personal identifiers were included in the dataset. Access to the data was restricted to authorized personnel, and all analyses were conducted in secure computing environments.

All data used in this study were fully deidentified prior to analysis. No personal identifiers were included in the dataset. Access to the data was restricted to authorized personnel, and all analyses were conducted in secure computing environments.

Dataset and Data Processing

Overview

The corpus for this study, the ClinCode Gastro Corpus, contains approximately 8.8 million deidentified and pseudonymized clinical notes [30] of adult patients treated at the Gastro-Surgical Department of the University Hospital of North Norway, Tromsø, from 2017 to 2022. The dataset was subjected to rigorous preprocessing, including deidentification using the NorDeid tool, to ensure patient privacy and data quality [30]. The NorDeid tool combines deep learning and rule-based approaches using regular expressions. This tool was adapted for the Norwegian clinical text to address the country's unique format and clinical terminology. The process involved identifying and pseudonymizing various protected health information types, such as names, dates, locations, and social security numbers.

We used the tokenizer associated with each corresponding backbone model during preprocessing: the NorBERT3-base tokenizer for NorDeClin-BERT-base, and the NorBERT3-large tokenizer for NorDeClin-BERT-large. Trained on a general corpus of Norwegian text, these tokenizers effectively handle the linguistic characteristics of the Norwegian language through their subword tokenization technique. Although not specifically constructed for clinical terminology, their subword approach allowed them to manage specialized medical terms and abbreviations present in our dataset during the continuous pretraining phase.

Data Processing for Continuous Pretraining

Two configurations of NorDeClin-BERT were pretrained using Norwegian clinical notes, each with a different data selection strategy. For NorDeClin-BERT-base, the dataset was filtered based on clinical relevance and practical feasibility, due to limited computational resources available at the time. Two of the authors of this paper (MATH and TOS) collaborated to identify and agree on the most informative files for the pretraining process. The selection criteria focused on document types containing longer and more meaningful clinical information, ensuring the model was pretrained on the most relevant data. As a result, the final dataset used for pretraining was optimized for both quality and relevance. After removing duplicates, the Norwegian clinical corpus used for the continuous pretraining of NorDeClin-BERT-base consisted of 1,670,464 text files (3.2 GB) from various sources, including discharge summaries, surgery notes, nurses' notes, laboratory notes, admission notes, pharmacology notes, and others. This dataset is further described in Table 1.

Table . Document types included in the Norwegian clinical corpus used for the continuous pretraining of NorDeClin-BERT-base (NorDeClin Bidirectional Encoder Representations from Transformers).

Document type	Number of files	Size
Anesthesia	46,310	94.8 MB
Treatment	29,919	49.3 MB
Discharge summaries	586,637	1.6 GB
Ergotherapy	33,220	38.4 MB
Pharmacy	3484	4.6 MB
Physiotherapy	69,324	80.4 MB
Individual plan	558	1.4 MB
Admission records	248,208	779,2 MB
Laboratory	66	53.8 kB
Surgery	313,795	446.8 MB
Summary records	5710	9.2 MB
Radiology	63,734	30.1 MB
Somatic care	110,248	211.3 MB
Nursing	299,212	220.7 MB
Training dataset (no duplicates)	1,670,464	3.2 GB

In contrast, NorDeClin-BERT-large was pretrained on the entire ClinCode Gastro Corpus, using updated hardware infrastructure with increased graphics processing unit (GPU) capacity. The only filtering applied at this stage was the removal of very short documents, excluding those with fewer than 50 tokens, to ensure a minimum level of linguistic and contextual content per note. After filtering, the dataset used for NorDeClin-BERT-large consisted of 8,337,664 text files, totaling approximately 13.2 GB. This broader dataset allowed the large model to capture a more comprehensive representation of the Norwegian clinical language used across document types.

The data processing pipeline for continuous pretraining began with loading and reading the text files from the specified directory. We applied the appropriate tokenizer to convert the text into token IDs while generating the corresponding attention masks. The text was processed in chunks, each constrained to a sequence length of 512 tokens, ensuring compatibility with the model's architecture.

XSL•FO
RenderX

Several key steps were involved in preparing the text data. Initially, empty lines and whitespace were removed, followed by tokenization without adding special tokens. We then introduced separation tokens (</s>), as recommended in the RoBERTa paper [31], to demarcate the end of individual documents within the text. After concatenating the tokenized text into segments of 510 tokens—leaving space for the model's classification (<s>) and separator (</s>) tokens—we added these tokens to the beginning and end of each segment, enabling the model to recognize the start and end of sequences effectively. Finally, the processed data was saved to disk in a structured format, ready for continuous pretraining.

Data Processing for ICD-10 Fine-Tuning

The *ICD-10* is a standardized system for coding diseases, signs, symptoms, and other health-related factors. The *ICD-10* is divided into 22 chapters, each representing a broad category of medical conditions. Our study focuses specifically on Chapter XI (K-codes), which covers "Diseases of the digestive system." This chapter contains approximately 500 "K" codes representing various gastrointestinal diseases out of the 38,000 *ICD-10* codes available. The presence of 87,938 discharge summaries with K-codes in our corpus underscores the richness and relevance of our dataset for gastroenterological research and NLP applications in this field. Furthermore, to prevent label leakage during the fine-tuning process, all *ICD-10* codes that match the label for each training sample were systematically removed from the training text. This step was essential to ensure the model learns to predict *ICD-10* codes based on clinical content rather than relying on explicitly mentioned codes within the text.

Model Continuous Pretraining

This study presents 2 versions of NorDeClin-BERT, both developed through continuous pretraining on Norwegian clinical text. The first, NorDeClin-BERT-base, is based on the NorBERT3-base architecture, consisting of 12 transformer layers, 12 self-attention heads per layer, and a hidden size of 768 dimensions, resulting in 123 million parameters. The second, NorDeClin-BERT-large, builds upon NorBERT3-large, which features 24 layers, 16 attention heads per layer, a hidden size of 1024 dimensions, and approximately 340 million parameters. These architectures were selected for their proven effectiveness in capturing contextual information and learning rich language representations.

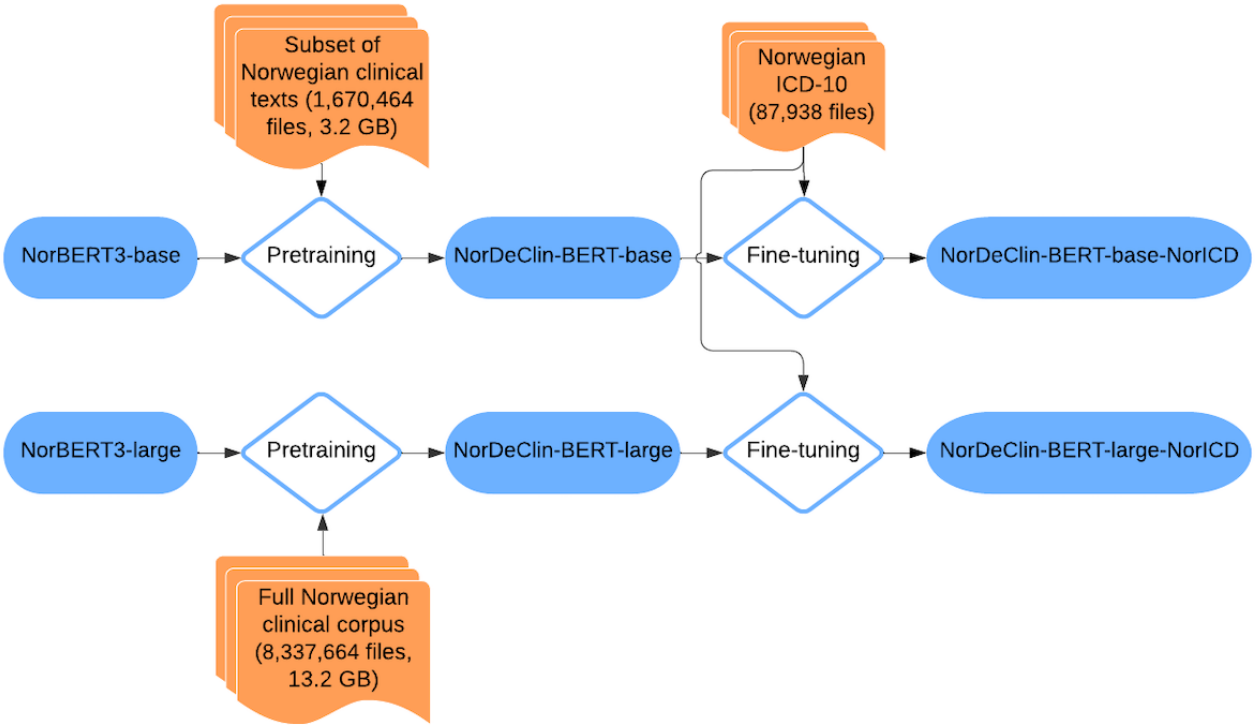
While both NorDeClin-BERT models retain the architecture of their respective backbone models, they differ in the domain-specific knowledge acquired through further pretraining. NorBERT3-base and NorBERT3-large were originally pretrained on general-domain Norwegian text, whereas we further trained both models on deidentified and pseudonymized Norwegian clinical text to create NorDeClin-BERT-base and NorDeClin-BERT-large, respectively. This continuous pretraining process enhanced the models' ability to understand and represent medical language more effectively, making them well-suited for downstream clinical tasks such as *ICD-10* code prediction.

To further pretrain the NorDeClin-BERT models on our specialized clinical text data, we used a well-structured training pipeline built upon the Hugging Face Transformers library [32]. The pretraining process was carried out on a Republic of Gamers server running Debian Linux, initially equipped with a single ASUS GeForce RTX 3090 GPU and later expanded to support dual GPUs for training larger configurations. The system has 64 GB of RAM (2×32GB 3200 MHz DDR4), and an 8 TB Gen4×4 M.2 NVMe SSD. The server storage was encrypted and located in a secure server room, accessible only to researchers who were specially authorized to work with the data and had signed confidentiality agreements. The server was not connected to the internet to ensure data security and remained offline throughout the project.

NorDeClin-BERT was continuously pretrained using the masked language modeling (MLM) objective. In MLM, a portion of the input tokens is randomly masked, and the model is trained to predict the original tokens based on the surrounding context. This approach allows the model to learn robust representations of words and their relationships. Following the findings from the RoBERTa paper [31], which indicated that the next-sentence prediction task was unnecessary, we opted to focus exclusively on MLM during the pretraining of both versions of NorDeClin-BERT.

The tokenized data parts were loaded and concatenated to form a complete training dataset. The dataset was designed to be dynamically masked during training, where tokens were randomly masked at a probability of 15% to train the model on the MLM objective. Training parameters were carefully configured to optimize the model's performance, closely following the RoBERTa paper [31]. Both NorDeClin-BERT-base and NorDeClin-BERT-large were pretrained for 40 epochs with a learning rate of 0.0001.

For NorDeClin-BERT-base, the batch size was configured for 8 sequences per device, with gradient accumulation steps set to 16, effectively simulating a larger batch size of 128 sequences. For NorDeClin-BERT-large, the configuration was adapted for dual-GPU training, using a batch size of 16 and accumulation steps of 2 per device, yielding an effective batch size of 64. While not identical, these settings were selected to maintain stable training dynamics under different hardware constraints. Additionally, the training process included a warmup phase (10,000 steps for base, 5000 for large), weight decay of 0.01, and no gradient clipping. The Adam optimizer was used with custom ε of 0.000001, β_1 of 0.9, and β_2 of 0.999. During the training process, checkpoints were saved periodically, with retention limits in place to manage disk space efficiently. The training could be resumed from a specific checkpoint if needed.



Fine-Tuning

After continuous pretraining, both NorDeClin-BERT-base and NorDeClin-BERT-large were fine-tuned for *ICD-10* code prediction using 87,938 discharge summaries with K-codes. The dataset was partitioned into training (70,350/87,938, 80%), validation (8794/87,938, 10%), and testing (8794/87,938, 10%) sets. The fine-tuning process began with data preparation, where the discharge summaries and their corresponding *ICD-10* codes were loaded from a CSV file using the Hugging Face datasets

XSL•FO
RenderX

library. Each summary's codes were split into a list format for further processing. Figure 1 illustrates this workflow, showing how the NorDeClin-BERT models were pretrained on Norwegian clinical texts and subsequently fine-tuned on the Norwegian *ICD-10* coding task to create the final classification models.

Figure 1. Workflow of the NorDeClin-BERT models. The models are initialized from NorBERT3-base and NorBERT3-large and further pretrained on Norwegian clinical texts to create NorDeClin-BERT-base and NorDeClin-BERT-large. Both are then fine-tuned on the Norwegian *ICD-10* coding task, resulting in the specialized classification models NorDeClin-BERT-base-NorICD and NorDeClin-BERT-large-NorICD. BERT: Bidirectional Encoder Representations from Transformers; *ICD-10*: *International Statistical Classification of Diseases, Tenth Revision*.

A custom preprocessing function was implemented to tokenize the text and prepare the labels. This function tokenized each discharge summary using the model's tokenizer with a maximum sequence length of 512 tokens. Labels were encoded using a multihot encoding scheme, where each unique *ICD-10* code was represented as a binary vector. The NorDeClin-BERT models were then loaded with a classification head adapted for multilabel classification, with the number of output labels set to match the total number of unique *ICD-10* codes in the dataset.

The training setup used a custom MultilabelTrainer class, extending the HuggingFace Trainer class for multilabel classification. The trainer used a binary cross-entropy loss function BCEWithLogitsLoss and was configured with specific hyperparameters: 40 epochs, a learning rate of 2e-5, and an early stopping patience of 1 epoch. To effectively manage memory constraints and increase the batch size, the training used a batch size of 4 with 16 gradient accumulation steps, resulting in a batch size of 64.

During the fine-tuning process, the model was trained on the prepared dataset, with evaluation performed on the validation set after each epoch. Early stopping was applied to prevent overfitting, and the best model was saved based on validation performance. The training process used a constant learning rate scheduler.

After training, the models were evaluated on the held-out test set using custom metric functions to compute accuracy, precision, recall, and F_1-score for multilabel classification. A threshold of 0.5 was applied to the model's output probabilities to determine the final predictions.

Evaluation and Benchmarking of the NorDeClin-BERT Models

Overview

To benchmark the NorDeClin-BERT models' performance, we carefully selected several other BERT-based models for comparison. Each model was chosen to provide specific insights into different aspects of language modeling and transfer learning in the context of Scandinavian languages and clinical text processing. Norwegian and Swedish, as closely related North Germanic languages, share significant lexical, syntactic, and morphological similarities, making cross-linguistic model transfer feasible. Medical terminology is also largely standardized across Scandinavian countries, further supporting the applicability of models trained on one language to another. Given these linguistic and domain-specific similarities, evaluating the NorDeClin-BERT models against models trained on Swedish and general-domain Scandinavian corpora provides valuable insights into how well these models generalize within the Nordic clinical context. To better illustrate the methodological differences across models, we provide individual workflow diagrams (Figures 1-4) and a summary table (Table 2), which highlight variations in model pretraining, fine-tuning, and dataset composition, facilitating direct comparison.

[a]BERT: Bidirectional Encoder Representations from Transformers.

[b]*ICD-10*: *International Statistical Classification of Diseases, Tenth Revision*.

[c]Not applicable.

The following sections contain a detailed explanation of each model and the rationale behind its inclusion.

SweDeClin-BERT

This model originates from KB-BERT [33], a standard Swedish BERT model, which was further pretrained on Swedish clinical texts [13]. It uses the base BERT architecture with 12 layers, 768 hidden units, and 12 attention heads, totaling approximately 110 million parameters. This comparison helps evaluate the importance of language-specific training in clinical NLP tasks. SweDeClin-BERT is represented by 2 variants in our evaluation task: SweDeClin-BERT-SweICD and SweDeClin-BERT-NorICD. SweDeClin-BERT-SweICD is a

XSL•FO
RenderX

variant of SweDeClin-BERT, which was further fine-tuned on Swedish datasets for *ICD-10* code classification. SweDeClin-BERT-NorICD represents SweDeClin-BERT further fine-tuned on the Norwegian ClinCode Gastro Corpus. Their inclusion allows us to assess the performance of models specifically designed for clinical text but in a closely related Scandinavian language. By comparing their performance with the NorDeClin-BERT models, we can also determine how well clinical knowledge and *ICD-10* classification capabilities transfer from Swedish to Norwegian. Figure 2 illustrates the training and fine-tuning process of SweDeClin-BERT, highlighting its pretraining on Swedish clinical text and subsequent fine-tuning for *ICD-10* classification in both Swedish and Norwegian.

ScandiBERT

A model [34] pretrained on a mix of Scandinavian languages designed to capture the linguistic characteristics of the region [28]. Its inclusion allows for evaluating the effectiveness of a multilingual model compared with a language-specific model in the *ICD-10* coding prediction task. Figure 3 illustrates the fine-tuning process of ScandiBERT, where the model is adapted to Norwegian clinical text using *ICD-10* coding data, resulting in the ScandiBERT-NorICD variant.

NorBERT3 (Base and Large Variants)

A model developed for the Norwegian language [29]. NorBERT3-base uses a similar architecture to the other base models, while NorBERT3-large uses a larger architecture with 24 layers, 1024 hidden units, and 16 attention heads, totaling approximately 340 million parameters. Including both base and large variants allows assessing the impact of model size on performance. Additionally, comparing these general-domain models with the NorDeClin-BERT-base and NorDeClin-BERT-large models provides a fair assessment of the effects of clinical domain adaptation versus general language pretraining for Norwegian. Figure 4 illustrates the fine-tuning process of NorBERT3-base and NorBERT3-large on Norwegian *ICD-10* coding tasks, resulting in the specialized models NorBERT3-base-NorICD and NorBERT3-large-NorICD.

Evaluation Metrics

Overview

Each model was fine-tuned and evaluated using the same training, validation, and testing splits of the dataset. We used a comprehensive evaluation strategy focusing on the following metrics: accuracy, precision, recall, and F_1-score [35]. Accuracy measures the proportion of correct predictions out of the total predictions made, providing an overall effectiveness of the model. Precision indicates the proportion of true positive predictions among all positive predictions, where high precision means that the model has a low false-positive rate. The recall represents the proportion of true positive predictions among all actual positives, with high recall indicating the model's ability to identify most of the relevant instances. The F_1-score, as the harmonic mean of precision and recall, provides a single metric that balances both concerns, which is particularly useful when the class distribution is imbalanced. These metrics were calculated considering the multilabel nature of the problem using weighted averages. The evaluation was carried out for both the complete set of codes and the top 80% codes that are used the most. We applied these metrics in 2 main evaluation strategies: multilabel evaluation and top-5 evaluation.

Multilabel Evaluation

Given the multilabel nature of *ICD-10* coding, where multiple codes may apply to a single clinical note, we analyzed model performance in predicting the exact set of relevant codes at the sample level. This was achieved by converting the model's output logits to probability scores and applying a threshold of 0.5 to generate binary predictions, where a label is considered predicted if its probability is greater than or equal to 0.5. These binary predictions were then compared against the true labels to compute accuracy, precision, recall, and F_1-score, providing a detailed view of the model's ability to handle multiple simultaneous labels correctly.

Top-5 Evaluation

This evaluation assesses the model's ability to predict the top-5 most probable codes for each clinical note at the sample level, reflecting practical coding scenarios where identifying the most relevant codes quickly is crucial. The process involved sorting the probability scores for each sample to identify the top 5 highest scoring labels and converting these indices to their corresponding *ICD-10* codes. The actual labels present in the ground truth were then extracted for each sample. Each actual label was checked to see if it was among the top 5 predicted labels. If the actual label was among the top 5 predicted labels, it was added to both the actual and predicted lists. If not, the actual label was added to the actual list, and the last element in the top-5 predictions was added to the predicted list. Finally, the evaluation metrics, including accuracy, precision, recall, and F_1-score, were calculated by comparing the predicted and label lists.

Model Interpretability

To provide insights into the decision-making processes of the NorDeClin-BERT models, an attention-based interpretability analysis was conducted. This involved generating a synthetic clinical text using ChatGPT, processing the text through both NorDeClin-BERT-base-NorICD and NorDeClin-BERT-large-NorICD models, extracting attention weights, aggregating and normalizing attention weights across all layers and heads, and visualizing attention distribution across input tokens during *ICD-10* code prediction.

This methodology allows for a comprehensive evaluation of the NorDeClin-BERT models' performance, their comparative advantages over other BERT variants, and insights into their internal decision-making processes, all crucial for assessing their potential in automating *ICD-10* coding in Norwegian health care settings.

Results

Model Performance

The evaluation of the NorDeClin-BERT models and their comparison with other BERT-based models across 4 critical metrics (accuracy, precision, recall, and F_1-score) yielded

XSL•FO
RenderX

meaningful insights into their performance on *ICD-10* code classification tasks. The analysis was conducted for 2 distinct scenarios: classification performance for all codes and the top 80% most frequently used codes. Performance was further categorized into multilabel and top-5 accuracy.

Accuracy

Table 3 presents the accuracy scores across all evaluated models under 4 evaluation settings. NorDeClin-BERT-large-NorICD achieved the highest accuracy across all scenarios, including multilabel (0.47) and top-5 (0.82) classification of the full *ICD-10* code set, as well as multilabel (0.56) and top-5 (0.88) classification of the top 80% most-used codes. It outperformed all other models, including the larger general-domain NorBERT3-large-NorICD, with the largest margin observed in the all codes multilabel setting (0.47 vs 0.42).

Table . Comparison of the accuracy of different BERT (Bidirectional Encoder Representations from Transformers) models.

Model size and model name	All codes, 95% CI		Top 80% codes, 95% CI	
	Multilabel	Top-5	Multilabel	Top-5
Base				
NorDeClin-BERT-base-NorICD[a]	0.44 (0.43-0.45)	0.81 (0.80-0.81)	0.54 (0.53-0.55)	0.87 (0.86-0.88)
SweDeClin-BERT-Swe-ICD	0.25 (0.24-0.26)	0.59 (0.58-0.60)	0.35 (0.34-0.36)	0.65 (0.63-0.65)
SweDeClin-BERT-NorICD	0.40 (0.39-0.41)	0.78 (0.77-0.79)	0.50 (0.49-0.51)	0.85 (0.84-0.86)
ScandiBERT-NorICD	0.39 (0.38-0.40)	0.78 (0.77-0.79)	0.51 (0.50-0.52)	0.85 (0.84-0.86)
NorBERT3-base-NorICD	0.43 (0.42-0.44)	0.80 (0.79-0.81)	0.52 (0.51-0.53)	0.86 (0.86-0.87)

NorBERT3-large-NorICD	0.42 (0.41-0.43)	0.81 (0.80-0.82)	0.53 (0.52-0.54)	0.88 (0.87-0.88)[b]

[a]*ICD-10*: *International Statistical Classification of Diseases, Tenth Revision*.

[b]Highest score for each scenario.

Among base-sized models, NorDeClin-BERT-base-NorICD also showed strong performance, surpassing SweDeClin-BERT-NorICD, ScandiBERT-NorICD, and SweDeClin-BERT-SweICD in all settings. Notably, it matched or exceeded the performance of the larger NorBERT3-large-NorICD in 3 out of 4 scenarios, highlighting the impact of clinical domain adaptation even in smaller models.

Precision

Table 4 presents precision scores across all models and evaluation scenarios. NorDeClin-BERT-large-NorICD achieved the highest precision in 3 out of 4 settings, including all codes multilabel (0.66), top-5 (0.82), and top 80% most-used codes top-5 (0.90). It performed comparably to NorBERT3-large-NorICD in the remaining setting, where NorBERT3-large-NorICD achieved a higher top 80% most-used codes multilabel precision (0.73 vs 0.72).

Base				
NorDeClin-BERT-base-NorICD[a]	0.65 (0.64-0.66)	0.80 (0.79-0.81)	0.71 (0.70-0.73)	0.89 (0.88-0.90)
SweDeClin-BERT-Swe-ICD	0.38 (0.36-0.40)	0.61 (0.60-0.62)	0.46 (0.44-0.48)	0.69 (0.67-0.70)
SweDeClin-BERT-NorICD	0.58 (0.56-0.59)	0.77 (0.76-0.78)	0.66 (0.65-0.68)	0.87 (0.86-0.88)
ScandiBERT-NorICD	0.57 (0.55-0.58)	0.77 (0.76-0.78)	0.67 (0.66-0.69)	0.87 (0.87-0.88)
NorBERT3-base-NorICD	0.63 (0.61-0.64)	0.79 (0.78-0.80)	0.69 (0.68-0.70)	0.88 (0.88-0.89)
Large				
NorDeClin-BERT-large-NorICD	0.66 (0.65-0.68)[b]	0.82 (0.81-0.82)[b]	0.72 (0.71-0.74)	0.90 (0.90-0.91)[b]
NorBERT3-large-NorICD	0.65 (0.64-0.67)	0.80 (0.79-0.81)	0.73 (0.72-0.74)[b]	0.89 (0.89-0.90)

[a]*ICD-10*: *International Statistical Classification of Diseases, Tenth Revision*.

[b]Highest score for each scenario.

Among base-sized models, NorDeClin-BERT-base-NorICD outperformed all other base models in every scenario, with precision scores of 0.65 (all codes multilabel), 0.80 (top-5), 0.71 (top 80% most-used codes multilabel), and 0.89 (top 80% most-used codes top-5). This performance closely approaches that of the large models, further reinforcing the strength of domain-specific pretraining even with smaller architectures.

Recall

Table 5 reports the recall scores across all models and evaluation scenarios. NorDeClin-BERT-large-NorICD consistently achieved the highest recall across all 4 evaluation settings, with scores of 0.48 (all codes multilabel), 0.82 (all codes top-5), 0.54 (top 80% most-used codes multilabel), and 0.88 (top 80% most-used codes top-5). The largest improvement was observed in the multilabel settings, where it outperformed the general-domain NorBERT3-large-NorICD by 5% points in all codes (0.48 vs 0.43) and 4 points in the top 80% codes (0.54 vs 0.50), underscoring the advantage of domain-specific pretraining at scale.

Table . Comparison of the recall of different BERT (Bidirectional Encoder Representations from Transformers) models.

Model size and model name	All codes, 95% CI		Top 80% codes, 95% CI

[b]Highest score for each scenario.

Among the base-sized models, NorDeClin-BERT-base-NorICD also performed strongly, achieving 0.45 recall in all codes multilabel, 0.81 in top-5, 0.51 in top 80% most-used codes multilabel, and 0.87 in top 80% most-used codes top-5. It

XSL•FO
RenderX

outperformed all general-domain baselines (ScandiBERT and NorBERT3-base), as well as the domain-specific Swedish models (SweDeClin-BERT-SweICD and SweDeClin-BERT-NorICD). Its recall closely matched or exceeded that of the larger NorBERT3-large-NorICD model in 3 of the 4 settings, further supporting the impact of domain-specific pretraining for improving recall in clinical coding tasks.

F_1-Score

Table 6 summarizes the F_1-scores for all models across the 4 evaluation scenarios. NorDeClin-BERT-large-NorICD achieved the highest F_1-score in all cases, with 0.54 for all codes multilabel, 0.81 for all codes top-5, 0.60 for the top 80% most-used codes multilabel, and 0.89 for top 80% top-5, consistently outperforming the general-domain NorBERT3-large-NorICD (0.50, 0.79, 0.58, and 0.88, respectively). The largest F_1-score margin between the large models was observed in the all codes multilabel setting (0.54 vs 0.50), highlighting the impact of domain adaptation on balancing precision and recall in complex coding tasks.

Table . Comparison of F_1-score of different BERT (Bidirectional Encoder Representations from Transformers) models.

Model size and model name	All codes, 95% CI		Top 80% codes, 95% CI	
	Multilabel	Top-5	Multilabel	Top-5
Base				
NorDeClin-BERT-base-NorICD[a]	0.52 (0.51-0.53)	0.79 (0.79-0.80)	0.58 (0.57-0.59)	0.88 (0.87-0.88)
SweDeClin-BERT-Swe-ICD	0.27 (0.26-0.27)	0.55 (0.54-0.56)	0.31 (0.30-0.32)	0.63 (0.62-0.64)
SweClin-BERT-NorICD	0.46 (0.45-0.47)	0.76 (0.75-0.77)	0.54 (0.53-0.55)	0.86 (0.85-0.87)

NorBERT3-base-NorICD	0.50 (0.49-0.51)	0.78 (0.78-0.79)	0.57 (0.56-0.58)	0.87 (0.86-0.88)
Large				
NorDeClin-BERT-large-NorICD	0.54 (0.53-0.55)[b]	0.81 (0.80-0.82)[b]	0.60 (0.60-0.61)[b]	0.89 (0.89-0.90)[b]
NorBERT3-large-NorICD	0.50 (0.49-0.51)	0.79 (0.78-0.80)	0.58 (0.56-0.59)	0.88 (0.87-0.89)

[a]*ICD-10*: *International Statistical Classification of Diseases, Tenth Revision*.

[b]Highest score for each scenario.

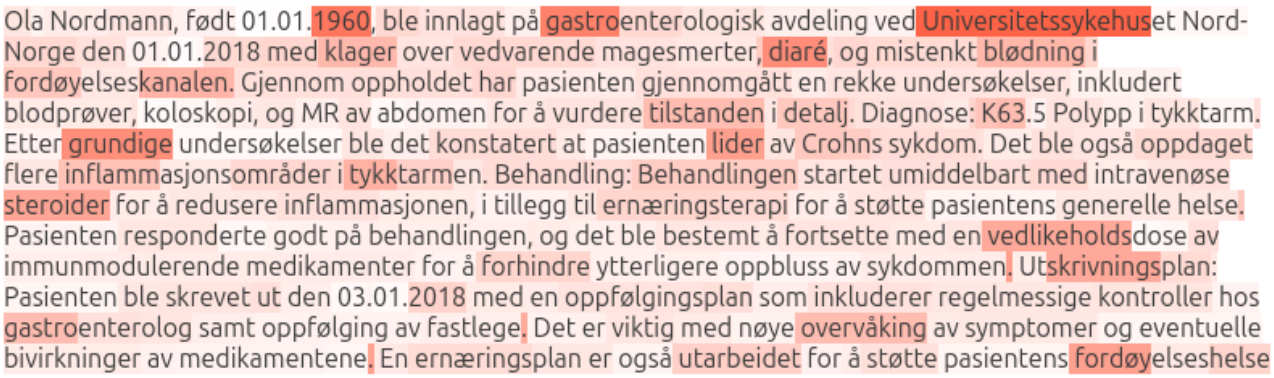
Among base-sized models, NorDeClin-BERT-base-NorICD also demonstrated strong performance with F_1-scores of 0.52, 0.79, 0.58, and 0.88, respectively. It outperformed all other base models across every scenario and matched or exceeded the performance of the larger NorBERT3-large-NorICD in all 4 settings, further validating the strength of clinical domain pretraining even in smaller architectures.

Interpretability

Figure 5 illustrates the attention distribution of NorDeClin-BERT-base-NorICD in a synthetic clinical text. The attention appears to be distributed relatively uniformly throughout the clinical description, suggesting that the model focuses on a comprehensive contextual understanding of the text to make predictions. Key medical terms like diaré (diarrhea), blødning (bleeding), Crohns sykdom (Crohn disease), and inflammatorisk tarmsykdom (inflammatory bowel disease) receive high attention, indicating their importance in the model's decision-making process. The model's interpretability is based on its attention to clinical descriptions and terminology. This approach provides valuable insights into how the model processes natural language to arrive at its predictions. It is particularly useful in understanding how the model infers *ICD* codes from medical text alone, mimicking the process a human expert might follow when assigning codes based on clinical narratives.

XSL•FO
RenderX

Figure 5. Attention distribution of NorDeClin-BERT-base-NorICD on a synthetic clinical text. A translation of the text is provided in Multimedia Appendix 1. BERT: Bidirectional Encoder Representations from Transformers; *ICD-10*: *International Statistical Classification of Diseases, Tenth Revision*.



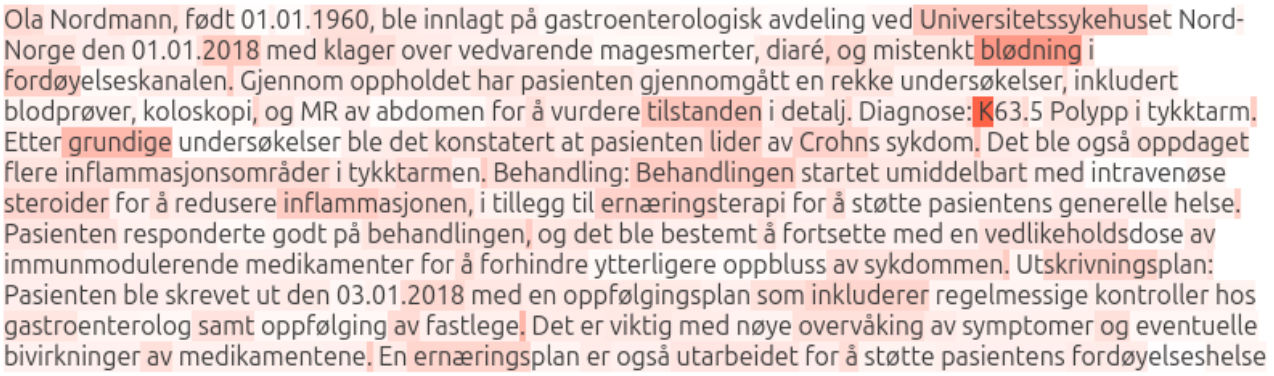


Figure 6 shows the attention distribution of NorDeClin-BERT-large-NorICD applied to the same synthetic clinical text. Like the base model, it assigns high attention weights to terms such as blødning, Crohns sykdom, and inflammatorisk tarmsykdom. However, the large model displays a slightly more focused and confident pattern, with attention concentrated more tightly around diagnostically relevant phrases. This may reflect the benefit of both greater model capacity and pretraining on the full corpus, resulting in more targeted representation learning.

Figure 6. Attention distribution of NorDeClin-BERT-large-NorICD on the same synthetic clinical text. A translation of the text is provided in Multimedia Appendix 1. BERT: Bidirectional Encoder Representations from Transformers; *ICD-10*: *International Statistical Classification of Diseases, Tenth Revision*.

Comparing the 2 models, both demonstrate strong interpretability by attending to clinically meaningful concepts. NorDeClin-BERT-large-NorICD appears to apply attention more selectively, in line with its superior classification performance. These visualizations support the idea that domain-specific pretraining not only improves predictive performance but also enhances transparency and trust in real-world clinical applications.

The distribution of attention across the text, focusing on key medical terms, suggests that the models have developed a nuanced understanding of clinical language. This method of interpretation allows us to understand which parts of the clinical narrative the models consider most relevant for predicting *ICD* codes. This ability to extract relevant information from various parts of the text indicates a robust and generalizable approach to *ICD* code prediction. It showcases the models' capacity to process and understand clinical narratives in a way that aligns with human expert reasoning.

This interpretability analysis highlights the NorDeClin-BERT models' potential to assist health care professionals and improve their trust by providing insight into the reasoning behind the predicted *ICD* codes. The models' attention to a broad range of clinical terms and contexts suggests their potential adaptability to various types of medical narrative, which is crucial for real-world applications in diverse health care settings.

Discussion

Principal Findings

The development and evaluation of 2 variants of NorDeClin-BERT for *ICD-10* code classification tasks have yielded insightful results, highlighting their capabilities and potential applications in Norwegian health care settings. Both NorDeClin-BERT-base-NorICD and NorDeClin-BERT-large-NorICD have emerged as frontrunners, demonstrating higher accuracy, precision, recall, and F_1-scores across both all codes and the top 80% most-used codes. These findings underscore the robustness and efficiency of the models in handling diverse and prevalent code classifications.

The good performance of the NorDeClin-BERT models, especially in the context of the top 80% most-used codes, suggests that these models have effectively captured the

XSL•FO
RenderX

underlying patterns and nuances of the most frequent classifications in Norwegian clinical texts. This capability is critical in practical applications where prioritizing common codes can substantially enhance operational efficiency and accuracy. At the same time, the models, particularly NorDeClin-BERT-large, showed notable improvements in multilabel classification across both full and frequent-code scenarios, outperforming all baseline models in recall and F_1-score. Furthermore, the high precision of the NorDeClin-BERT models indicates their utility in scenarios where the cost of false positives is high, making them an ideal choice for critical applications in medical coding and documentation.

An important aspect of our study is the comparison of models with different sizes and architectures. NorDeClin-BERT was developed in both base and large configurations, with the base model built on the BERT-base architecture (≈110 million parameters) and the large model using a BERT-large architecture (≈340 million parameters). NorDeClin-BERT-base consistently outperformed or matched the performance of other models, including the larger general-domain NorBERT3-large model. This finding is particularly noteworthy, as it challenges the common assumption that larger models invariably lead to better performance. The success of NorDeClin-BERT-base suggests that, for specialized tasks such as *ICD-10* coding in Norwegian clinical texts, a well-tuned base-size model can be highly effective and potentially more efficient in terms of computational resources and inference time.

The comparable or better performance of NorDeClin-BERT-base to larger models such as NorBERT3-large also highlights the importance of domain-specific pretraining and fine-tuning. It appears that the targeted approach of training on Norwegian clinical texts has allowed even the smaller NorDeClin-BERT variant to develop a more nuanced understanding of medical terminology and context, compensating for its reduced size. This observation has significant implications for model development in specialized domains, suggesting that carefully curated training data and domain-specific adaptation can be as important as, if not more important than, raw model size.

Furthermore, the efficiency of a smaller model like NorDeClin-BERT-base has practical advantages in clinical settings. It can be more easily deployed in environments with limited computational resources, potentially allowing for faster inference times and lower hardware requirements. This could facilitate broader adoption across various health care institutions, including those with constrained IT infrastructures.

The findings of this study have broader implications for the implementation of machine learning in Norwegian clinical settings. The NorDeClin-BERT models can substantially reduce the workload of health care professionals by automating routine coding tasks, allowing them to focus more on patient care and less on administrative duties. In addition, the enhanced accuracy and precision of these models can contribute to better patient outcomes by ensuring more accurate reporting and documentation, which, in turn, can lead to more targeted and effective patient care plans in Norwegian hospitals.

The attention-based interpretability analysis provides valuable insight into NorDeClin-BERT models' decision-making process, which could enhance trust and adoption among health care professionals. The models' ability to focus on relevant clinical terms when *ICD* codes are not present demonstrates their potential to generalize well to various clinical narratives.

Our study not only demonstrates the effectiveness of the NorDeClin-BERT models in *ICD-10* coding tasks but also provides valuable insights into the trade-offs between model size, domain-specific training, and performance in specialized NLP tasks. These findings could guide future research and development in clinical NLP, potentially leading to more efficient and effective AI solutions in health care.

Broader Implications of *ICD-10* Coding Performance

While this study focuses on *ICD-10* coding for clinical documentation, structured coding also plays a crucial role in several other domains, including billing, epidemiological research, clinical registries, and decision support systems. In billing and insurance claims, accurate *ICD-10* coding ensures proper reimbursement and minimizes administrative errors. In epidemiological studies, these codes are essential for monitoring disease prevalence and public health trends, where high recall is particularly important to ensure comprehensive case identification and minimize underreporting. Similarly, clinical registries rely on structured diagnostic coding to maintain high-quality datasets, where both precision and recall influence the completeness and reliability of registry-based research. Additionally, in clinical decision support systems, *ICD-10* codes are often used to trigger alerts, inform risk assessments, or guide treatment recommendations, where high precision is crucial to avoid false-positive alerts that could contribute to alert fatigue and unnecessary interventions. While our study does not directly evaluate these applications, our findings suggest that models like NorDeClin-BERT-base-NorICD and NorDeClin-BERT-large-NorICD have the potential to improve coding accuracy in such contexts, thereby enhancing the quality of structured health data across multiple domains. Future research could explore domain-specific adaptations to optimize NLP-driven *ICD-10* coding for these different use cases.

Limitations and Future Directions

While the results of this study are promising, several limitations must be acknowledged. First, the performance of the NorDeClin-BERT models might vary with different datasets or coding systems not covered in this study, particularly those outside the gastroenterology domain. This suggests the need for wider validation across various medical specialties and health care institutions in Norway to fully understand the generalizability of the findings.

Future research should aim to address these limitations by expanding the scope of the datasets and coding systems, potentially including other medical specialties and health care institutions across Norway. Exploring the integration of the NorDeClin-BERT models into real-world clinical workflows in Norwegian hospitals and assessing their impact on efficiency and patient care outcomes would provide valuable insights into their practical utility.

XSL•FO
RenderX

Furthermore, investigating the interpretability of the NorDeClin-BERT models and user trust in automated coding systems represents a crucial research area, as these factors greatly influence the adoption of AI technologies in health care. Developing explainable AI techniques tailored to the Norwegian clinical context could further improve the transparency and trustworthiness of these models, potentially accelerating their integration into Norwegian health care systems.

Conclusions

This study introduced 2 versions of NorDeClin-BERT, domain-specific BERT models specifically developed for automating *ICD-10* code assignments from clinical notes within the Norwegian gastroenterological domain. By benchmarking these models against both general-domain and cross-lingual BERT baselines, we addressed 3 core RQs. First (RQ1), we found that domain-specific pretraining on Norwegian clinical text consistently improved *ICD-10* classification performance across all evaluation metrics, compared with general-domain Norwegian models and Swedish clinical models. Second (RQ2), we showed that scaling the model size from base to large further enhanced performance, most notably in multilabel scenarios, demonstrating that model capacity can amplify the benefits of domain adaptation. Third (RQ3), NorDeClin-BERT-base matched or outperformed NorBERT3-large in multiple scenarios, highlighting the value of targeted pretraining even with smaller architectures.

Compared with previous work on Swedish *ICD-10* classification using SweDeClin-BERT [15], our models achieved competitive or superior performance, especially under strict multilabel evaluation, despite differences in language and dataset structure. To our knowledge, this is the first study to develop and evaluate BERT-based models for *ICD-10* coding in the Norwegian language, setting a new benchmark for future clinical NLP research in this area.

Through detailed analysis of accuracy, precision, recall, and F_1-score, our findings demonstrate the potential of domain-specific language models to support structured clinical documentation, reduce administrative burden, and enable more accurate downstream analytics in Norwegian health care. The results highlight the NorDeClin-BERT models as superior in terms of accuracy, precision, recall, and F_1-score for both all codes and the top 80% most-used codes, consistently outperforming other BERT variants, including ScandiBERT, NorBERT3-base, NorBERT3-large, and SweDeClin-BERT. NorDeClin-BERT-large-NorICD demonstrated the highest overall performance, while NorDeClin-BERT-base-NorICD matched or exceeded the performance of larger general-purpose models in multiple scenarios. Both models demonstrate an improved ability to capture the nuances of the Norwegian language and the complexity of medical coding. The study also underscores the relevance of language-specific and domain-specific models, as evidenced by NorDeClin-BERT's improved performance compared with models pretrained on general Scandinavian languages.

The attention-based interpretability analysis provided valuable insight into the NorDeClin-BERT models' decision-making processes, demonstrating their ability to focus on relevant clinical terms and adapt to the presence or absence of explicit *ICD* codes in the text. This feature enhances the models' potential for generalization and practical application in diverse clinical settings across Norway.

Acknowledgments

The publication charges for this article have been funded by a grant from the publication fund of UiT The Arctic University of Norway. The authors used OpenAI's ChatGPT to assist with language editing and rephrasing portions of the manuscript. All content was reviewed and edited by the authors for accuracy and correctness. ChatGPT was also used to generate the synthetic clinical text used in the interpretability analysis. No generative artificial intelligence was used for data analysis or original scientific content. The research was funded by the Norwegian Research Council under the project ClinCode Computer-Assisted Clinical *ICD-10* (*International Statistical Classification of Diseases, Tenth Revision*) Coding for improving efficiency and quality in health care (project number 318098).

Abstract

Background: Systematic literature reviews (SLRs) build the foundation for evidence synthesis, but they are exceptionally demanding in terms of time and resources. While recent advances in artificial intelligence (AI), particularly large language models, offer the potential to accelerate this process, their use introduces challenges to transparency and reproducibility. Reporting guidelines such as the PRISMA-AI (Preferred Reporting Items for Systematic Reviews and Meta-Analyses–Artificial Intelligence Extension) primarily focus on AI as a subject of research, not as a tool in the review process itself.

Objective: To address the gap in reporting standards, this study aimed to develop and propose a discipline-agnostic checklist extension to the PRISMA 2020 statement. The goal was to ensure transparent reporting when AI is used as a methodological tool in evidence synthesis, fostering trust in the next generation of SLRs.

Methods: The proposed checklist, named PRISMA-trAIce (PRISMA–Transparent Reporting of Artificial Intelligence in Comprehensive Evidence Synthesis), was developed through a systematic process. We conducted a literature search to identify established, consensus-based AI reporting guidelines (eg, CONSORT-AI [Consolidated Standards of Reporting Trials–Artificial Intelligence] and TRIPOD-AI [Transparent Reporting of a Multivariable Prediction Model of Individual Prognosis or Diagnosis–Artificial Intelligence]). Relevant items from these frameworks were extracted, analyzed, and thematically synthesized to form a modular checklist that integrated with the PRISMA 2020 structure.

Results: The primary result of this work is the PRISMA-trAIce checklist, a comprehensive set of reporting items designed to document the use of AI in SLRs. The checklist covers the entire structure of an SLR, from title and abstract to methods and discussion, and includes specific items for identifying AI tools, describing human-AI interaction, reporting performance evaluation, and discussing limitations.

Conclusions: PRISMA-trAIce establishes an important framework to improve the transparency and methodological integrity of AI-assisted systematic reviews, enhancing the trust required for the responsible application of AI-assisted systematic reviews in evidence synthesis. We present this work as a foundational proposal, explicitly inviting the scientific community to join an open science process of consensus building. Through this collaborative refinement, we aim to evolve PRISMA-trAIce into a formally endorsed guideline, thereby ensuring the collective validation and scientific rigor of future AI-driven research.

KEYWORDS

systematic literature review; reporting guideline; artificial intelligence; AI; large language models; Preferred Reporting Items for Systematic Reviews and Meta-Analyses; PRISMA; transparency; evidence synthesis

Introduction

Evidence-based practice is the cornerstone of modern science and decision-making across a wide range of disciplines, from clinical medicine and social sciences to engineering and computer science. One method of generating this evidence is a systematic literature review (SLR) [1,2]. In contrast to narrative reviews, SLRs follow a rigorous and predefined methodology to identify, appraise, and synthesize the totality of relevant research on a specific question. The goal is to minimize author bias and provide a reliable answer to the research question through a comprehensive and reproducible process [2].

Despite its widely recognized value, conducting an SLR presents considerable challenges. The requirement for completeness necessitates extensive searches across various scientific databases, often yielding thousands of potentially relevant

XSL•FO
RenderX

publications. Each of these must then be manually screened for relevance, typically by at least 2 independent reviewers. This is followed by detailed data extraction and quality assessment of the included studies. The process is not only methodologically demanding but also extremely time-consuming and labor intensive, which significantly hinders the broad application of SLR methodology outside well-funded research groups [3].

Recent breakthroughs in natural language processing, particularly the development and wide availability of large language models such as GPT-4 or Claude 3, offer new possibilities to overcome these challenges. Today, artificial intelligence (AI)–supported tools can assist in almost all phases of the SLR process [4,5], from generating and optimizing search strategies to semiautomating the screening of titles and abstracts and extracting structured data from full texts [5,6]. Studies indicate that these technologies can reduce the manual workload by 50% to 75% [7], bringing the promise of democratizing SLR methodology within reach [8].

However, the integration of AI tools into the scientific process poses a new, fundamental challenge: ensuring transparency, traceability, and trust in the results [9]. The "black box" nature of many LLMs and their known weaknesses, such as "hallucinations" [10,11] or the reproduction of bias from training data [12,13], stand in direct contradiction to the core principles of SLRs. To ensure trust in traditional SLRs, the scientific community relies on established reporting guidelines, most notably the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 statement, which mandates detailed documentation of each step in the SLR process [14].

An analogous guideline including the use of AI in SLRs is clearly needed. Although a corresponding extension, the PRISMA-AI (PRISMA–Artificial Intelligence Extension), was announced in 2022, it has not yet been published. More importantly, according to the planning document, its conceptual focus is primarily on reporting SLRs that investigate AI as a subject of research in clinical medicine [15]. There is still a complete lack of a guideline for using AI as a tool within the research process applicable across all disciplines and an urgent need to formulate globally recognized guidelines for the use of AI tools [16]. This gap creates the risk of AI-supported SLRs becoming a nonstandardized and nontransparent method and therefore scientifically questionable.

To close this reporting gap and, thereby, mitigate the associated risks, we propose PRISMA-trAIce (PRISMA–Transparent Reporting of Artificial Intelligence in Comprehensive Evidence Synthesis). This checklist synthesizes key principles from established AI reporting guidelines to provide a structured and well-founded starting point. We offer this framework as a catalyst for community discussion, aiming to accelerate the collaborative development of a formal, consensus-based standard for transparent AI reporting in SLRs.

Methods

Formulation of the PRISMA-trAIce Checklist

We developed the PRISMA-trAIce checklist through a systematic, multistage process.

First, our targeted literature review focused on established, consensus-based AI reporting guidelines, primarily sourced from the EQUATOR (Enhancing the Quality and Transparency of Health Research) Network, a recognized authority on such standards [17-22]. Our search included keywords such as "artificial intelligence," "machine learning," and "reporting guideline." The methodological approach was designed to build on robust, existing scientific consensus established by leading reporting guidelines. Many of these foundational guidelines, such as the CONSORT-AI (Consolidated Standards of Reporting Trials–Artificial Intelligence) and TRIPOD-AI (Transparent Reporting of a Multivariable Prediction Model of Individual Prognosis or Diagnosis–Artificial Intelligence), were chosen as they represent the most widely adopted, cross-domain standards for research involving AI, thus providing the most robust and consensus-driven foundation for our synthesis. From this search, the following core guidelines were selected for adaptation: CONSORT-AI [18], SPIRIT-AI (Standard Protocol Items: Recommendations for Interventional Trials–Artificial Intelligence) [19], TRIPOD-AI and TRIPOD-LLM (Transparent Reporting of a Multivariable Prediction Model of Individual Prognosis or Diagnosis–Large Language Model) [20,23], DECIDE-AI (Developmental and Exploratory Clinical Investigations of Decision Support Systems Driven by Artificial Intelligence) [21], and the GAMER (Generative Artificial Intelligence Tools in Medical Research) guideline [24]. Leveraging this foundation is scientifically sound and resource efficient. Given the rapid pace of technological development in AI, a multiyear, de novo consensus process would risk producing an obsolete guideline upon publication. Therefore, we synthesized and adapted relevant elements from already existing, established frameworks, creating a focused, cross-disciplinary, and applicable checklist for AI-assisted SLRs.

Second, we extracted all individual checklist items from the selected guidelines for a qualitative content analysis. The guiding question for this analysis was as follows: is this reporting principle relevant and applicable to the use of AI as a methodological tool in an SLR? Each item was evaluated for its relevance to reproducibility, feasibility for authors, and adaptability to the SLR context. Items not considered relevant (eg, those concerning the patient safety of an AI intervention) were excluded. The analysis focused on principles such as the detailed disclosure of AI models, data origins, and the explicit description of human-AI interaction and oversight.

Third, the resulting relevant items were thematically synthesized to identify recurring core concepts (eg, "AI tool identification" and "human-AI interaction"). These thematic clusters were then mapped to the existing structure of the PRISMA 2020 statement to ensure seamless integration and user-friendliness.

Limitations

We recognize that the proposed checklist has limitations as it results from a systematic synthesis and adaptation, not a formal, broad-based Delphi study or consensus meeting. While its foundation is built on prior consensus, the checklist has not yet undergone this process. Its feasibility was assessed based on expert knowledge, but it has not been validated through a formal user study. Therefore, this work is explicitly intended as a

XSL•FO
RenderX

well-founded proposal that provides an immediate solution and can serve as the foundation for a subsequent, community-driven formal consensus process.

Ethical Considerations

This paper presents a methodological proposal for a reporting guideline and does not involve research on human participants or animals. Therefore, approval from an institutional review board or an ethics committee was not required. The development of this work adheres to the ethical principles for medical research outlined in the World Medical Association Declaration of Helsinki and follows the guidelines on publication ethics of the Committee on Publication Ethics. The use of generative AI during the preparation of this manuscript is disclosed in the Acknowledgments section. The authors retain full responsibility for the scientific integrity and content of this work.

Results

The previously described method resulted in the PRISMA-trAIce checklist and a corresponding adapted PRISMA flow diagram, which we present in the following sections.

The PRISMA-trAIce Checklist

The PRISMA-trAIce checklist is an extension to the PRISMA 2020 statement designed to guide the transparent reporting of AI use in SLRs. It comprises 14 items that are categorized according to the structure of an SLR (title, abstract, introduction, methods, results, and discussion) and addresses critical aspects of AI use, from tool identification and human-AI interaction to performance evaluation and limitations.

The complete checklist is presented in Table 1. A detailed explanation of each checklist item, including its rationale, elaboration, sources, and application examples, is provided in Multimedia Appendix 1.

XSL•FO

Table . The PRISMA[a]-trAIce (Preferred Reporting Items for Systematic Reviews and Meta-Analyses–Transparent Reporting of Artificial Intelligence in Comprehensive Evidence Synthesis) checklist for documenting artificial intelligence (AI) tool use in systematic literature reviews (SLRs).

Structural element and item ID		Details
Title		
	P-trAIce T1 - Title	If AI tools played a substantial role in the review process (eg, primary screening, data extraction), consider indicating the use of AI assistance in the title or subtitle.
Abstract		
	P-trAIce A1 - Abstract	Briefly summarize the AI tool(s) used, the SLR stage(s) at which they were applied, and their primary role.
Introduction		
	P-trAIce I1 - Introduction	Briefly state the rationale for choosing to use AI tools for specific tasks in the review (eg, managing large volume of literature, enhancing efficiency, exploring novel methods).
Methods		
	P-trAIce M1 - Protocol and Registration	If specific AI tools or AI-assisted methods were pre-specified in the review protocol, state this and provide details of where the protocol can be accessed. Report any deviations from the protocol regarding AI use.
	P-trAIce M2 - Identification and Access	For each AI tool or system used: a. Specify the name, version number (if applicable), and developer/provider. b. Provide details on how the tool can be accessed (eg, URL, software repository, commercial availability, local instance). c. If a custom-developed AI tool or script was used, describe its core functionality and how it can be accessed or replicated (eg, link to code repository, dataset or base model of a given fine-tuning process).
	P-trAIce M3 - Purpose and Stage of Application	For each AI tool, clearly describe: a. The specific SLR stage(s) where it was applied (e.g., search, screening, data extraction, Risk of Bias assessment, synthesis, drafting). b. The precise task(s) the AI was intended to perform at each stage.
	P-trAIce M4 - Input Data	Describe the input data provided to each AI tool for its operation: a. For tools that learn or are fine-tuned: Describe the origin, nature, and preparation of any data used for training, fine-tuning, or calibration specific to this review. b. For tools applied to review data: Describe the data fed into the tool (eg, search results, abstracts, full-text articles, specific datasets for analysis).
	P-trAIce M5 - Output Data	Describe the output data generated by each AI tool. This description must include the format of the output (eg, structured JSON, plain text, classification labels with confidence scores) and detail any automated post-processing steps applied to the raw output before it was presented for human review or use.

XSL•FO
RenderX

Structural element and item ID		Details
	P-trAIce M6 - Prompt Engineering (if any)	For each LLM[b]/GenAI[c] tool used, report: a. The full prompt(s) employed for each specific task. If prompts are extensive, provide a detailed description of their structure, key instructions, context provided (eg, inclusion/exclusion criteria, PICO[d] elements), and any few-shot examples used. Indicate where full prompts can be accessed (eg, supplementary material, repository). b. Key parameters influencing output (eg, model temperature, max tokens, top-p). c. Describe any iterative refinement process for the prompts based on initial outputs or pilot testing.
	P-trAIce M7 - Operational Details and Settings	For AI tools other than LLMs/GenAI (or in addition to prompts for them), describe: a. Key algorithms or models employed by the tool (if known and relevant). b. Specific settings, parameters, or configurations used that could influence performance (eg, thresholds for classification in screening tools, active learning model parameters).
	P-trAIce M8 - Human-AI Interaction and Oversight	Describe the process of human interaction with and oversight of the AI tool(s) at each stage: a. How many reviewers interacted with/validated the AI outputs for each task? b. Did reviewers work independently when validating AI outputs? c. What were the qualifications or training of reviewers for AI-assisted tasks? d. How were AI outputs presented to reviewers? e. What proportion of AI outputs were manually reviewed/verified? f. How were discrepancies between AI and human reviewers, or among multiple human reviewers, resolved? g. Describe any processes for calibrating human reviewers or the AI tool. f. Describe the standard procedure for human verification of AI-generated outputs
	P-trAIce M9 - AI Performance Evaluation (Methods)	Describe methods used to evaluate the AI tool(s) performance for the specific tasks within the review (if applicable and feasible). This may include: a. The reference standard used for evaluation (eg, consensus human decisions). b. The metrics used (eg, accuracy, sensitivity, specificity, precision, recall, F1-score). c. Analyzes conducted to access model bias or rate of erroneous ouputs d. Any pilot testing or validation phases conducted prior to full implementation.
	P-trAIce M10 - Data Governance and Ethics	Describe how data handled by AI tools (input, output, intermediate data) was managed and stored, and any measures taken to ensure data privacy, security, and compliance with copyright or terms of service, especially when using third-party cloud-based AI tools.
Results		
	P-trAIce R1 - Study selection (AI-assisted)	The PRISMA flow diagram and text clearly distinguish between records/reports excluded or included based on AI tool decisions versus human reviewer decisions at each screening stage where AI was used. Report the number of records processed by AI and the outcomes of that processing.

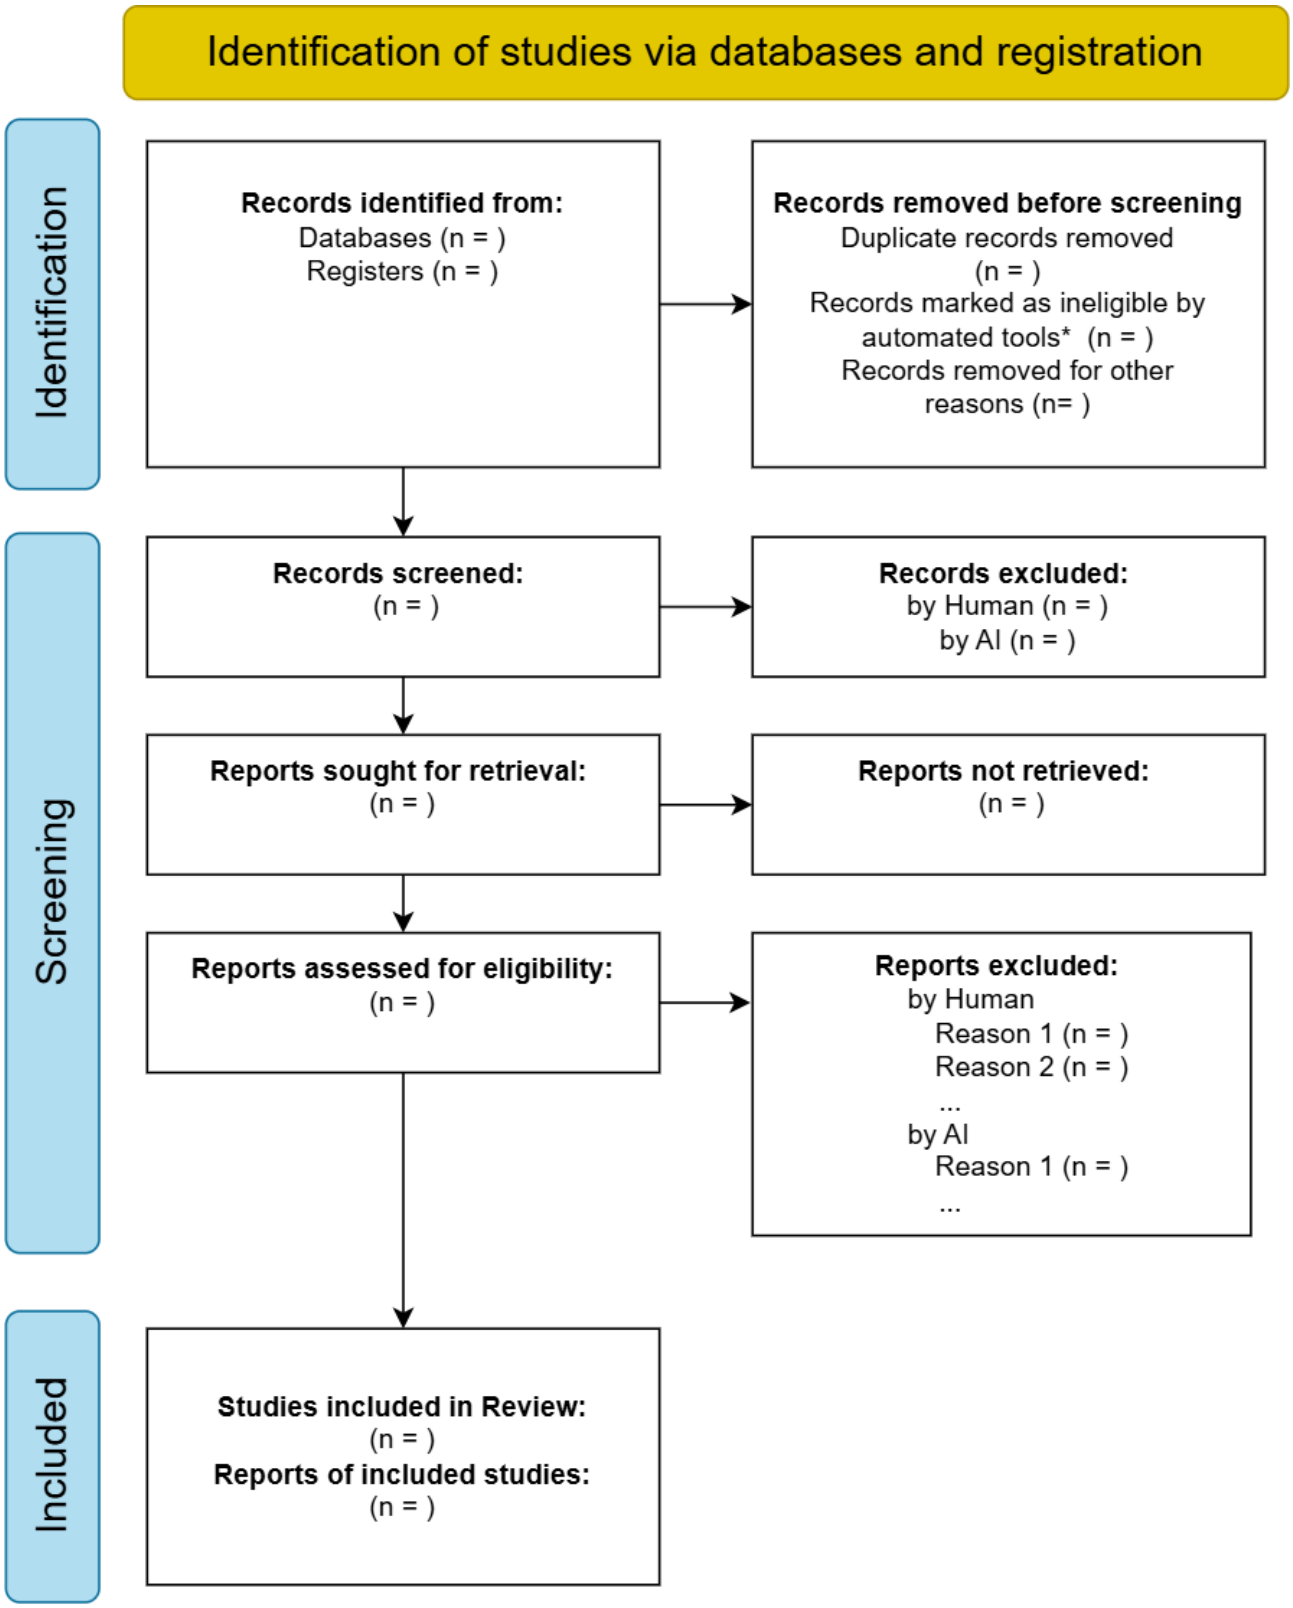
XSL•FO
RenderX

Structural element and item ID		Details
	P-trAIce R2 - AI Performance Metrics (Results)	Report the results of any performance evaluations of the AI tool(s) for the specific tasks within the review (as described in P-trAIce M9). Include quantitative results (see M9) and measures of agreement between AI and human reviewers if assessed.
Discussion		
	P-trAIce D1 - Limitations of AI Use	Discuss any limitations encountered in using the AI tool(s) (eg, technical issues, biases identified, challenges in prompt engineering, unexpected outputs, limitations in AI performance for specific sub-tasks). Discuss how these limitations might have influenced the review process or findings.
	P-trAIce D2 - Implications of AI Use	Briefly discuss the experience of using AI tools in the review, including any perceived benefits (eg, efficiency gains, ability to handle larger datasets) or challenges. Reflect on the usability of the AI tools and the implications for future similar reviews.

[a]PRISMA: Preferred Reporting Items for Systematic Reviews and Meta-Analyses.

[b]LLM: large language model.

[c]GenAI: generative AI.



[d]PICO: population, intervention, comparison, and outcome.

The PRISMA-trAIce Flow Diagram

To enhance the transparency of the study selection process, the standard PRISMA 2020 flow diagram was adapted (Figure 1). While the original diagram already includes “automation tools,” our proposed version sharpens this concept by distinguishing between rule-based administrative tools (eg, for deduplication) and evaluative AI systems. Therefore, the adapted diagram provides specific fields to report the number of records screened separately by AI systems versus human reviewers and the reasons for exclusion. This visual guide offers a more granular and immediate overview of the AI’s role in the screening process.

XSL•FO
RenderX

Figure 1. The PRISMA-trAIce (Preferred Reporting Items for Systematic Reviews and Meta-Analyses–Transparent Reporting of Artificial Intelligence in Comprehensive Evidence Synthesis) flow diagram, an adaptation of the standard PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 flowchart. The core modification is the addition of separate fields to distinguish between exclusions made by human reviewers and those made by artificial intelligence (AI) systems, enhancing the transparency of the screening process while preserving the familiar workflow.

*An automated tool is fundamentally different from an AI application and refers to rule-based tools for administrative tasks (e.g. deduplication).

RenderX

Discussion

Principal Results

This work's primary contribution is the PRISMA-trAIce proposal, a checklist designed as an extension to the PRISMA 2020 statement. Its purpose is to provide a standardized framework for the transparent reporting of AI as a methodological tool in SLRs while maintaining ease of use for everyone who is already familiar with the original PRISMA 2020 statement. By systematically synthesizing core principles from established, consensus-based AI reporting guidelines, we offer a robust starting point to address a critical gap in the current landscape of scientific reporting.

Rationale for a "Living Guideline"

The central challenge in creating reporting guidelines for a field as dynamic as AI is the tension between methodological rigor and timely relevance. A formal consensus process, while it is the standard, risks delivering a meticulously crafted guideline for an already outdated technological landscape. We argue that the immediate risk posed by the nontransparent use of AI tools outweighs the risk of introducing a well-reasoned albeit preliminary guideline. Therefore, our approach is pragmatic, positioning PRISMA-trAIce as a solution that the research community can immediately adopt and refine.

Limitations

The primary limitation of this proposal is inherent in its nature: it is the result of a systematic adaptation, not a formal, large-scale consensus-building exercise, such as a Delphi study. While grounded in established principles, its items have not yet been empirically validated across diverse research contexts. We do not see this as a shortcoming to be rectified later through traditional means but rather as justification for a more modern, agile approach to standard setting.

Therefore, we propose a community-driven, 2-tiered framework to guide the evolution of PRISMA-trAIce into a living standard. This includes (1) a central, stable anchor on GitHub [25] to serve as the single source of truth for the checklist, enabling transparent, version-controlled development; and (2) a dynamic community hub on Discord to foster rapid and low-friction collaboration. To provide a predictable development cycle, we envision a schedule of annual reviews to incorporate community feedback into future versions. This strategy applies the principles of open-source development to scientific standard setting, ensuring that PRISMA-trAIce can evolve in step with the technology it seeks to describe. We invite experts in evidence synthesis, methodology, and AI to contribute to this initiative. Our long-term vision is to foster a self-sustaining ecosystem. To this end, we are committed to facilitating the establishment of a formal steering committee constituted from dedicated members of the expert community, to which stewardship of the standard will ultimately be transferred.

Comparison With Prior Work

PRISMA-trAIce occupies a unique and critical niche within the landscape of AI reporting guidelines by providing the first framework specifically designed for AI as a methodological tool in evidence synthesis, a gap not addressed by existing standards. We position our contribution by highlighting 2 key distinctions.

On the one hand, it focuses on AI as a tool, not the subject. Guidelines such as CONSORT-AI [18] and the TRIPOD (Transparent Reporting of a Multivariable Prediction Model of Individual Prognosis or Diagnosis) statements (including TRIPOD-LLM) [20,23] are indispensable for studies in which AI is the subject of the research, for instance, as a diagnostic intervention or a clinical prediction model. These frameworks guide the reporting of the AI's performance and impact as a study outcome. In contrast, PRISMA-trAIce is designed for the scenario in which AI is part of the research process itself. It guides the reporting on how this tool was used to produce the final systematic review.

On the other hand, it is a discipline-agnostic and SLR-specific framework. While some guidelines offer advice on reporting the use of AI tools, their scope is often domain specific. The GAMER [24] guideline, for example, provides valuable recommendations but is explicitly tailored to the field of medicine. PRISMA-trAIce, by design, is an extension of the universally adopted PRISMA 2020 statement. This makes it inherently discipline agnostic and directly integrable into the established workflow of systematic reviews across any field, from engineering to social sciences. Its structure is mapped directly onto the sections of an SLR, a level of specificity for the evidence synthesis process that other AI reporting guidelines do not provide.

Therefore, by focusing on AI as a methodological tool in a discipline-agnostic and SLR-specific manner, PRISMA-trAIce complements existing guidelines and addresses a critical, unmet need for transparency in the next generation of evidence syntheses.

Conclusions

The integration of AI into systematic reviews marks a disruptive moment in evidence synthesis, promising efficiency but demanding a renewed commitment to rigor. The current lack of a standardized reporting framework represents a critical threat to the transparency and trustworthiness of these AI-assisted reviews. The proposed PRISMA-trAIce checklist provides a foundational tool to address this challenge, aiming to immediately improve transparency while paving the way for a formal, community-endorsed standard.

Acknowledgments

The authors would like to thank their colleagues for their insightful discussions and feedback during the development of this manuscript. The authors acknowledge the use of the artificial intelligence (AI) model Gemini 2.5 Pro (Google DeepMind), including its research and collaborative features, during the preparation of this manuscript from June 2025 to July 2025. The

XSL•FO
RenderX

model was used via its web-based user interface to assist with conceptual brainstorming and the elaboration of ideas, supplementary web research and fact-checking, writing to improve readability and linguistic precision, and initial consistency checks of arguments and terminology. The interaction process involved providing the AI with specific prompts, manuscript drafts, and various source documents. All AI-generated outputs were critically reviewed, verified, and edited by the authors. While the model proved effective, the authors observed rare instances of erroneous outputs ("hallucinations"), which reinforces that rigorous human quality control is mandatory. The authors retain full and final responsibility for the scientific integrity of this work.

Abstract

Background: Pathophysiological responses to viral infections such as COVID-19 significantly affect sleep duration, sleep quality, and concomitant cardiorespiratory function. The widespread adoption of consumer smart bed technology presents a unique opportunity for unobtrusive, real-world, longitudinal monitoring of sleep and physiological signals, which may be valuable for infectious illness surveillance and early detection. During the COVID-19 pandemic, scalable and noninvasive methods for identifying subtle early symptoms in naturalistic settings became increasingly important. Existing digital health studies have largely relied on wearables or patient self-reports, with limited adherence and recall bias. In contrast, smart bed–derived signals enable high-frequency objective data capture with minimal user burden.

Objective: The aim of this study was to leverage objective, longitudinal biometric data captured using ballistocardiography signals from a consumer smart bed platform, along with predictive modeling, to detect and monitor COVID-19 symptoms at an individual level.

Methods: A retrospective cohort of 1725 US adults with sufficient longitudinal data and completed surveys reporting COVID-19 test outcomes was identified from users of a smart bed system. Smart bed ballistocardiography-derived metrics included nightly pulse rate, respiratory rate, total sleep time, sleep stages, and movement patterns. Participants served as their own controls, comparing reference (baseline) and symptomatic periods. A two-stage analytical pipeline was used: (1) a gradient-boosted decision-tree "symptom detection model" independently classified each sleep session as symptomatic or not, and (2) an "illness-symptom progression model" using a Gaussian Mixture Hidden Markov Model estimated the probability of symptomatic states across contiguous sleep sessions by leveraging the temporal relationship in the data. Statistical analyses evaluated within-subject changes, and the model's ability to discriminate illness windows was quantified using receiver operating characteristic metrics.

Results: Out of 122 participants who tested positive for COVID-19, symptoms were detected by the model in 104 cases. Across the cohort, the model captured significant deviations in sleep and cardiorespiratory metrics during symptomatic periods compared to baseline, with an area under the receiver operating characteristic curve of 0.80, indicating high discriminatory performance. Limitations included reliance on self-reported symptoms and test status, as well as the demographic makeup of the smart bed user base.

Conclusions: Smart beds represent a valuable resource for passively collecting objective, longitudinal sleep and physiological data. The findings support the feasibility of using these data and machine learning models for real-time detection and tracking of COVID-19 and related illnesses. Future directions include model refinement, integration with other health signals, and applications for population-scale surveillance of emerging infectious diseases.

Introduction

COVID-19 is responsible for a pandemic with hundreds of millions of confirmed cases and millions of deaths worldwide [1]. The majority of patients with COVID-19 (~80%) have mild influenza-like symptoms, 15% have severe symptoms, and approximately 5% develop a critical condition [2]. COVID-19 symptoms overlap with other respiratory illnesses, such as influenza, severe acute respiratory syndrome (SARS), and Middle East Respiratory Syndrome (MERS) [3,4].

"Smart" devices capable of collecting longitudinal biosignal datasets hold promise for infectious illness monitoring [5]. Consumer devices that track biometric signals over prolonged periods, such as fitness trackers and smartwatches, may be ideal tools for this task [6]. If worn consistently, these devices can establish baseline values for biometric signals and then detect deviations from baseline, such as during illness [7,8]. When used in conjunction with predictive platforms, symptoms of COVID-19 can be detected and symptom exacerbation monitored in participants using wearable smart devices [9,10]. Some studies have demonstrated that changes from baseline in certain biometric indicators measured by these devices, including resting heart rate, sleep duration, oxygen saturation, or breathing rate, might predict the onset of COVID-19 before symptoms are present [9-18].

Sleep metrics are revealing health indicators due to sleep's important role in immunity. Studies have shown that sleep duration affects the susceptibility to, and survival from, infectious disease [19]. Certain antimicrobial peptides and cytokines act to prolong sleep, and increased sleep during infection is protective [20]. Thus, a possible immunological function of sleep is to support host defense, which has the evolutionary advantage of preparing the immunological response during a period of low metabolic need and quiescence [21].

Conversely, sleep disturbance appears to negatively impact immune function. For example, sleep deprivation induces a temporal shift in circulating levels of interleukin-6 (IL-6), such that IL-6 is undersecreted at night and oversecreted during the day, leading to excessive levels of daytime inflammation [22]. Moreover, sleep disturbance may impair the adaptive immune response, which could compromise the effectiveness of vaccines [23,24]. Although prior research suggests that perivaccination sleep influences antibody response, evidence on whether sleep disturbances impact real-world vaccine effectiveness remains limited and sometimes inconclusive. Notably, sleep metrics such as awakening frequency have shown associations with breakthrough infections beyond traditional risk factors [25].

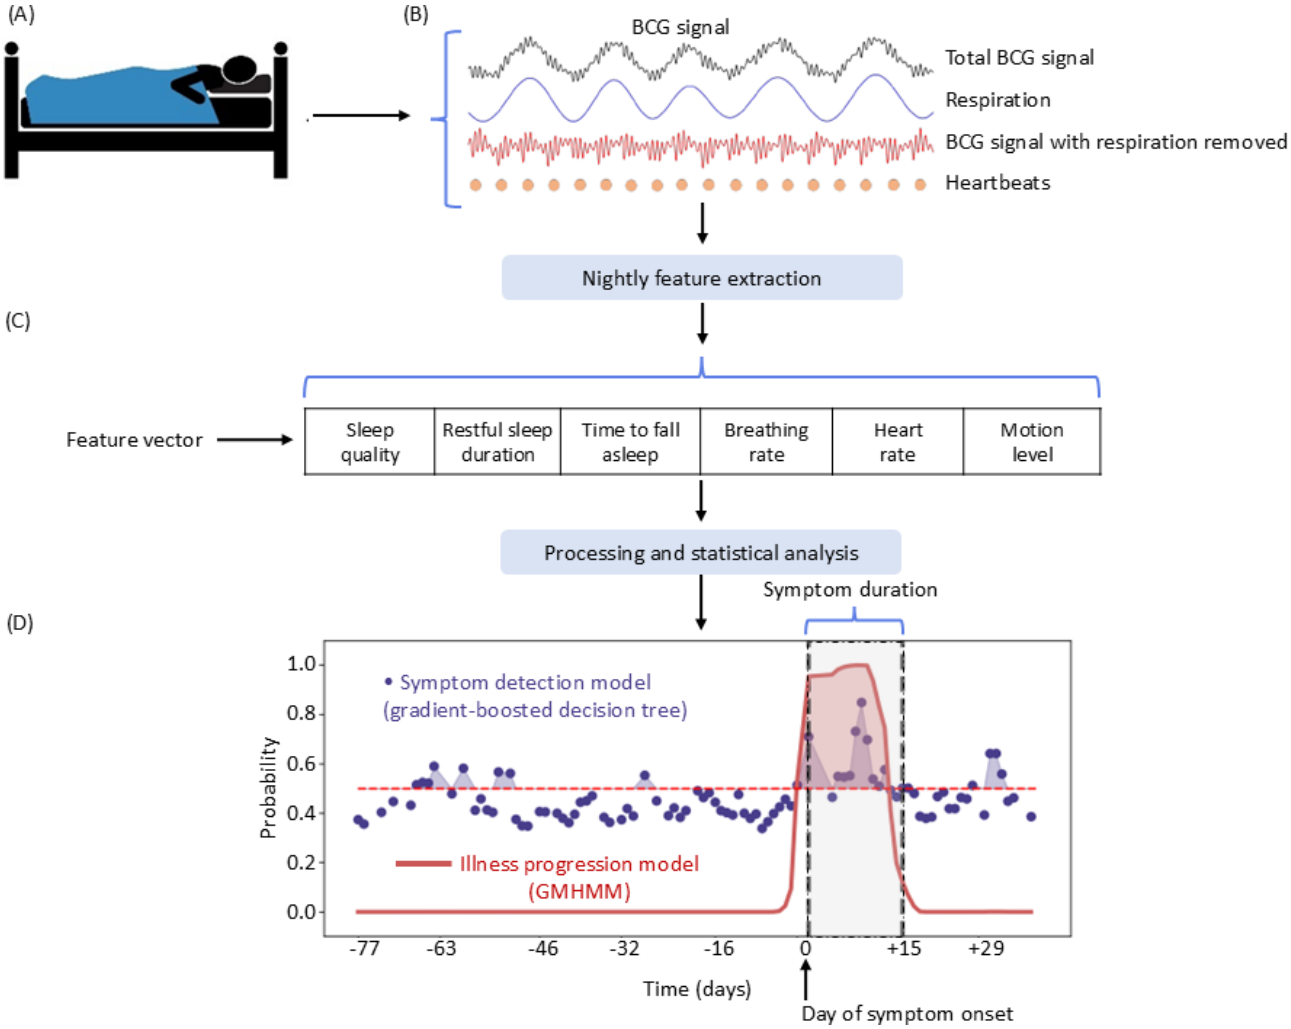
While reduced sleep has been associated with an increased risk of respiratory infections, such as pneumonia and susceptibility to the common cold [26,27], immune activation triggered by microbial infections has also been linked to disruptions in both non–rapid eye movement and rapid eye movement sleep stages [19].

Previously, we demonstrated the ability to use sleep metrics collected from users of a smart bed platform to detect influenza-like illness (ILI) symptoms [28,29]. Using aggregated sleep data, we investigated whether seasonal trends in ILI rates reported by the US Centers for Disease Control and Prevention (CDC) could be approximated using predictions from our ILI symptom detection model described below [28]. The model predictions correlated with the reported ILI rates in the period from January 2019 to December 2020.

The ILI symptom detection model described herein comprises 2 stages: first, the binary detection-level stage that is based on the association between disturbed sleep and immune activation due to infection; and second, a temporal-dimension stage that is based on the association between disturbed sleep and immune activation due to infection. A temporal-dimension stage based on a Gaussian Mixture Hidden Markov State transition model (GMHMM) that accounts for the fact that the transition between ill and healthy states likely depends on historical data.

The aim of this study was to leverage longitudinal, retrospective, biometric data captured using ballistocardiography signals from a consumer smart bed platform [30] along with predictive modeling to detect and monitor COVID-19 symptoms at an individual level. Importantly, the data were acquired unobtrusively during sleep.

Methods



Smart Bed Technology

The Sleep Number smart bed technology tracks the user's bed presence, body movements, heart rate, and breathing rate in real time to determine the duration and quality of sleep [30]. Similar to bed sensors used in health care facilities and consumer solutions located under the mattress [31,32], the smart bed uses a single pressure sensor embedded inside the mattress's inflatable bladder to capture high-resolution full-body ballistocardiography readings, sampled at 1 kHz [30]. This type of smart bed is currently used by several hundred thousand individuals across the United States, spanning a broad age range, and operates without the need for specific sensor calibration [33].

The smart bed starts collecting data as soon as the participant gets into bed and stops once they leave the bed (Figure 1A–D). Embedded software processes the data and sends the sleep metrics to the cloud [30]. Features used for this model include breathing rate (all-night mean of the instantaneous breathing rate), heart rate (all-night mean of the instantaneous heart rate), motion (mean normalized motion: difference between maximum and minimum pressure signal for 10 seconds; normalized motion is then calculated by dividing motion by the personal pressure), total sleep duration (time in bed while asleep), restful sleep duration (sleep duration minus restless time: amount of time where the motion level is higher than the motion-noise-threshold [baseline noise for an in-bed interval]), time to fall asleep (time between getting into bed and falling asleep), and sleep quality (the "Sleep IQ" score provided in the Sleep Number mobile app that correlates with sleep quality). The data are then organized into sleep sessions, defined by a continuous time spent in bed not containing any out-of-bed period longer than 2 hours.

Survey Description and Inclusion Criteria

The survey included questions on demographics, pre-existing health conditions, general health and behaviors, and COVID-19–specific questions about exposure, testing, diagnosis, symptomatic period, and hospitalization that occurred before November 2020. The full survey is provided in the Multimedia Appendix 1. The survey collected data between August 2020 and November 2020. Of the participants who completed the survey, the respondents who provided the results of a COVID-19 test were considered for further analysis.

We included COVID-19–positive responders who satisfied the following inclusion criteria: both the start and end dates of the symptomatic period (mo/d) for their "first positive test" or "most recent test" were reported, the start date was before the end date, the available smart bed data included at least 3 sleep sessions during the symptomatic period, and the smart bed data included at least 3 sleep sessions outside the symptomatic period.

The symptomatic period was assessed based on participant responses to 2 survey items. The first item asked participants to indicate when they initially experienced symptoms and when those symptoms became most severe. The second item asked when their symptoms began to subside. Specifically, participants provided three dates: the onset of symptoms, the onset of the most severe symptoms, and the beginning of symptom resolution. COVID-19 test results obtained prior to the survey period (August 2020 to November 2020) were included in the analysis, with the testing period spanning March 2020 to November 2020.

We included COVID-19–negative responders who satisfied the following inclusion criteria: the test date (mo/d) was reported, there was no symptomatic period, the smart bed data included at least 3 sleep sessions in the COVID-19 test interval of ± 7 days, and the data included at least 3 sleep sessions outside of the test interval.

Participant cohort comparisons were made using Cohen *d* effect size. Mann-Whitney and Fisher exact tests were performed to analyze the differences between groups.

Model Development

Figure 1A–D represents the overview of our approach, which includes the use of ballistocardiography-enabled measurement of motion, position changes, breathing, and small movements within the body, such as those generated by the ejection of blood with every heartbeat [30]. The data were organized into sleep sessions, each corresponding to 1 night of sleep. For each sleep

XSL•FO
RenderX

session, we obtained the following metrics: total sleep duration, sleep quality, restful sleep duration, time to fall asleep, mean breathing rate, mean heart rate, and mean motion level (Figure 1C).

Each sleep session in either the COVID-19–positive or COVID-19–negative group included start and end dates. The end date was used to define the date to which a sleep session corresponds. Multiple sleep sessions with the same end date were merged as follows: values for breathing rate, heart rate, and motion were averaged; values for sleep duration, restful sleep duration, and time to fall asleep were summed; and the sleep quality of the combined sleep session was obtained by weighted (ie, according to sleep duration) average of the sleep quality of individual sessions. Each variable was centered by subtracting the median and dividing by the interquartile range. Such normalization was found to slightly improve the classification performance compared to the standard scaling.

We developed our detection model in 2 stages. First, a gradient-boosted, decision-tree [34] "symptom detection model" was created to classify each sleep session as symptomatic or not (Figure 1D). Second, an "ILI-symptom progression model" was built on the symptom detection model to include the temporal dimension of the symptoms and to estimate the probability of experiencing ILI symptoms (Figure 1D).

Symptom Detection Model

The symptom detection model used self-reported data as a reference to classify each sleep session as symptomatic or not, using the range of symptomatic days provided by the survey respondents who reported a positive COVID-19 diagnosis.

Since the model detected periods of sleep metrics consistent with other ILIs, there were a few unlabeled positives in the validation data that were not specific to COVID-19. Thus, any prolonged ILI episode was an unlabeled positive in the data. As our dataset did not have negative ground truth labels (ie, ranges of dates labeled as healthy), we followed the approach in [35] and trained a propensity-weighted estimator. To create the symptom detection model, an initial estimator based on a gradient boosted decision tree [34] was used to predict the probability that a point belonging to the positive class had been assigned a positive label. Then, a second estimator was trained to classify the data into positive and negative classes using the labeling weights produced by the first estimator. These 2 estimators were iteratively trained with the Expectation Maximization algorithm until convergence [35].

The symptom detection model was used as the base model to produce the propensity score of a sleep session to be labeled as symptomatic. The hyperparameters were tuned using stratified, five-fold cross-validation to maximize a modified F_1-score [36], which can be estimated using positive labels alone. The modified F_1-score is defined as $F_1=\mathrm{TPR}^2/(1-\mathrm{NR})$.

TPR is the true positive rate, and NR is the negative rate of the predictions on the whole dataset. This formula prioritizes sensitivity by squaring TPR and penalizes models that over-predict negatives. Unlike the traditional F_1-score, this metric does not rely on precision and recall, as the unreliability of negative ground truth labels could distort precision estimates.

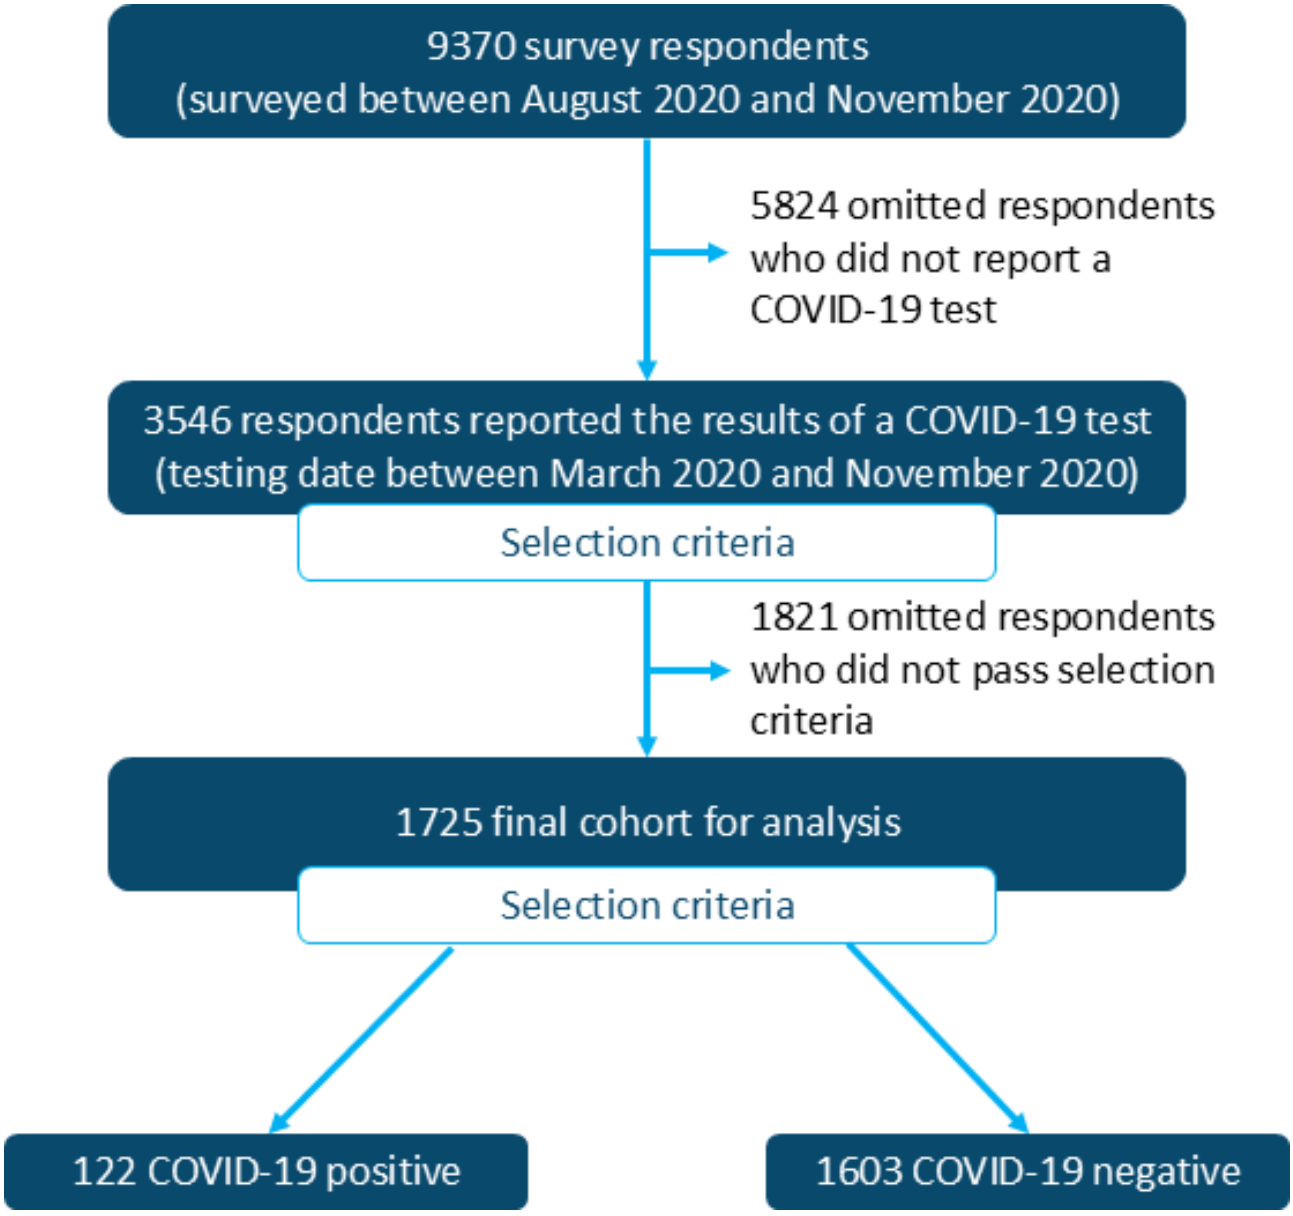
ILI-Symptom Progression Model

The "symptom detection model" was augmented with a second-level "ILI-symptom progression model" to estimate the probability of each sleep session to be symptomatic or not by leveraging the temporal dimension of the study (Figure 1). We used a GMHMM [37] because of its ability to generalize to multidimensional continuous observations and represent particular stages of several illnesses, enabling granular progression tracking.

At a given time, an individual could be in one of the two hidden states: 'ill' or 'healthy.' The estimated probability of the symptoms from the first-level model was taken as the observed emissions in the GMHMM. To detect illness, we calculated the posterior probabilities of the hidden states, which can be thought of as a smoothing filter.

The GMHMM parameters (ie, prior, transition, and emission probabilities) were also tuned to maximize the modified F_1-score [36]. The simulated annealing optimizer from Python's SciPy library [38] was used for this purpose. The input scores from the symptom detection model were calculated using a leave-one-out cross-validation approach.

Ethical Considerations



This research was conducted in accordance with US federal guidelines (Common Rule) regulating the protection of human participants in biomedical and behavioral research. The protocol describing this research (#P2020/03001 NEIRB 17-1323071-1) was approved by the WCG New England Institutional Review Board (IRB). Participants were users of the Sleep Number smart bed. Data were collected daily. Informed consent was obtained from all participants using the Sleep IQ app (Sleep Number Corporation) on the participant's smartphone, computer, or other electronic device of their choice. Participants gave access to nightly physiological measurements, which were electronically stored in the cloud after being anonymized. Participants completed an IRB-approved survey between August 2020 and November 2020. Participants did not receive any form of compensation for participation in this research. All collected data were anonymized before analysis, and no individual participant could be identified from the data. No images or supplementary materials contain identifiable participant information.

Results

More than 9000 (N=9370) Sleep Number bed users ("participants") responded to an IRB-approved survey from August 2020 to November 2020. Of the 9370 participants who completed the survey, 3546 (37.8%) reported results of a COVID-19 test (Figure 2).

XSL•FO
RenderX

Figure 2. The final study cohort was composed of participants who reported a COVID-19 test result and met the inclusion criteria.

The final cohort used in subsequent analyses was composed of 1725 participants with a known COVID-19 test outcome between March 2020 and November 2020 (Figure 2). The study cohort had a mean age of 49.5 (SD 13) years; 47.5% (820/1725) of the participants were male and had a mean BMI of 30.2 (SD 6.9) kg/m^2. The cohort's ethnic composition was 83.5% (1441/1725) White, 4.5% (165/3576) Black, 5.86% (101/1725) Hispanic, and 2.09% (36/1725) Asian (Table 1). In addition, 9.6% (166/1725) of the cohort smoked, 16.2% (279/1725) had asthma, 10.1% (174/1725) had diabetes, and 3.4% (58/1725) had cardiovascular disease.

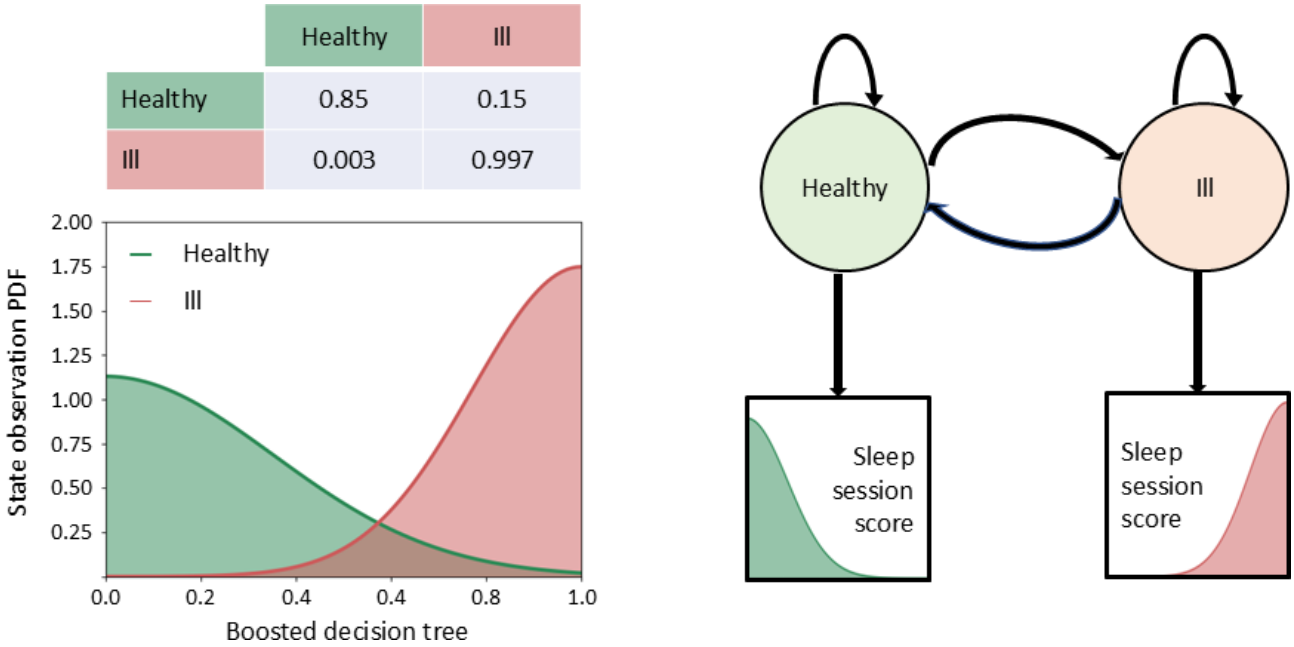
[a]Mann–Whitney *U* test (1-sided) was used to compare distributions of age and BMI. Fisher exact test (2-sided) was used to compare the rates for gender and comorbidities.

[b]Participants with COVID-19 (n=3546) test versus those meeting the inclusion criteria (n=1725).

[c]COVID-19–postive cohort (n=122) versus COVID-19–negative cohort (n=1603)

[d]CVD: cardiovascular disease.

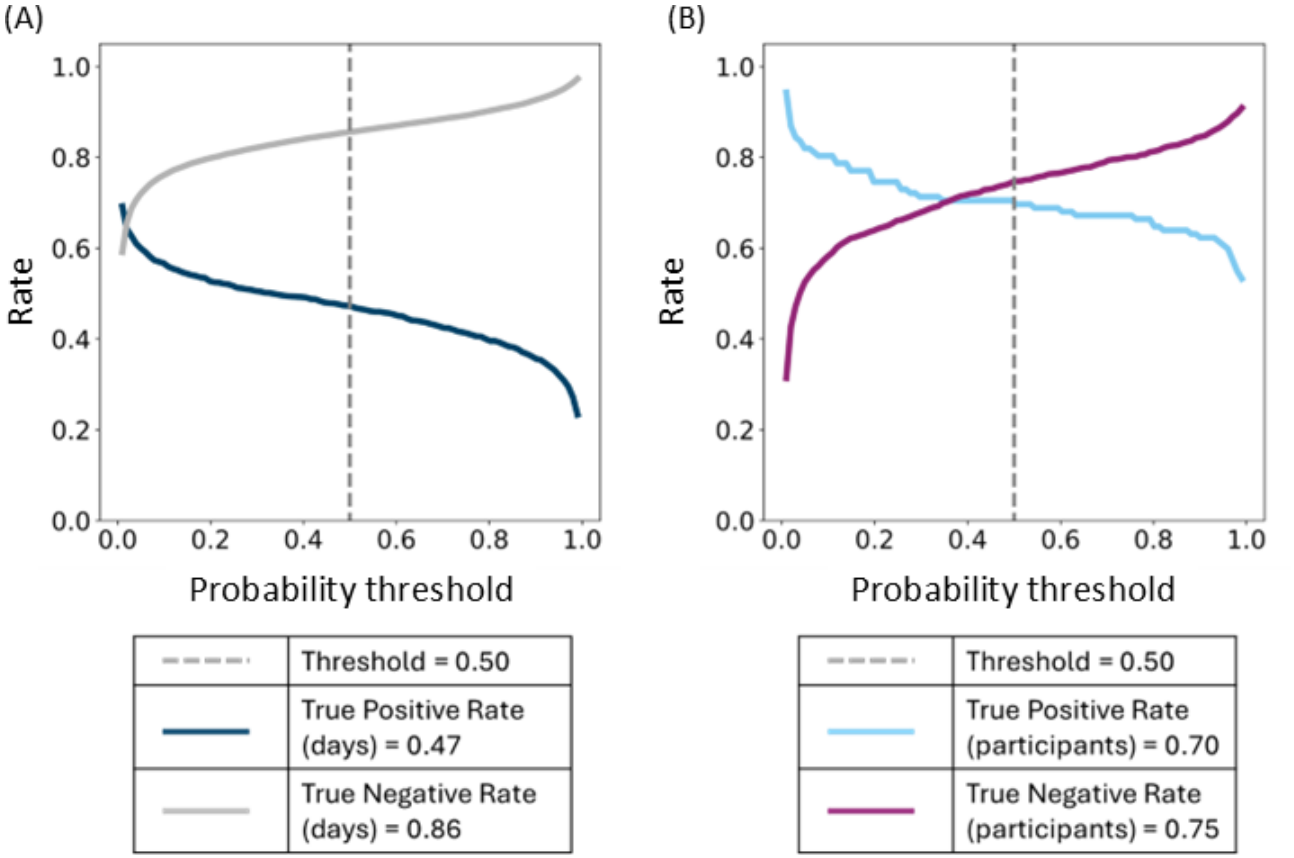
Of this cohort, 7.1% (122/1725) reported a positive test result for COVID-19. There were 2 significant differences between the COVID-19–positive and COVID-19–negative groups in terms of demographic and comorbidity measures. (1) Age: the COVID-19–positive group was significantly younger than the COVID-19–negative group (mean age 45.6, SD 11.9 years vs 49.8, SD 13.1 years; Cohen *d*=0.33; *P*<.001). (2) Percent of Hispanics: the COVID-19–positive group had a significantly higher percent of Hispanic individuals than the COVID-19–negative group (13/122, 10.7% vs 88/1603, 5.49%).



There were significant differences in the demographics of the total population of survey respondents and respondents who met the inclusion criteria age (mean age 48, SD 12.9 years vs 49.5, SD 13 years; Cohen *d*=0.11; *P*<.001), gender (male 43.5 % vs female 49.2 %; *P*<.01), and percent of White individuals (83.5 % vs 80.4%; *P*=.001).

For the COVID-19–positive cohort, the symptomatic window median was 10 days and the mean was 13.7 days. In total, 1674 person-days for the symptomatic period and 18 negative sleep sessions were used to build the symptom detection and ILI-symptom progression models.

The estimated parameters of the 2-state GMHMM model resulted in the prior probabilities and transition probabilities reported in Figure 3.



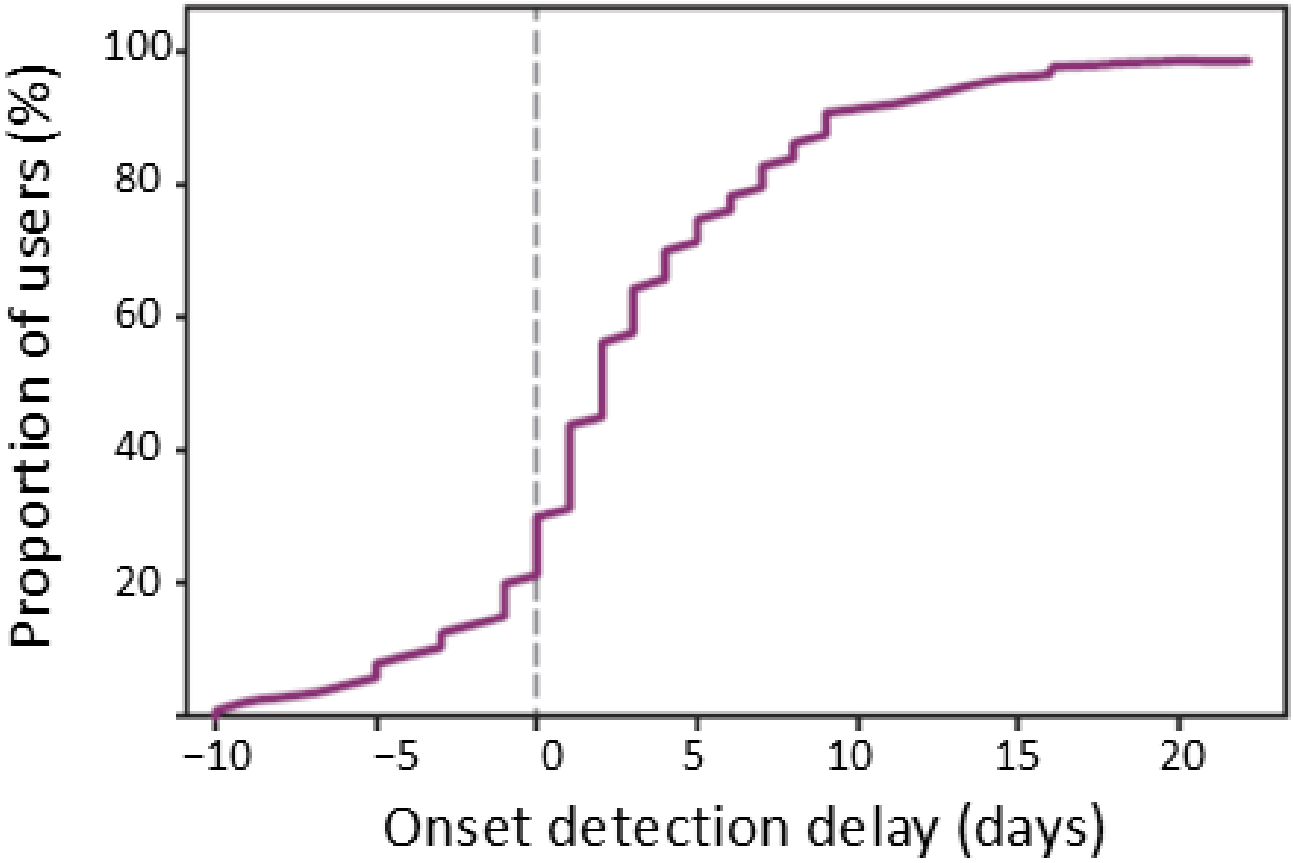
XSL•FO
RenderX

Figure 3. Gaussian Mixture Hidden Markov State transition model states and transition probability. PDF: probability density function.

The combined performance of the 2-model system was evaluated as follows. First, we calculated true positive rates for the reported symptomatic days and the negative rates for the unlabeled days as a function of the probability (of being in the illness state) threshold=0.5 (Figure 4A; true positive rate: 0.47; true negative rate: 0.86; false positive rate: 0.14).

Figure 4. Evaluation of model performance. Symptom detection rates were calculated for (**A**) individual observed days or (**B**) participants, as a function of the probability threshold.

Next, we aggregated the results per participant and, as was done in the study by Krueger et al [20], recorded a successful detection if at least 1 day within the reported symptomatic interval was classified as positive (Figure 4B; true positive rate: 0.70; true negative rate: 0.75; false positive rate: 0.25). If a day or multiple days outside the participant's self-reported symptomatic period are detected as positive by the model, the participant is categorized as negative. This approach ensures that model predictions outside the symptomatic period do not influence the classification of a participant's overall status.



XSL•FO
RenderX

For the negative cohort, the 2-week interval around the date of the COVID-19 test administration was analyzed in the same manner as for the positive cohort. During this interval, 25% (401/1603) of the negative individuals had at least 1 day detected as positive by the model. Specifically, 401 of 1603 (25%) negative individuals were identified with at least 1 day of positive detection within the 2-week period. Conversely, 1202 of 1603 (75%) negative individuals were correctly classified as negative.

Using the 0.5 threshold on the probability, symptoms were detected in 104 of the 122 positive cases. The remaining 18 cases were categorized into 3 groups: (1) missing data before or during the symptomatic range (n=2); (2) the reported symptomatic range was abnormally short (n=2); or (3) the presence of mild symptoms was not detected by the model (n=14). Conversely, symptoms may have been detected in the negative cases due to abnormal sleep patterns not associated with a COVID-19 diagnosis, or COVID-19 tests may have been conducted too early or too late to detect a positive result (ie, a false-negative result).

To assess the temporal performance of our model, we calculated the detection delay (ie, the difference between the predicted first day of symptoms and the reported one). Using the 0.5 threshold, we obtained the median delay of 2 days, with 75% of the cases detected by the fifth day (Figure 5).

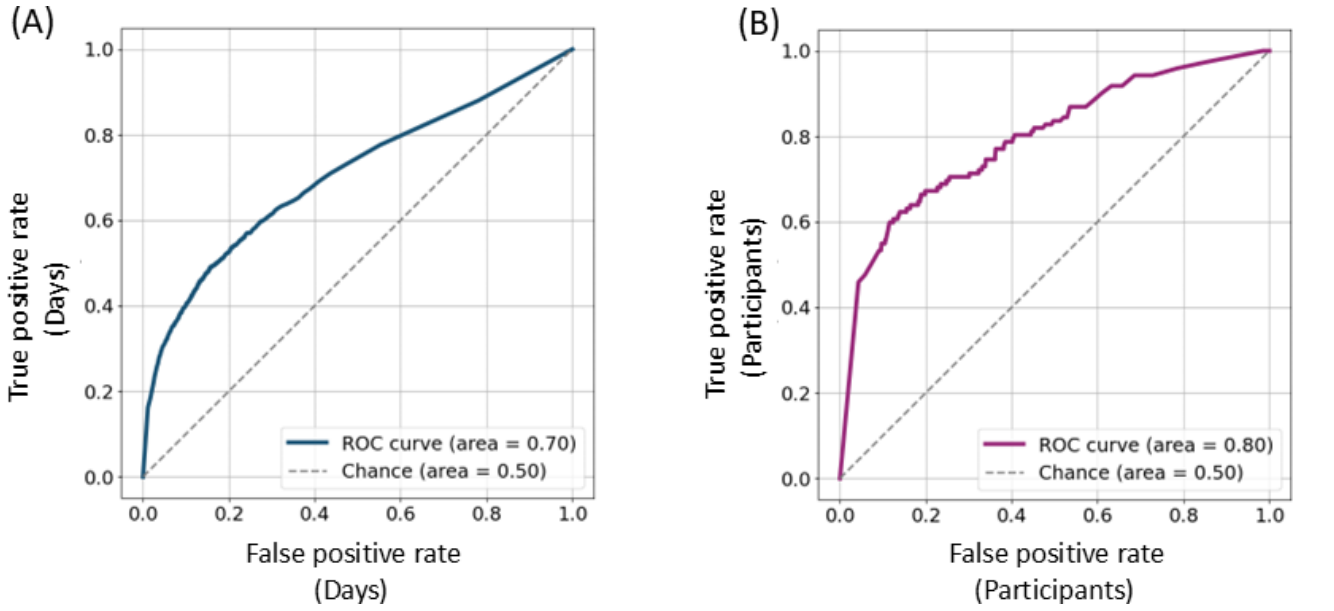


Figure 5. Distribution of the detected symptom onset day relative to the reported onset day.

The threshold on the probability of being in the illness state was used as a parameter to build a receiving operating characteristic (ROC) curve at a day-level (Figure 6A) and at a participant level (Figure 6B). The estimated area under the ROC curve is 0.70 and 0.80, respectively. The latter, according to the interpretation in [39], indicates that our model may have diagnostic use.

XSL•FO
RenderX

Figure 6. Receiving operating characteristic curve. True-positive and false-positive rates were calculated for (**A**) individual observed days or (**B**) participants as a function of the probability threshold. ROC: receiver operating characteristic.

Discussion

Principal Findings

This study demonstrates the potential value of smart bed technology for early detection and longitudinal monitoring of influenza-like illnesses, with a focus on COVID-19, using unobtrusively collected real-world sleep and physiological data.

By leveraging a 2-stage predictive modeling approach that classifies sleep sessions and tracks symptom progression, we were able to accurately detect the onset and duration of symptoms in most individuals with a positive COVID-19 diagnosis from a large, naturalistic cohort of smart bed users. The model's high true positive rate underscores the potential of passive, continuous biometric monitoring for supporting timely health interventions and for providing reassurance to users about evolving illness trajectories. Notably, our approach requires only routine bed use rather than the consistent wearing of a device, facilitating high adherence even during periods of illness.

Comparison to Prior Work

Several studies have demonstrated the use of smart devices to track or predict COVID-19 symptoms [9-18]. However, these typically require consistent use of wearable devices that may prove difficult during symptomatic periods. In contrast, our method passively gathers physiological and sleep data without requiring extra effort from the user.

We have previously demonstrated the ability of a smart bed, using ballistocardiography, to detect ILIs [28]. This system has been validated against the gold standard, polysomnography, to provide reliable longitudinal sleep metrics and only requires that the user sleep in their bed consistently [30].

To our knowledge, this is the first study that considers real-world, longitudinal data collected during sleep that was unobtrusively and noninvasively acquired from a smart bed to track and detect COVID-19 symptoms. Our predictive model was built in 2 stages. First, survey data were used to classify participants into groups by self-report of negative or positive COVID-19 test results. These results were used in the symptom detection model to estimate the probability that a sleep session should be labeled "ill." Second, the GMHMM ILI-symptom progression model was used to refine the probability estimation by incorporating the temporal dimension.

Our data analytics approach and subsequent classification model successfully detected the presence of symptoms and the duration of symptoms with a high true positive rate. As was previously demonstrated [28,29], the ability of our system to capture these endpoints is not limited to COVID-19 and can be broadly applicable to other respiratory illnesses.

Future Directions

The sleep metrics measured with a smart bed platform are a unique source of longitudinal data, collected in a real-world and unobtrusive manner [30]. In the future, this system may serve as an asset in predicting and tracking the development of symptoms associated with a wide variety of respiratory illnesses.

A potential avenue for extending the utility of smart bed technology involves providing participants with actionable feedback about detected health anomalies, such as COVID-19–related symptoms. Recent research has demonstrated the feasibility of alert-based systems to prompt diagnostic testing in decentralized settings, combining self-reported symptoms and wearable physiological data to identify respiratory infections [40].

To better establish specificity for COVID-19 and related illnesses, future research should incorporate additional control groups representing other respiratory infections, such as influenza, SARS, and MERS.

Limitations

There are several limitations to this study. First, the study cohort consisted entirely of Sleep Number customers, and this cohort

XSL•FO
RenderX

may not be representative of the general population in terms of demographics or socioeconomic factors.

Second, a subset of the COVID-19–positive participants did not consistently sleep on their smart bed during the duration of their illness, indicating that as illness arises, smart device usage may change. Decreases in the smart bed usage were likely due to COVID-19 guidelines that suggested sleep isolation to mitigate the spread of illness among members of a household. Furthermore, as changes in sleep metrics are associated with general immune responses, the observed changes could represent several illnesses, respiratory or otherwise [10,41].

Third, several unlabeled positives representing other potential ILIs or undiagnosed COVID-19 infections were used in model validation. Hence, our "true negative rate" is biased and is more appropriately called "negative rate," as is conventional in positive-unlabeled machine learning. Furthermore, it is possible that negative test results could have been obtained when COVID-19 testing was conducted outside of the window in which a positive result would have been detected.

Fourth, the study did not rely on objective data alone; instead, retrospective recall was required to identify COVID-19–positive symptom periods. The latter may introduce recall bias, particularly regarding the accuracy of reported illness periods. The 2-stage model used in this research refines the model predictions, which can mitigate the bias to some extent, but its influence cannot be entirely eliminated.

Fifth, the specificity of our approach for COVID-19 remains to be validated, as other illnesses —such as influenza, SARS, and MERS—exhibit similar symptomatology. To test the specificity of COVID-19 symptom detection, future research should incorporate a control group with respiratory infections exhibiting similar symptoms to COVID-19. Furthermore, while our model accounts for COVID-19–related symptoms, it does not explicitly address the influence of external factors, such as stress, anxiety, or other health conditions, which are known to affect sleep metrics (eg, sleep duration and fragmentation) [42]. These factors could introduce variability in the observed sleep patterns, potentially influencing the model's predictions. Future studies should consider collecting and incorporating data on mental health, comorbidities, and other relevant factors to better isolate the effects of COVID-19 on sleep metrics and improve the robustness of the approach.

Conclusions

This study demonstrates the feasibility of using smart bed–derived, longitudinal sleep and physiological data to detect and monitor self-reported symptoms of COVID-19. Our 2-stage modeling approach identified deviations in sleep duration, heart rate, and breathing rate during illness periods, correctly detecting symptoms in 104 out of 122 COVID-19–positive cases. The model achieved an area under the receiver operating characteristic curve value of 0.80 at the participant level, supporting the use of passive, in-bed monitoring for illness detection in naturalistic settings.

Acknowledgments

A first draft of this manuscript was written by Jessica Irons, PhD, at Oxford PharmaGenesis and was funded by Sleep Number Corporation. Kevin Monette helped program the survey and monitored responses. No external funding was received for this research. Because of strict company policies, no generative artificial intelligence or large language models were used in the preparation of this manuscript text, except for standard spelling and grammar checking tools.

Abstract

Background: The visual similarity of melanoma and seborrheic keratosis has made it difficult for older patients with disabilities to know when to seek medical attention, contributing to the metastasis of melanoma.

Objective: This study aimed to present a novel multimodal deep learning-based technique to distinguish between melanoma and seborrheic keratosis.

Methods: Our strategy is three-fold: (1) use patient image data to train and test three deep learning models using transfer learning (ResNet50, InceptionV3, and VGG16) and one author-designed model, (2) use patient metadata to train and test a deep learning model, and (3) combine the predictions of the image model with the best accuracy and the metadata model, using nonlinear least squares regression to specify ideal weights to each model for a combined prediction.

Results: The accuracy of the combined model was 88% (195/221 classified correctly) on test data from the HAM10000 dataset. Model reliability was assessed by visualizing the output activation map of each model and comparing the diagnosis patterns to that of dermatologists. The addition of metadata to the image dataset was key to reducing the false-negative and false-positive rates simultaneously, thereby producing better metrics and improving overall model accuracy.

Conclusions: Results from this experiment could be used to eliminate late diagnosis of melanoma via easy access to an app. Future experiments can use text data (subjective data pertaining to how the patient felt over a certain period of time) to allow this model to reflect the real hospital setting to a greater extent.

Introduction

Incidence rates of melanoma have been on an increase since 1999, with 15.1 per 100,000 in 1999 and rising to 23.0 per 100,000 in 2021 [1]. In contrast, seborrheic keratosis is a benign skin appearance that commonly occurs in older adults. While the pathology, epidemiology, and histology of melanoma and seborrheic keratosis are well understood [2, 3, 4, 5], on a surface level, these 2 lesions can seem almost identical to the untrained eye, making it difficult for individuals to know when to seek care [6]. Delayed care can allow a malignant lesion to progress into metastatic melanoma. As the stage of melanoma progresses, the survival rate can decrease as much as 67% [7]. Thus, timely diagnosis and treatment are paramount.

The current diagnostic paradigm has not significantly advanced despite staggering technological leaps. A typical process involves a patient visiting a primary care clinic, followed by a referral to a dermatologist if there are any unusual skin lesions [8]. The dermatologist repeats the skin exam, and then further performs biopsies or excision as required [9]. These samples are sent for pathology, which makes the final diagnosis. This process requires an iterative process involving appropriate presentation to a primary care provider, appropriate referral, appropriate visual analysis, appropriate surgical excision, all before a diagnosis can be made [10].

Deep learning models have commonly been used to encourage at-home, self-diagnosis, or easier physician diagnosis of melanoma [11, 12]. One such experiment used an Iterative Dichotomiser 3 (ID3) algorithm to learn rules from image data using texture patterns, a method known as automatic induction [13]. Another method employed transfer learning [14] and used ResNet152 to develop a binary classifier between benign and malignant skin lesions [15].

Table 1 describes the average area under the curves (AUCs) for medical imaging segmentation for various dermatological machine learning models proposed in literature. The

XSL•FO
RenderX

best-performing model was a combination of ResNet-50 and InceptionV3, with an accuracy of 80%. Most of these approaches aim to optimize models through transfer learning and various preprocessing techniques in an attempt to increase accuracy.

Table . Comparison of machine learning approaches taken in 65 dermatological applications across the internet, with analysis on either the HAM10000 dataset, ISIC dataset, DFUC dataset, or other common datasets ranging from 46 - 33126 data points for evaluation [14].

Model	Accuracy (area under the curve)
ResNet-50	71.620
VGG	68.408
InceptionV3	74.311
ResNet-50 and Inception V3	85.977
ResNet-50 and VGG	83.065
ID3[a]	71.000
BottleNeckCSP	81.000

[a]ID3: Iterative Dichotomiser 3.

Tabular data has been extensively used in various health applications, serving as the basis of many prediction algorithms and machine learning models [16]. One relevant dermatological example used clinical features to represent the redness, flakiness, definite border extent, and other qualities to classify 6 types of erythemato-squamous skin diseases using the UCI Dermatology dataset [17]. Past tabular metadata for health applications have been used to diagnose other, nondermatological-related diseases. A Dual Bayesian ResNet50 model was used to train metadata regarding heart murmurs using XGBoost [18]. Broader applications of tabular metadata have been used through a method called MediTab, in which diverse, out-of-sample data is consolidated and aligned to improve prediction accuracy [19]. Time progression tabular deep learning was used for hypercholesterolemia, in which a multistage deep learning architecture was used to analyze familial hypercholesterolemia [20]. However, this method was not integrated with image data and was purely reliant on tabular data.

Image and tabular predictions can be combined into a hybrid model by using nonlinear least squares regression (NLS) by incorporating both image and tabular predictions in a unified regression model. Past studies have found NLS useful for fusion of heterogeneous sources of data due to its ability to model complex, nonlinear relationships inherent in such data [21]. NLS is a common technique used to fit a model to data by minimizing the square sum of residuals or the squared differences between observed data points and values predicted by the nonlinear model. Minimizing this difference allows for the predictions to more accurately reflect the true value. NLS has been used in pharmacokinetics to understand drug absorption, distribution, metabolization, and excretion [22]. Other applications of NLS appear in tumor growth analysis and medical imaging to enhance image quality [23,24].

Because melanoma prevalence can vary among different demographics, image inputs or metadata inputs alone may not be sufficient in formulating an accurate diagnosis [25]. This paper aims to build on the previous experiments stated and incorporate metadata into the model inputs. While NLS regression has been previously commonly used on raw medical data, this application of NLS leverages its square residuals minimizing abilities to determine ideal weights for the combination of tabular and image data at the output. Finally, providing the model with multiple input modalities helps capture heterogeneous factors that decrease the chances of the model formulating false patterns during classification.

Methods

Overview

Our multimodal deep learning architecture assembly is threefold: (1) use patient image data to train and test three deep learning models using transfer learning (ResNet50, InceptionV3, and VGG16) and one author-designed model, (2) use patient metadata to train and test a deep learning model, and (3) combine the predictions of the image model with the best accuracy and the metadata model, using nonlinear least squares regression to specify ideal weights to each model for a combined prediction.

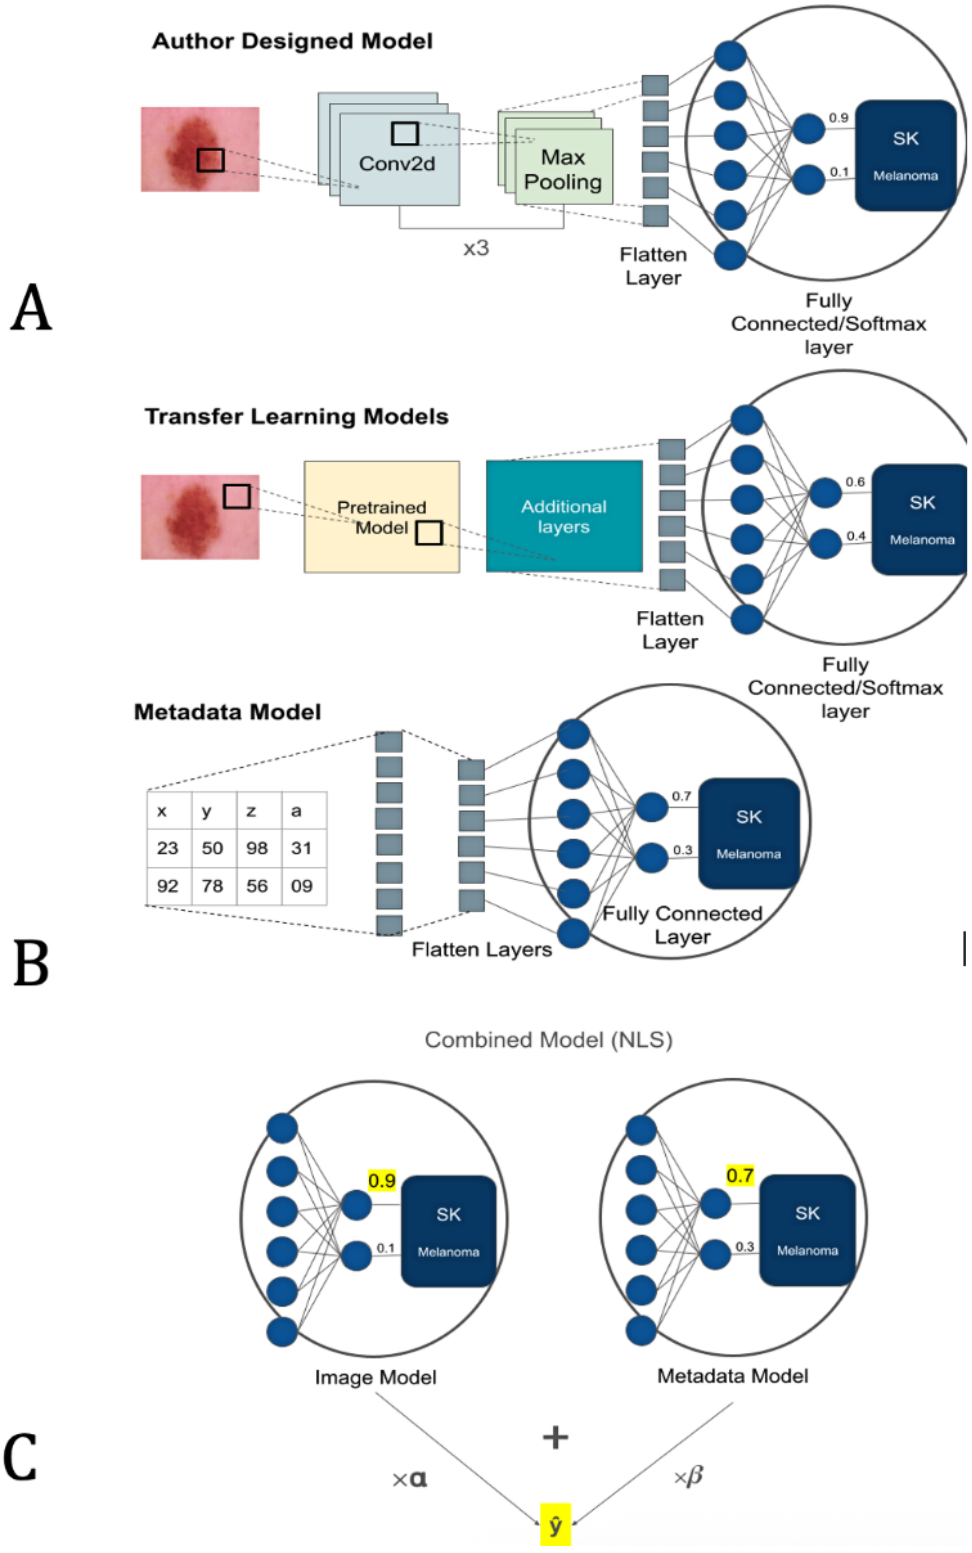
Dataset Analysis

The data used in this experiment was obtained from the HAM10000 dataset [26]. 2259 images were taken from the practice of Cliff Rosendahl consecutively starting 2008 until 2017. 7756 images were taken from the University of Vienna in 1988. Because images were collected from different time periods, some were preprocessed with enhanced contrast and zoom while others were not. While all types of skin conditions were captured in the dataset, for the purposes of this analysis, those images not classed as seborrheic keratosis or melanoma were removed. There were a total of 2210 images, with 50% (1105 images) belonging to melanoma and 50% (1105 images) belonging to seborrheic keratosis.

Data Preparation and Cleaning

Deduplication based on lesion ID was performed to prevent train and test overlap due to the presence of preaugmented images. Using the Python package TensorFlow, the data was split into train (70% or 1547/2210 images), test (10% or 221/2210 images), and validation (20% or 442/2210 images) and then into batches to allow for parallel processing. All splits

XSL•FO
RenderX



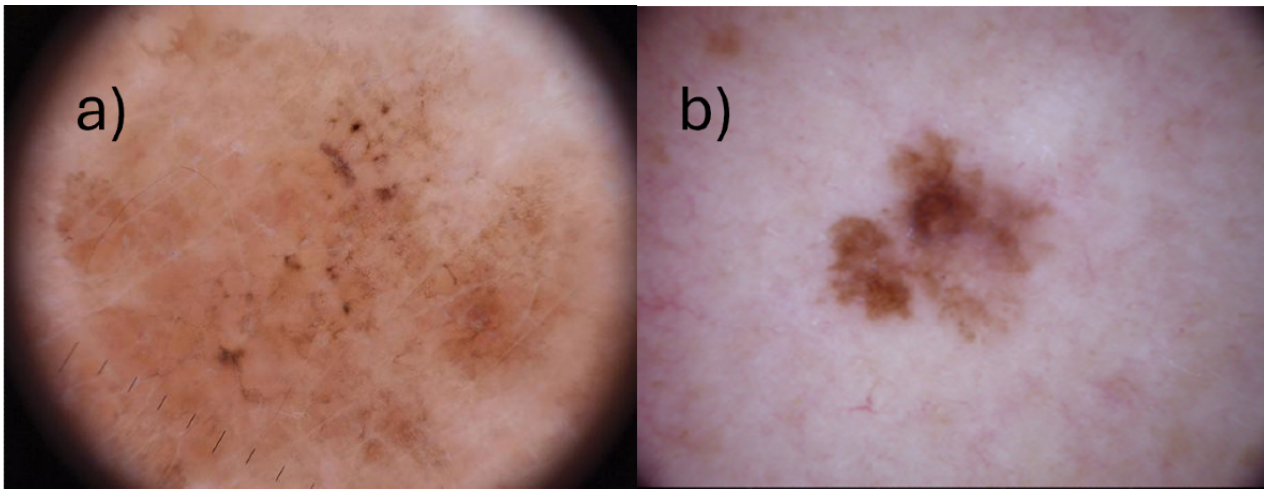
of data were then augmented and normalized to reduce overfitting and ensure equal scaling of pixel values.

Build and Train Image Models

Four image models were developed as depicted in Figure 1: an author-designed model and 3 transfer learning models. The author-designed model contained 3 convolutional layers with max pooling layers following each one, one flatten, and 2 dense layers. Convolutional layers help with extracting features from the image by applying certain weights to them, and max pooling layers assist in this by performing dimensionality reduction on the convolution layer output. Flatten layers once again change the dimensions, and dense layers help with forming global connections between the learned input. The output of this model was determined by the SoftMax layer, which generates a probability of the input belonging to the malignant class. The transfer learning models include pretrained ResNet50, InceptionV3, and VGG16, which were frozen to keep existing memory, and additional trainable layers were added to fine-tune the overall system. Dropouts of 0.3 and L2 weights of 0.01 were used to attempt to mitigate overfitting. All models were run for the same number of epochs, and the run time per epoch was recorded. A larger time was spent on training the transfer learning models because they have more convolutional layers and therefore take longer to output a feature map from each layer.

XSL•FO
RenderX

Figure 1. Architecture of the author designed and transfer learning models. (A) describes the architecture of the image model with three convolutional layers and transfer learning layers, (B) describes the metadata model for processing structured data, and (C) outlines the NLS method used to combine the predictions from each model.



Improving Image Model Accuracy

To improve model accuracy, further data cleaning was performed. Train, test, and validation datasets were manually parsed through with the following metrics in mind:<72 DPI and <600 x 800 px with visuals depicted in Figure 2. 8.3% (183/2210) of the data was eliminated this way and rerun with the same model structure to analyze the effect of image quality on model accuracy.

XSL•FO
RenderX

Figure 2. Examples of faulty and good images. Specific metrics were used for data cleaning. (A) Faulty images, with dots per inch (DPI) <72 and approximate zoom <600×800px were removed. (B) Good images, with DP>72 and approximate zoom 600 × 800px were kept. 200 out of 2400 faulty images were removed from the dataset using these specifications, 100 from each class.

Metadata Cleaning and Run

After optimizing and validating the image model, the metadata was cleaned and split similar to the image data. A train, test, and validation dataset was built that matched that of the images using matching image IDs to ensure controlled training. Categorical columns were made numerical through manual mapping, and the data was standardized using a built-in package called StandardScaler. A simple model architecture with only dense layers was used as visual patterns are not necessary for structured data. However, even without convolutional layers, global knowledge pattern formation was achieved through dense (fully connected) layers that connected each “node,” or learned pattern, to each other.

Combining the Two: Non-Linear Least Squares (NLS) Regression

The image and metadata model output SoftMax probabilities for each class (melanoma and seborrheic keratosis). The NLS regression method was applied to determine optimal weights for combining each model’s prediction. The coefficients were determined through analysis of image and metadata outputs for the training dataset.

(1)0.75X1+0.25X2=y^

The above equation, outputted from the NLS function, describes the weights applied to both image (x_1) and metadata (x_2) model outputs to achieve an ideal accuracy. $\hat{y}$ represents the combined prediction, with values>0.5 being classified as malignant (melanoma) and values<0.5 being classified as seborrheic keratosis.

Ethical Considerations

No human participants were involved in this research. All data used in this research was obtained from the HAM10000 dataset, an open source and publicly available dataset. The authors of the HAM10000 dataset state that data sources were approved by the ethics committee at the Medical University of Vienna (Protocol No. 1804/2017) and the institutional ethics board at the University of Queensland (Protocol No. 2017001223).

Results

Comparing Model Accuracies

The simple model had the highest accuracy of 83.4% (369/442 images classified correctly) on validation data. All transfer learning models had high training accuracy but low validation accuracies, showing signs of overfitting. With the number of epochs in training constant, the transfer learning models show significantly more training time than the self-built model, as well as depicted in Table 2.

Table . Comparing model accuracies.

Model name	Training accuracy, N=1547, n (%)	Validation accuracy, N=442, n (%)	Number of epochs	Run time per epoch
ResNet50	1526 (98.65)	240 (54.29)	500	229 seconds
InceptionV3	1512 (97.75)	296 (67.04)	500	315 seconds
VGG16	1524 (98.52)	270 (61.13)	500	401 seconds
Self-Built Model (pre-data cleaning)	1242 (80.27)	348 (78.62)	500	2 seconds
Self-Built Model (post-data cleaning)	1488 (96.2)	369 (83.4)	500	2 seconds

XSL•FO
RenderX

ROC Curves

ROC (receiver operating characteristic) curves were plotted as another method of showcasing the accuracy of each model. The self-built model had the highest AUC of 83% (369/442 images classified correctly) on validation data, consistent with the self-built model accuracy from the validation data. This model reaches its highest true-positive rate while achieving lower false-positive rates than the transfer learning models. The transfer learning models had significantly lower AUCs with ResNet50 approaching the random guess line.

Validating Image Model

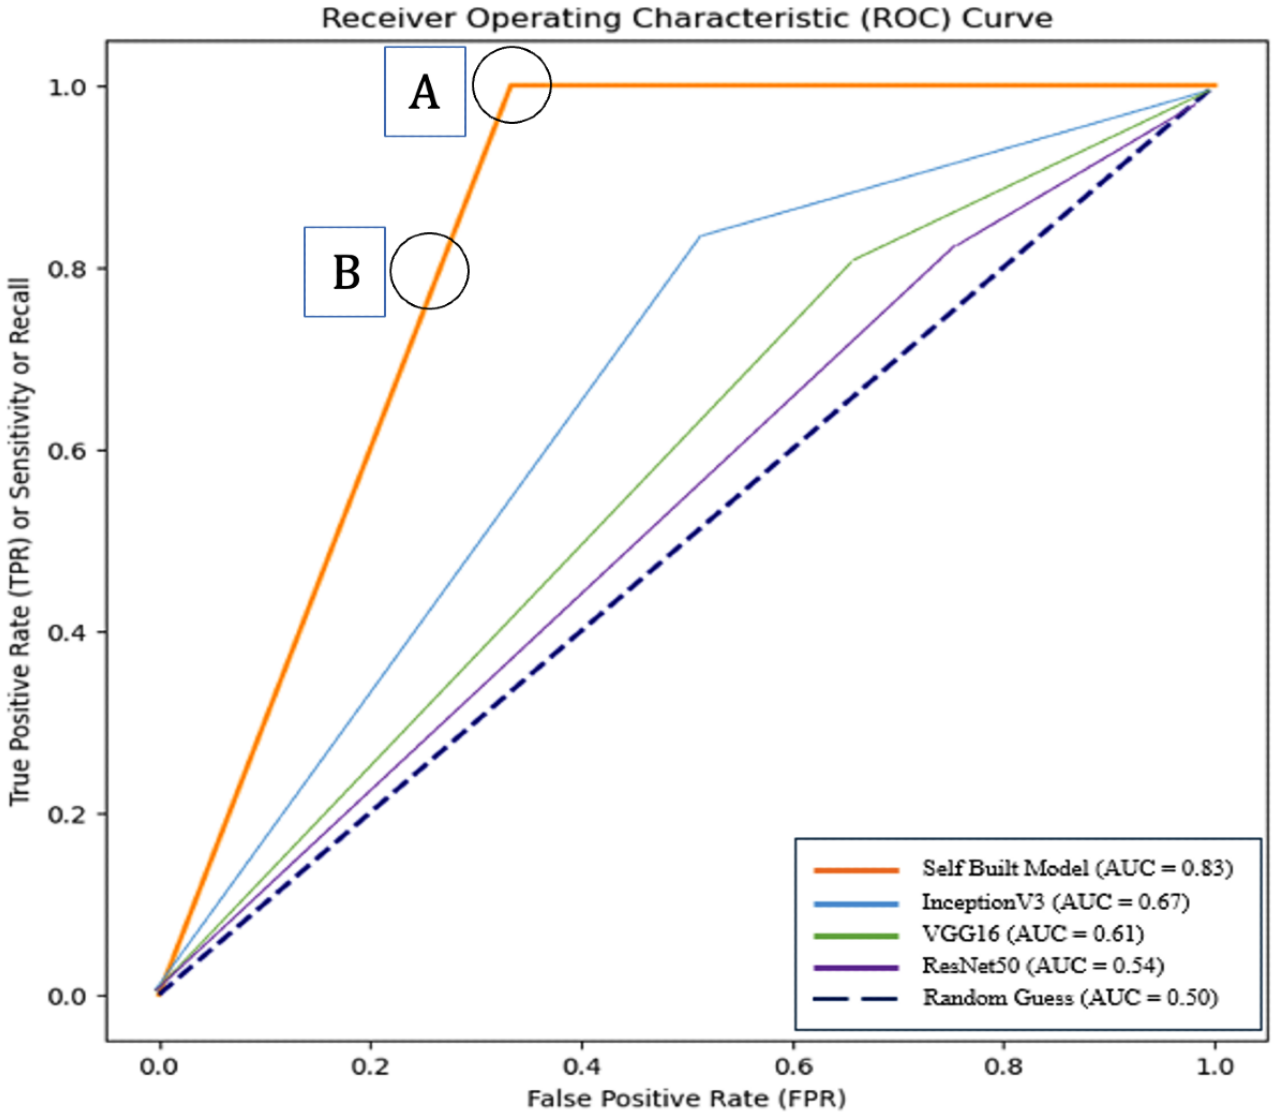
Saliency maps on test data illustrate the region of interest identified by different convolutional neural network architectures, allowing for greater model reliability and interpretability. They were generated from the last convolution layer, to help visualize which regions of an image are important for final classification. Each model demonstrates varying focus patterns, reflecting differences in feature extraction and attention and accounting for varying accuracies across all models.

Combined Model: Confusion Matrices

The classification performance of the image, metadata, and combined models was evaluated through confusion matrices reflecting sensitivity and specificity. The image-based model shows a balanced distribution of correct classifications, achieving a true-negative rate of 42% (93/221) and a true-positive rate of 41% (91/221) on test data. The metadata-based model exhibited lower overall performance. When both image and metadata inputs were integrated, better performance was achieved across all metrics.

Discussion

Comparing Model Accuracies



Contrary to what was expected, the transfer learning models appear to perform worse than the author-designed model. The differences in model accuracy can be attributed to model architecture, particularly the number of convolutional layers. Transfer learning models have far more convolutional layers than the self-built model (ie, ResNet50 has 50 convolutional layers while the self-built model has only 3). As the number of convolutional layers increases, the ability of the model to detect more complex and finer features increases. Therefore, the transfer learning models are more susceptible to overfitting as they can detect more minute details like hair and wrinkles. This accounts for the overfitting occurring in the transfer learning models as seen in the large difference between training and validation accuracy.

ResNet50 differs from the author-constructed model as it contains a residual layer that directly connects the output layers to the input layers as opposed to “stacking” them. The author constructed model optimizes the accuracy by using backpropagation, where the gradients used to determine the minimum loss value are calculated using the chain rule. Rather than using the chain rule, ResNet avoids the subsequent derivation between each layer and instead connects each output to the input. While this is important for models with a large number of convolutional layers, the author constructed model only contains 3 convolutional layers, so the effect of chain rule is less amplified, deeming the residual layer unnecessary. Inception V3 differs from the author-constructed model as it uses parallel convolutional layers to analyze a wider feature range in the input images. However, because melanoma is often centered in one specific region and is attributed with a set of consistent features defined by the ABCDE rule, the detection of too many features is harmful. VGG16 specializes in using smaller kernel strides to center on more minute features, which can lead to overfitting in this situation as small details in the skin are not vital and sometimes confusing in making a classification. While past studies have shown that ResNet50 and InceptionV3 perform well in these applications, the ability of the simple model to generalize to this particular problem makes it better compared to these previous approaches.

In real-world deployment, frontend image capture tools [27] will ensure image inputs conform to these predetermined metrics as shown in Figure 3, thereby increasing usability of the model. Upon deployment of this model to the primary care office, physicians are further advised to take good quality images of their patients’ lesions to ensure accurate diagnosis.

XSL•FO
RenderX

Figure 3. ROC curves: receiver operating characteristic curves plot the false-positive rate versus the true-positive rate. The ideal point on the curve is (0,1). FPR: false-positive rate; ROC: receiver operating characteristic; TPR: true-positive rate.

ROC Curves

ROC curves in Figure 3 are used to determine a cutoff point that optimizes the sensitivity and specificity of a specific test [28]. In medical applications, this is especially important since false-negative results could be life-threatening. As the false-negative rate is a direct function of the true-positive rate, in order to lower the false-negative rate, the true-positive rate must be increased, even if it comes at the expense of the false-positive rate. Consequently, point A would be preferred to point B.

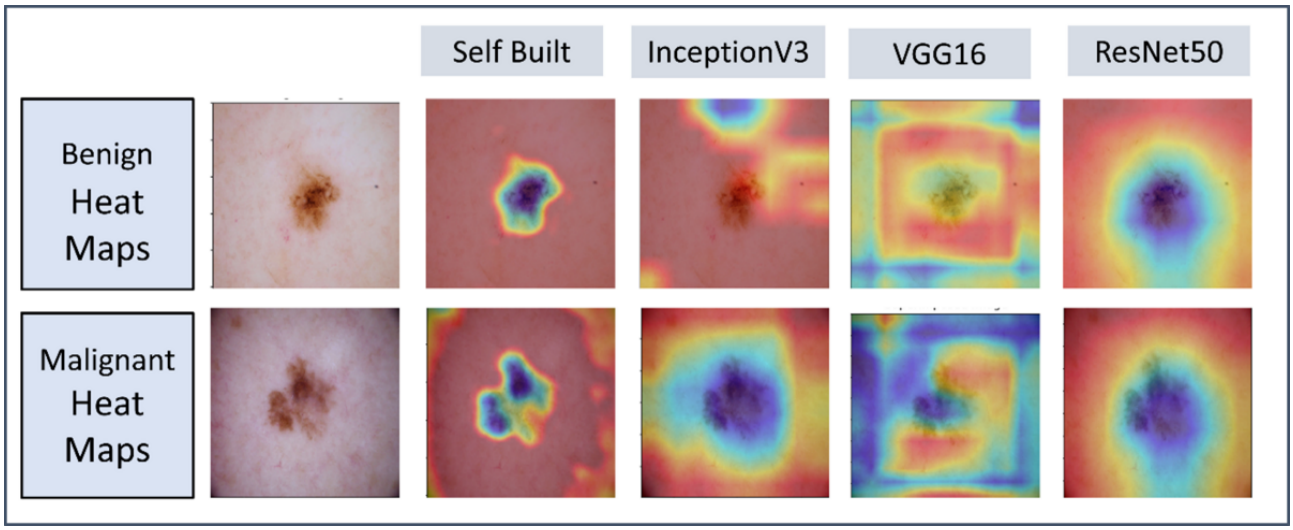
In addition, ROC curves can also be a measure of accuracy through the AUC depicted in the key shown in Figure 3. As the models get worse (as shown by the accuracies in Table 3), the ROC curve moves further away from the ideal point (0,1) and towards the random guess line [29].

Table . The final testing accuracy of the combined model is significantly higher than the existing accuracies from the literature review, which averaged around 70%.

Model type	Sensitivity	Specificity	Testing accuracy
Image	0.82	0.84	0.83
Metadata	0.76	0.52	0.64
Combined	0.875	0.875	0.875

Heatmaps

A major problem in artificial intelligence models today is lack of interpretability [30]. Artificial intelligence is often referred to as a “black box” with limited explainability regarding its decisions [31]. However, Figure 4 allows users to “see through the eyes” of the model through heatmaps.



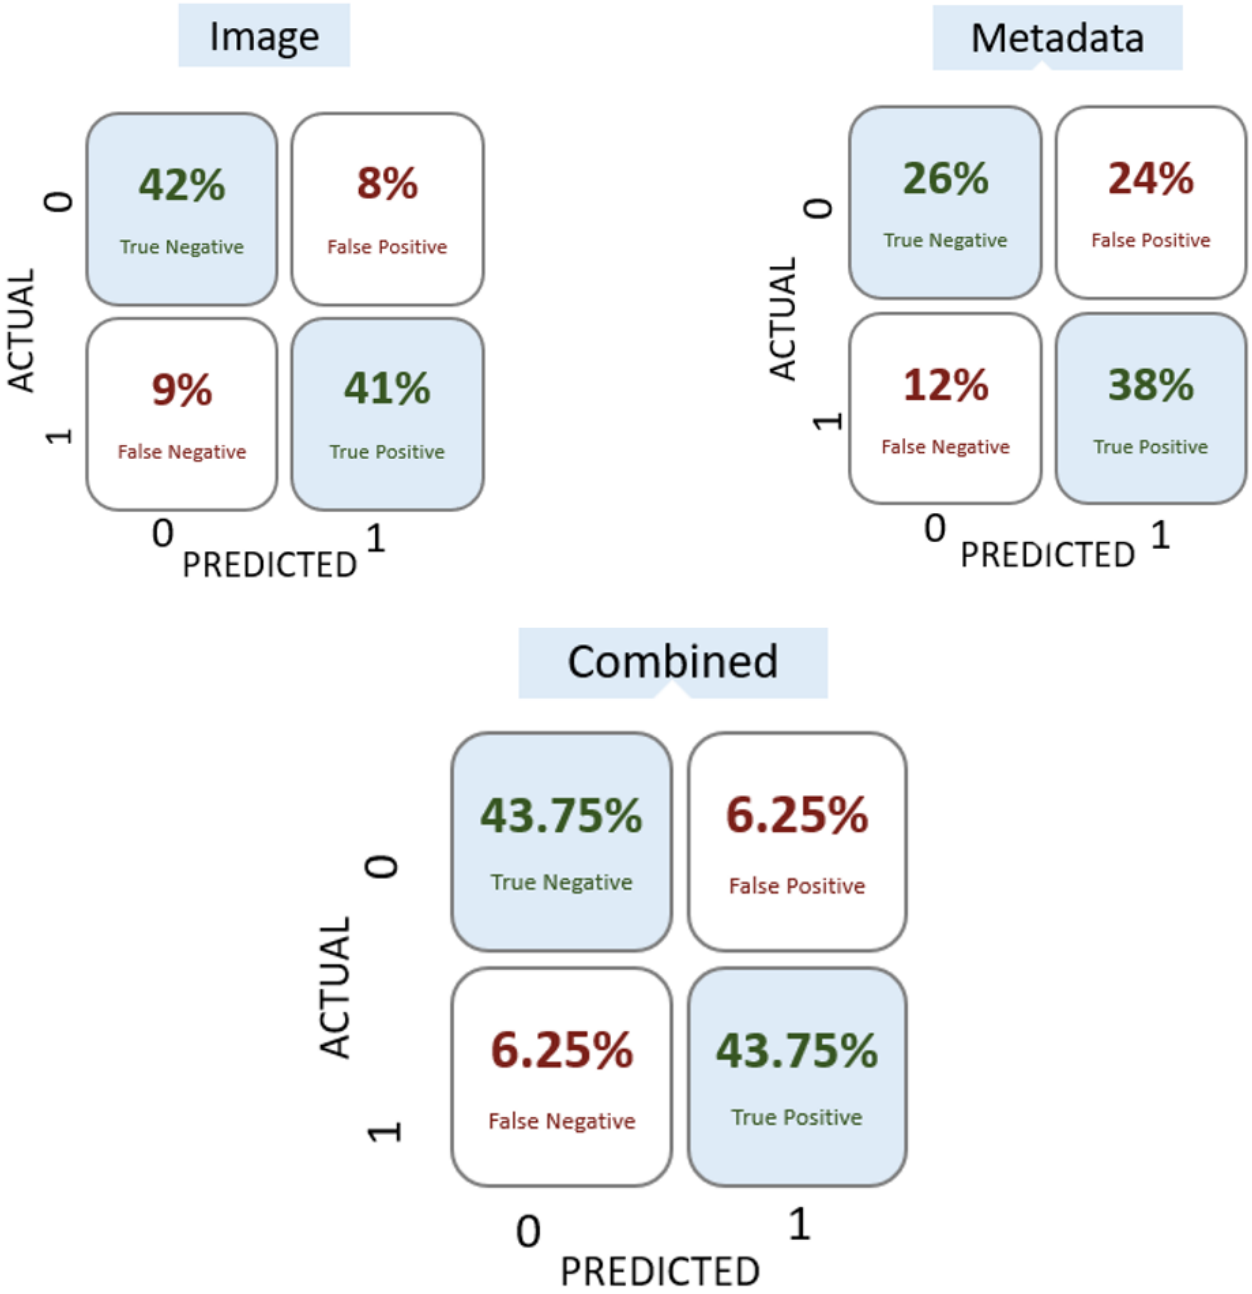
The author-designed model has a more “fixed” area of concentration as opposed to the other three transfer learning

XSL•FO
RenderX

models. However, unlike InceptionV3, ResNet50 offers human interpretability and appears to follow the pattern presented in the author-designed model to a limited extent. However, it fails to capture differences between benign and malignant lesions as shown in the similar weight distributions between the 2 classes.

As shown in Figure 4, the author-designed model that performed the best appears to primarily look at the differences in border between the two lesions, connecting back to the ABCDE method used by dermatologists for clinical diagnosis [32]. This gives the model more reliability, as it is dissecting the image similar to how a dermatologist would.

Figure 4. Comparison of Grad-CAM heat maps for benign and malignant skin lesions using different CNN architectures (Self-Built, InceptionV3, VGG16, ResNet50) for one example from each class.



Confusion Matrices

Referring back to Figure 5, as the true-positive rate increases, it does so at the expense of the false-positive rate until a certain saturation point (A). Therefore, the 9% false-negative rate shown on the image confusion matrix (top left of Figure 5) can only be reduced at the expense of increasing the false-positive rate.

The incorporation of the metadata adds critical heterogeneous information enabling the joint system to achieve a higher true-positive rate (lower false-negative rate) while simultaneously lowering the false-positive rate as shown in Figure 5 below. This thereby allows for the significant improvement in overall model accuracy as shown in Table 2.

XSL•FO
RenderX

Figure 5. Confusion matrices depicting various metrics (false-positive and false-negative rates) as related to the ROC curve. A cutoff of 0.5 was used for prediction, with predictions over 0.5 being classified as melanoma. ROC: receiver operating characteristic.

Comparison to Past Studies

Past work on dermatological applications of machine learning is compiled in Table 1, showing an accuracy ranging around 75%. The AUC of the transfer learning models (ResNet50, InceptionV3, and VGG16) matches that of past experiments. This study showcases an improvement of overall accuracy through the incorporation of additional metadata as well as constructing a simple model with fewer convolutional layers. These two approaches were successful in increasing the overall accuracy to 87.5% (194/221), showing promising implications for a multimodality approach to deep learning in dermatology.

Applications and Improvements for Future Studies

Out of sample testing will be used through the deployment of this model in local hospital settings in cases with known diagnoses to ensure model feasibility and usability outside the controlled environment of HAM10000. To achieve this, this model will be employed in local dermatological centers and results will be compared against dermatologist-determined diagnosis to determine out-of-sample accuracy.

Cross-validation using different train-test-validation splits will be tested to increase the confidence of the model with access to more storage and compute units. To make this possible, a resource-efficient approach to training a convolutional neural network is necessary as images occupy a large amount of storage space.

Currently, the model does poorly when presented with patients aged 40 and younger as well as lesions present on curved areas of the body such as the eyelids. This is due to the lack of data from these demographics and areas, forcing the model to use

XSL•FO
RenderX

generalized patterns to predict on these data points. Access to more granular metadata from younger patients and certain areas of the model can help address this issue. However, given the predominance of melanoma in older age groups, the authors believe this to be a natural obstacle of diagnosis in unusual populations.

As machine learning is a rapidly growing field, many new techniques can be used to improve the accuracy of the model. Combining metadata and image model predictions can be done through deep learning rather than regression, thereby enabling end-to-end joint training of the system to improve accuracy. Alternate architecture designs that combine image and metadata at the input or intermediate layers can also be explored. Additionally, using more granular metadata with less repetitions and more variations (eg, more data on different ages) can decrease the possibility of overfitting.

Using text data can also be a major change to this experiment. While this study only used structured data (patient metadata) and image data, in the real hospital setting, anecdotes, pain scale, lesion progression, and other descriptive factors can greatly influence a doctor when making a diagnostic decision. Using these records and combining them into the deep learning network through natural language processing can improve robustness and applicability of this model to the real world.

In order to make the application useful to a wider range of common citizens, making the model more robust by supporting a multi-way classification will allow older patients to use it in the home setting. Training the model on multiple types of lesions will motivate a more patient-friendly output as simply differentiating between benign and malignant eliminates the need to narrow down lesion possibilities.

Conclusion

In this manuscript, we introduce a multimodal technique that employs heterogeneous forms of data to produce a probability of the lesion belonging to either class. The model expands upon current model architectures and is adapted and trained for the specific problem at hand. This strategy can be applied to a multitude of medical applications in addition to current studies to provide a more comprehensive diagnosis of a certain disease through the addition of multiple data modalities.

Acknowledgments

We gratefully acknowledge all data contributors, ie, the Authors and Compilers of the HAM10000 dataset, and the submitting institutions that made this data publicly available.

Data Availability

All data generated or analyzed during this study are included in this published article [18].

Abstract

Background: Artificial intelligence (AI) is becoming increasingly popular in the scientific field, as it allows for the analysis of extensive datasets, summarizes results, and assists in writing academic papers.

Objective: This study investigates the role of AI in the process of conducting a systematic literature review (SLR), focusing on its contributions and limitations at three key stages of its development, study selection, data extraction, and study composition, using glaucoma-related SLRs as case studies and Preferred Reporting Items for Systematic reviews and Meta-Analyses (PRISMA)-based SLRs as benchmarks.

Methods: Four AI platforms were tested on their ability to reproduce four PRISMA-based, glaucoma-related SLRs. We used Connected Papers and Elicit to perform research of relevant records; then we assessed Elicit and ChatPDF's ability to extract and organize information contained in the retrieved records. Finally, we tested Jenni AI's capacity to compose an SLR.

Results: Neither Connected Papers nor Elicit provided the totality of the results found using the PRISMA method. On average, data extracted from Elicit were accurate in 51.40% (SD 31.45%) of cases and imprecise in 13.69% (SD 17.98%); 22.37% (SD 27.54%) of responses were missing, while 12.51% (SD 14.70%) were incorrect. Data extracted from ChatPDF were accurate in 60.33% (SD 30.72%) of cases and imprecise in 7.41% (SD 13.88%); 17.56% (SD 20.02%) of responses were missing, and 14.70% (SD 17.72%) were incorrect. Jenni AI's generated content exhibited satisfactory language fluency and technical proficiency but was insufficient in defining methods, elaborating results, and stating conclusions.

Conclusions: The PRISMA method continues to exhibit clear superiority in terms of reproducibility and accuracy during the literature search, data extraction, and study composition phases of the SLR writing process. While AI can save time and assist with repetitive tasks, the active participation of the researcher throughout the entire process is still crucial to maintain control over the quality, accuracy, and objectivity of their work.

KEYWORDS

artificial intelligence; systematic literature review; AI-assisted academic writing; AI-assisted data analysis; AI in systematic reviews; Connected Papers; Elicit; JenniAI; ChatPDF; AI; SLR

Introduction

Systematic literature reviews (SLRs) represent the highest level of evidence in scientific literature; therefore, playing a vital role in the field of research and academia [1]. The main purpose of SLR is to analyze and synthesize all the existing evidence related to a specific research topic, by adopting a methodical and rigorous manner, in order to minimize subjective judgments and provide a systematic and transparent approach [1,2]. The Preferred Reporting Items for Systematic reviews and Meta-Analyses (PRISMA) framework is widely used for conducting and reporting systematic reviews and meta-analyses in the health care field. It provides guidelines to ensure transparent and complete reporting, thereby facilitating assessment of study quality [3]. The method consists of a 27-item checklist and a flow diagram; its key components include title or abstract, introduction, methods, results,

XSL•FO
RenderX

discussion, conclusion, and funding disclosure, all aimed at emphasizing transparency, completeness, and reproducibility in reporting systematic reviews and meta-analyses [3]. Nevertheless, the process of writing an SLR is complex and presupposes mastery of a working methodology that may be elaborate and time-consuming.

Artificial intelligence (AI) is becoming increasingly popular in the scientific field, as it can provide a fast and easy way to analyze large volumes of data and review records, summarize results, and assist in writing academic papers.

Generative AI refers to a subset of AI technologies that can generate new content, such as text, images, music, speech, video, or code, based on learning to predict the next word or sequence of words given the preceding context [4]. Large language models (LLMs) are a subset of generative AI that specifically focus on text generation, using deep learning algorithms to process and analyze data for complex pattern recognition and prediction [4,5]. They are considered generative because they can construct full sentences, paragraphs, or documents that did not exist before, effectively "generating" new content based on their understanding of language patterns and structures learned during their training phase [5].

In the context of medicine, generative AI and LLMs can be used for a variety of purposes, including assisting in medical research by reviewing and summarizing large volumes of literature [4].

One of the key challenges for LLM and generative models is the ethical use of AI and the potential for biases in the underlying training data; incomplete or inaccurate datasets can lead to unreliable results [5]. This would cause the loss of the ultimate purpose of the SLR, which is to give a complete and objective overview of the literature. Therefore, it is crucial to acknowledge the downsides of relying completely on AI in the process of scientific writing and conveying information.

This study aims to investigate whether and how AI may support the writing of an SLR, by evaluating its potential advantages at three key stages: literature search, data organization and extraction, and drafting of the final study. Using glaucoma as a case study, a field in which the authors have domain expertise, we aimed to provide a guide on how some of the most popular AI software used in the scientific field operates. Our goal was to illustrate their possible contributions and current limitations in assisting with SRL composition.

Methods

AI Tools Overview

Four of the most popular AI platforms currently used in academic scientific research (Elicit [6], Connected Papers [7], ChatPDF [8], and Jenny AI [9]) were tested and compared in their ability to perform research on four already published, glaucoma-related SLRs.

Elicit [6] is an AI tool that provides the function of researching papers of interest by entering keywords in the research box. The platform provides a summary of the "top 8 papers" identified. The studies are presented in the form of a list, with a little summary shown alongside, which can be useful in the selection process. Records can either be selected or deleted from the list and be sorted by publication date, number of citations, and title.

Filters can be applied for refining the results, which are restricted to specific criteria like publication date and study design, encompassing randomized controlled trials, longitudinal studies, reviews, and meta-analyses.

Elicit offers the possibility to upload PDFs and organize their information according to criteria of interest (main findings, outcome measured, intervention effect, study design, study count, duration, length of follow-up, patients' sex and age, etc); moreover, authors can customize columns according to their preferences and include instructions for data presentation and any additional necessary [6].

Connected Papers [7] is a tool able to provide a visual representation of relevant research papers based on specific keywords, which can be entered in the research box [7]. It uses Semantic Scholar as a database to identify papers of interest; results will appear in the form of a list. Connected Papers does not offer the option to apply filters for refining the results, such as publication date and study design. Once a record of choice has been selected within the list of results, Connected Papers creates a visual graph, based on studies' similarities with regard to citations and references [7,10]. The generated graph places related papers close to each other, with the more recent ones shown in a darker tone and the most cited ones displayed in larger sizes. The results are also represented as a list.

ChatPDF [8] is an AI-powered tool that can analyze and extract relevant information from research papers in PDF format. Records can be uploaded and stored in the ChatPDF library, and folders can be created to organize them [8]. We created four folders, one for each SLR included in our investigation. Queries can be directed at individual records or entire folders. Our investigation found that posing questions to a specific paper yielded more accurate responses compared to asking questions to all papers within a folder, where answers were frequently incomplete or inaccurate. As a result, we chose to direct queries toward single papers individually.

Jenny AI [9] is a "writing assistant" designed to assist researchers in academic paper writing. The writing process is automated, using AI algorithms to generate content based on the input provided [9]. The "writing assistant" feature uses natural language processing algorithms to optimize the text and suggest improvements in word choice [9]. Given detailed instructions on what to write, Jenny is able to write entire paragraphs, such as introduction and conclusion; moreover, we can ask Jenny to write an opposing argument or write with more depth [9]. A paragraph can be selected, and we can edit it by asking to summarize it or make it longer, simplify what has been written, improve fluency, translate, or paraphrase in the linguistic register of our choice. Additionally, it enables the creation of content based on selected PDFs, facilitating the writing of tailored material [9].

In order to test the above-cited AI tools, we evaluated four already published, glaucoma-related SLRs. The initial analysis was focused on the review entitled "Glaucoma Pseudoexfoliation and Hearing Loss: A Systematic Literature Review" which we

XSL•FO
RenderX

authored [11]. Subsequently, our research expanded to incorporate three additional SLRs. These were identified by conducting research in the journal "*Survey of Ophthalmology.*" We used "glaucoma" as a keyword filter and sorted results by publication date, starting from the most recent. We then selected the first three SLRs that the research produced. The first one focused on assessing the "Efficacy of Ahmed and Baerveldt glaucoma drainage device implantation in the pediatric population: A systematic review and meta-analysis" [12]. The second one analyzed "Standalone XEN45 Gel Stent implantation in the treatment of open-angle glaucoma: A systematic review and meta-analysis" [13], and the third one focused on "Nutritional supplementation in the treatment of glaucoma: A systematic review" [14]. The research was conducted on February 15, 2023.

Literature Search

We first tested the ability of the AI software, Connected Papers [7] and Elicit [6], to identify studies of interest for our investigation. Using keywords specific to each systematic review of interest, searches on both platforms were conducted, mirroring the approach used in traditional databases like PubMed [15] or Embase [16]. When available, we used the exact search terms specified by the authors. The keywords applied were: "Glaucoma pseudoexfoliation and hearing loss" for the first SLR of interest [11]; "Efficacy of Ahmed and Baerveldt glaucoma drainage device in pediatric population" for the second SLR [12]; "Standalone XEN45 Gel Stent implantation in the treatment of open-angle glaucoma" for the third [13]; "Nutritional supplementation in the treatment of glaucoma" for the last evaluated SLR [14]. We compared the findings obtained from Elicit [6] and Connected Papers [7] with the studies included in each of the four SLRs under study, which were carried out using the PRISMA method. Our evaluation focused exclusively on the identification phase of the PRISMA [3] framework, assessing how well the AI tools retrieved relevant studies based on these keywords. Subsequent PRISMA [3] stages, such as records' screening, eligibility, or inclusion, were not evaluated. The goal was to determine the effectiveness of Elicit [6] and Connected Papers [7] in replicating or streamlining the initial identification step typically performed in systematic reviews.

Data Extraction

We explored the potential of Elicit and ChatPDF by testing their ability to extract and organize information contained in the records' text, thus facilitating the understanding of the content of scientific studies. In order to obtain these results, all papers contained in each review were uploaded into two of the examined software tools, Elicit and ChatPDF, and asked them to create the same tables as the ones presented in the SLRs of our interest. Subsequently, the generated results were compared with the original tables presented in the SLRs, categorizing the obtained results as follows: "accurate" for responses that were both appropriate and precise, "imprecise" for responses that lacked critical details specified by the original authors, "missing" for instances where no response was provided, and "incorrect" when a response was factually inexact.

AI-Assisted Writing

We tested Jenni AI's ability to write an SLR by simulating various writing scenarios and assessing its efficacy. We gave Jenny specific instructions on writing an SLR with the purpose of reproducing the four reviews of interest. We asked Jenni to "write an SLR on glaucoma, pseudoexfoliation, and hearing loss," for the first SLR of interest [11]; "write an SLR on the Efficacy of Ahmed and Baerveldt glaucoma drainage device in pediatric population," for the second SLR [12]; "write an SLR on Standalone XEN45 Gel Stent implantation in the treatment of open-angle glaucoma" for the third [13]; "write an SLR on nutritional supplementation in the treatment of glaucoma" for the last analyzed SLR [14]. To ensure precise and relevant outputs, we used Jenni AI's "Library" feature by uploading the records included in each of the SLRs of interest into the system. This enabled Jenni AI to tailor the generated content based on these specific studies and ensured that the citations provided were accurate and directly tied to the relevant studies. Two authors (LAM and GM) independently evaluated the generated content, focusing on language fluency, technical proficiency, suitability of the content, appropriateness and number of citations, defined methods (definition of research terms, inclusion and exclusion criteria, definition of data extraction, and risk of bias assessment), results (number of records identified, number of records excluded, description of each selected study, synthesis of results, statistical analysis, and risk of bias), discussion (interpretation of results), and conclusions. Each item was evaluated for the purpose of an SLR using a scale of 1=poor to 5=excellent. The two authors also measured the time used to write the paper using Jenni AI.

Ethical Considerations

This study is based entirely on secondary analysis of publicly available scientific literature and publicly accessible AI-based tools; it did not involve human participants, identifiable personal data, or any form of medical or behavioral intervention. Therefore, ethical approval was not required.

Results

Literature Search

Connected Papers

The research of relevant records on the first SLR, "Glaucoma pseudoexfoliation and hearing loss" produced 22 results, which included 7 of 30 papers selected with the PRISMA method for our SLR, and the review of interest [11].

The second review, "Efficacy of Ahmed and Baerveldt glaucoma drainage device implantation in the pediatric population: A systematic review and meta-analysis," included 32 studies. None of the original 32 records were identified by Connected Papers [12]. The third review, "Standalone XEN45 Gel Stent implantation in the treatment of open-angle glaucoma: A systematic review and meta-analysis," included 14 studies; none of them were found by Connected Papers [13]. The research produced 4 results, including the review of interest. In the fourth review, "Nutritional supplementation in the treatment of glaucoma", 30 papers were selected [14]. Among these, no studies were found by Connected Papers. The research produced

XSL•FO
RenderX

3 results, which included the review of interest. An example of a Connected Papers-generated graph is provided in Figure S1 in Multimedia Appendix 1; it was produced by entering the keywords "glaucoma, pseudoexfoliation, and hearing loss" in the research field and then selecting the first result that appeared on the list.

Elicit

The research of relevant records on the first SLR, "Glaucoma pseudoexfoliation and hearing loss," produced 270 results, which included 15 of 30 studies selected with the PRISMA method for our SLR [11]. Boolean operators were not useful for the research in this platform: none of the 30 previously selected studies were found when we inserted "glaucoma OR PXS OR PXG) AND "hearing loss" in the research box. The second review, "Efficacy of Ahmed and Baerveldt glaucoma drainage device implantation in the pediatric population: A systematic review and meta-analysis," included 32 studies; 2 papers of the original 32 were identified by Elicit [6,12]. The third review, "Standalone XEN45 Gel Stent implantation in the treatment of open-angle glaucoma: A systematic review and meta-analysis," included 14 studies, of which 6 were found by Elicit [6,13]. In the fourth review, "Nutritional supplementation in the treatment of glaucoma", 30 studies were selected by the authors [14]. Among these, 3 papers were found by the Elicit [6]. An example of Elicit's search results using the keywords "glaucoma pseudoexfoliation and hearing loss" is provided in Figure S2 in Multimedia Appendix 1.

Results of Connected Papers [7] and Elicit [6] research are summarized in Table 1.

Table . Records found by Connected Papers and Elicit.

	Review 1[a] (n=30)		Review 2[b] (n=32)		Review 3[c] (n=14)		Review 4[d] (n=30)

Selected records found, n (%)	7 (23)	15 (50)	0 (0)	2 (6)	0 (0)	6 (49)	0 (0)	3 (10)

[a]Review 1: "Glaucoma, Pseudoexfoliation, and Hearing Loss: A Systematic Literature Review" [11].

[b]Review 2: "Efficacy of Ahmed and Baerveldt glaucoma drainage device implantation in the pediatric population: A systematic review and meta-analysis" [12].

[c]Review 3: "Standalone XEN45 Gel Stent implantation in the treatment of open-angle glaucoma: A systematic review and meta-analysis" [13].

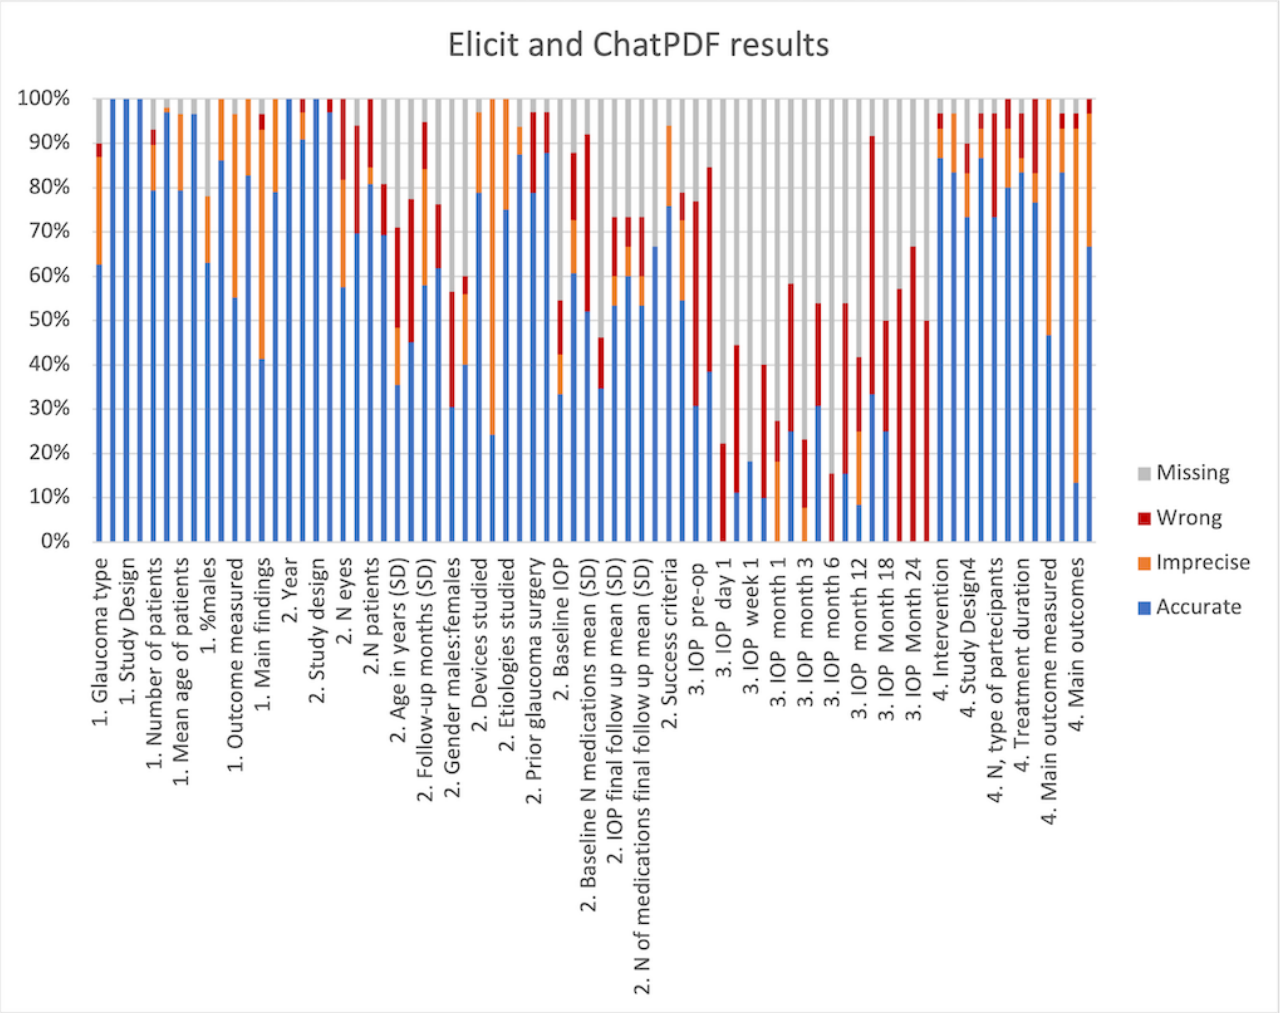
[d]Review 4: "Nutritional supplementation in the treatment of glaucoma: A systematic review" [14].

Data Extraction

Elicit

Data extracted from Elicit resulted overall accurate in 655 of 1274 responses (mean 51.4%, SD 31.4%) of cases, with an additional 175 responses (mean 13.7%, SD 18%) correct but lacking necessary and required details (imprecise responses). A total of 285 responses (mean 22.4%, SD 27.5%) were missing, while 159 (mean 12.5%, SD 14.7%) were incorrect.

ChatPDF



Data extracted from ChatPDF resulted overall accurate in 768 of 1274 responses (mean 60.3%, SD 30.7%) of cases, with an additional 94 responses (mean 7.4%, SD 13.9%) correct but lacking necessary and required details (imprecise responses). A total of 224 responses (mean 17.6%, SD 20%) of responses were missing, while 187 (mean 14.7%, SD 17.7%) were incorrect.

Figure S3 in Multimedia Appendix 1 illustrates the ChatPDF interface used to extract data from the systematic review studies.

The results of our comparison between the data presented by Elicit, ChatPDF, and the original SLRs are presented in Figure 1.

XSL•FO
RenderX

Figure 1. Elicit and ChatPDF data extraction evaluation. Numbers 1 - 4 indicate the analyzed review. Review 1: “Glaucoma, Pseudoexfoliation, and Hearing Loss: A Systematic Literature Review”; Review 2: “Efficacy of Ahmed and Baerveldt glaucoma drainage device implantation in the pediatric population: A systematic review and meta-analysis”; Review 3: “Standalone XEN45 Gel Stent implantation in the treatment of open-angle glaucoma: A systematic review and meta-analysis”; Review 4: “Nutritional supplementation in the treatment of glaucoma: A systematic review”. For each variable, the first bar represents Elicit results, and the second bar represents ChatPDF results. IOP: intraocular pressure.

AI-Assisted Writing

The two authors (LAM and GM) evaluated Jenni AI’s outputs across multiple dimensions, reaching a consensus on the items under review. The content generated by Jenni AI exhibited satisfactory language fluency, technical proficiency, and suitability. The text produced by Jenni AI was clear, easily understandable, and used appropriate terminology, but it was judged as insufficient for the remaining items. Jenni AI’s number of citations was inadequate, as it only referenced up to three studies throughout its four attempts at writing an SLR. The methods lacked clarity as they did not provide definitions for research terms, specify inclusion and exclusion criteria, or define data extraction and risk of bias assessment. The results section of the study did not provide clear information regarding the number of records identified and excluded, as well as a description of each selected study. In terms of synthesis of results, the study did not present a comprehensive analysis or statistical analysis and did not mention the risk of bias. The discussion section lacked a thorough interpretation of the results. The conclusion paragraph provided a brief overview of the key points covered in the preceding paragraphs, yet it lacked specific details. Each study was typically completed in under 30 minutes, depending on each author’s willingness to revise and rephrase Jenni AI’s writing. To provide a quantitative representation of Jenni AI’s writing performance, the evaluated dimensions are summarized in Table 2. Each item was scored on a scale of 1=poor to 5=excellent. A screenshot of the Jenni AI [9] interface displaying an example of the generated text and features is provided in Figure S4 in Multimedia Appendix 1.

XSL•FO
RenderX

Table . Quantitative evaluation of Jenni AI's SLR[a] writing performance.

Dimension	Score (1-5)	Evaluation
Language fluency	4	Satisfactory: clear and coherent text with appropriate language use, minor grammatical issues.
Technical proficiency	4	Satisfactory: proper use of terminology with acceptable structure, but lacking depth in analysis.
Relevance and suitability	3	Moderate: content is generally on-topic but occasionally lacks focus or depth in specific sections.
Citations	1	Insufficient: limited citations (up to 3) across all drafts, failing to meet SLR standards.
Methods definition	2	Weak: lacks clarity in defining research terms, inclusion or exclusion criteria, and methodology.
Results	2	Weak: insufficient detail on identified or excluded records, and lacks comprehensive data reporting.
Discussion	2	Weak: minimal interpretation of results, lacking critical analysis or synthesis.
Conclusions	3	Vague: summarizes key points but lacks specific insights.

[a]SLR: systematic literature review.

Discussion

Summary of Study Objectives and Findings

This study evaluated the capabilities and limitations of AI tools in the SLR writing process, comparing their performance to the established PRISMA framework [3]. Using four glaucoma-related reviews as case studies, we focused on three key steps in the SLR process: records identification, data extraction, and study composition. We found that while AI tools like Elicit, Connected Papers, ChatPDF, and Jenni AI can streamline certain steps in the SLR process, they exhibit notable gaps in accuracy, completeness, and methodological rigor when compared to the PRISMA framework [3].

Records search

Starting from the records' research and selection, we noticed that neither Connected Papers nor Elicit was able to provide the totality of the results found using the PRISMA method. In addition, Elicit's filters for the papers' selection were limited and sometimes not precise (for instance, some reviews would be included in the results even though they were excluded in the filters). The given results still needed to be reviewed by an expert, since many of them did not relate to the topic of interest. Many attempts were necessary to understand how to perform the research, in terms of the input mode of keywords (ie, Boolean Operators were not useful to find more studies of interest using both Elicit and Connected Papers); these platforms do not provide instructions on how to correctly perform the research to make it more effective. In regard to Connected Papers, we found that the visual representation of the studies can provide a more direct approach to research and helps with the selection of the most relevant papers. The most cited and most recent papers can be easily recognized immediately thanks to the graphic differentiation of studies by color and size. Regarding SLR, it may be necessary to do more than one research and build various graphs to find the totality of the records present in the literature. This study specifically focused on the Identification stage of the PRISMA [3] framework, representing a limited application of the full process. While PRISMA [3] encompasses a multistep, iterative approach including Screening, Eligibility, and Inclusion, we deliberately constrained our evaluation to the Identification phase. This allowed us to assess the standalone capabilities of AI tools in replicating this initial step and determine if they can streamline the literature search by reducing the need for extensive manual refinement. However, we acknowledge that further research is necessary to evaluate AI tools' performance across all PRISMA [3] stages, including screening and eligibility assessments.

Data Extraction

Summaries given by Elicit were still far from how an SLR should be written since they were based on only a few studies (less than 10). Nevertheless, we found the Elicit function of sorting information in the form of tables useful, since it facilitates the understanding and the extrapolation of data and saves time in the process of elaborating the results. The possibility to customize columns was very helpful to obtain the wanted information. Nevertheless, the accuracy of answers was still far from accurate, which indicates the impossibility of relying entirely on this tool to create tables for SLRs. ChatPDF can be used to easily search specific information within a paper, making it easier for the author to quickly access the data of interest without the need to read the entire paper. However, it was not able to reproduce the tables contained in the SLRs object of study, even after providing the software-specific instructions. Additionally, when addressing a folder of studies, the software was unable to answer many questions but could do so when dealing with individual PDFs. This results in a more time-consuming process for generating tables, as each paper needs to be examined individually. As a result, it is not as efficient as Elicit, which can produce the necessary tables much

XSL•FO
RenderX

faster. Nevertheless, ChatPDF often provides more accurate results, enhancing its reliability in many cases. As for Elicit, the precision of responses provided by this tool remained inadequate for the purpose of an SLR. While we used structured and targeted queries to maximize the tool's performance (eg, asking for specific details such as year of publication and baseline intraocular pressure), we opted not to use advanced prompting strategies like iterative rephrasing or chain-of-thought techniques. This decision was made to ensure that the tools were evaluated under practical, real-world conditions and not under artificially optimized scenarios. The observed variability in the accuracy of AI tools can be largely attributed to two key factors: the complexity of the datasets and tool-specific limitations. Studies with straightforward reporting of results in the main text generally yielded higher accuracy, as the tools could easily interpret their structure. In contrast, more complex studies, where critical information was embedded in tables, graphs, or figures, were less effectively processed. These findings highlight the inherent challenges AI tools face when extracting nuanced data from unstructured or nontextual elements. To address these issues, it is critical to align tool selection with the nature of the data being analyzed. Future research should also explore methods to enhance the adaptability of AI tools for more complex datasets, potentially through training or algorithm optimization. Despite these limitations, the variability observed in our results reflects real-world use cases, reinforcing the importance of setting realistic expectations for AI-assisted systematic reviews.

AI-Assisted Writing

In regard to Jenni AI writing assistant, we found that its suggestions aid in expediting and streamlining the writing process, while also helping prevent "writer's block." The paper can be customized based on the author's preferences by selecting the options among the AI commands, making the draft unique. Nevertheless, the author should, in any case, have mastery of the topic of interest to be able to choose the best option among the ones proposed by the AI, as well as guide the writing in the right direction. Moreover, results showed that there is a need for more systematic and detailed methods in Jenni AI's literature review process. The paper written by Jenni AI lacked accurate and exhaustive results, which were supported by too few citations; moreover, the discussion of results was vague. The paper written by Jenni was overall inadequate and did not meet the requirements of an SLR. As a result, we believe that Jenni AI can be helpful in assisting writers in text paraphrasing or summarization, but its limitations in accuracy and completeness indicate that it should not be solely relied upon for generating high-quality content.

We acknowledge that this study was specifically focused on glaucoma-related SLRs, as our expertise in this domain enabled a critical evaluation of AI tools' outputs. However, this narrow scope may limit the generalizability of our findings, and further research across diverse fields is necessary to validate the applicability of these tools more broadly.

Nonetheless, there are other aspects to be taken into consideration: conducting a comprehensive review of academic literature allows us to generate our own research concepts, thus enhancing our ability for critical analysis and originality [17]. Engaging in bibliographical research is crucial for developing critical analysis skills, establishing academic identity, identifying gaps and areas for further exploration, and contributing to the advancement of our research field; these frameworks contribute to ongoing discussions about thoughts and methodologies with those who came before us. Leaving this role entirely to AI may result in us missing the core objective of performing research, which is to actively engage in and enrich existing knowledge through critical evaluation [17]. Furthermore, we think that authors should specify in their papers if AI was used in the SLR writing process, in order to provide transparency and clarity regarding the methodology of their work. Indeed, many journals ask authors to disclose in their studies the use of AI and AI-assisted technologies [18].

Conclusions

Our research showed that the PRISMA method continues to exhibit clear superiority in terms of reproducibility and accuracy at three key steps of conducting an SLR, starting from the search of relevant records, through the collection and organization of data, up to the writing of the final paper. Although its contribution can save time and help with repetitive tasks, it is important to note that AI lacks critical thinking, and expert analysis continues to be necessary to identify potential biases in the algorithms. For this reason, researchers must approach AI-generated content with a thoughtful and discerning mindset, recognizing the benefits while also acknowledging the need for careful scrutiny. While this study focused on glaucoma research due to our domain-specific expertise, its findings highlight the potential and limitations of AI tools in SLRs. Further validation across diverse domains and datasets is needed to enhance their applicability. As AI continues to advance, it holds promise for providing support and improvement to the SLR process. However, at present, human oversight and refinement are still crucial for the comprehensive and accurate completion of SLRs. Therefore, it is imperative that while leveraging AI, researchers should continue to apply their expertise and critical thinking skills to ensure the quality, accuracy, objectivity, and integrity of their work.

Authors' Contributions

GM conceived the original idea of the study. LAM and GM designed the study. LAM wrote the original draft, LAM and AR analyzed the data, GC and AR reviewed and edited the draft, and GM and SDC supervised the project. All authors have read and agreed to the published version of the manuscript.

Conflicts of Interest

Abstract

Background: Mpox (monkeypox) outbreaks since 2022 have emphasized the importance of accessible health education materials. However, many Japanese online resources on mpox are difficult to understand, creating barriers for public health communication. Recent advances in artificial intelligence (AI) such as ChatGPT-4o show promise in generating more comprehensible and actionable health education content.

Objective: The aim of this study was to evaluate the comprehensibility, actionability, and readability of Japanese health education materials on mpox compared with texts generated by ChatGPT-4o.

Methods: A cross-sectional study was conducted using systematic quantitative content analysis. A total of 119 publicly available Japanese health education materials on mpox were compared with 30 texts generated by ChatGPT-4o. Websites containing videos, social media posts, academic papers, and non-Japanese language content were excluded. For generating ChatGPT-4o texts, we used 3 separate prompts with 3 different keywords. For each keyword, text generation was repeated 10 times, with prompt history deleted each time to prevent previous outputs from influencing subsequent generations and to account for output variability. The Patient Education Materials Assessment Tool for Printable Materials (PEMAT-P) was used to assess the understandability and actionability of the generated text, while the Japanese Readability Measurement System (jReadability) was used to evaluate readability. The Journal of the American Medical Association benchmark criteria were applied to evaluate the quality of the materials.

Results: A total of 119 Japanese mpox-related health education web pages and 30 ChatGPT-4o–generated texts were analyzed. AI-generated texts significantly outperformed web pages in understandability, with 80% (24/30) scoring ≥70% in PEMAT-P (P<.001). Readability scores for AI texts (mean 2.9, SD 0.4) were also higher than those for web pages (mean 2.4, SD 1.0; P=.009). However, web pages included more visual aids and actionable guidance such as practical instructions, which were largely absent in AI-generated content. Government agencies authored 90 (75.6%) out of 119 web pages, but only 31 (26.1%) included proper attribution. Most web pages (117/119, 98.3%) disclosed sponsorship and ownership.

Conclusions: AI-generated texts were easier to understand and read than traditional web-based materials. However, web-based texts provided more visual aids and practical guidance. Combining AI-generated texts with traditional web-based materials may enhance the effectiveness of health education materials and improve accessibility to a broader audience. Further research is needed to explore the integration of AI-generated content into public health communication strategies and policies to optimize information delivery during health crises such as the mpox outbreak.

KEYWORDS

mpox; patient education; AI-generated health education; readability; Japan; health communication; artificial intelligence

Introduction

Since May 2022, outbreaks of mpox (formerly known as monkeypox) have been reported primarily in Europe and the United States, with more than 99,500 cases and more than 200 deaths reported from 122 countries [1]. Japan has reported 247 cases and 1 death [1]. Outbreaks of mpox appear to occur disproportionately among men who have had sexual contact with other men [2], but infection can also occur through close and prolonged physical contact, regardless of sex, gender identity, or sexual orientation [3].

The increasing availability of health education materials online has transformed public health education, particularly regarding topics related to sexual health, where accessibility and anonymity are important [4]. However, many patient education materials created by medical professionals are written at a reading level higher than that recommended for the general adult population, thereby creating a barrier to understanding critical health information [5-10]. The National Workgroup on Cancer and Health [11], the American Medical Association [12], and the Centers for Disease Control and Prevention [13] recommend that patient educational texts be readable at a sixth- to eighth-grade level or lower. However, evaluations of mpox-related content on the internet to date have indicated that much of this material is difficult for the general public to understand [14].

Artificial intelligence (AI) tools such as ChatGPT offer novel approaches to making health education materials more accessible. Recent studies have shown that AI-generated texts can simplify complex medical information and improve readability, outperforming traditional web-based materials [14-16]. By enhancing clarity and accessibility, AI-generated texts have the potential to reduce health disparities and ensure equitable access to vital health information, particularly during public health crises such as the mpox outbreak.

This study aims to evaluate the comprehensibility, actionability, and readability of Japanese online health education materials on mpox in comparison with content generated by ChatGPT-4o. Our findings may guide public health policies by demonstrating how AI tools can improve the clarity of health education materials. Further, this research will support the integration of AI-generated text into public health strategies, potentially reducing the burden on health care professionals and enhancing communication during emergencies.

Methods

Information Generation and Website Selection

We conducted a systematic quantitative content analysis of online texts adopting a cross-sectional design. From August 20 to August 30, 2024, we searched for web pages by using the Google search engine. Concurrently, texts were generated using ChatGPT-4o. We used the Google search engine to identify web pages by entering the terms “mpox” (in English), “エムポックス” (Japanese phonetic transcription), and “サル痘” (the traditional Japanese term for monkeypox). From the top-ranking results, we excluded videos, social networking services, expert websites, academic papers, subscription-based or paywalled sites, non-Japanese language websites, and pages that only listed URLs. We identified 119 web pages for analysis.

For ChatGPT-4o, we used the prompt “Please tell me about [keyword],” entering each of the 3 keywords (mpox, エムポックス, サル痘) separately. For each keyword, text generation was repeated 10 times, with prompt history deleted each time to prevent previous outputs from influencing subsequent generations and to account for output variability. This methodological design was intended to reflect realistic information-seeking behavior among general users, particularly those with limited prior knowledge of mpox, who are likely to initiate searches by using only simple keyword terms.

An epidemiology researcher independently scored all the documents. To ensure validation, we randomly selected 20% (30/150) of the documents for independent scoring by a physician. Each document was first assigned a unique ID, and Microsoft Excel’s RAND() function was used to generate a random number for each entry. The documents were then sorted by a random number, and the top 20% were selected. A physician then scored the selected subset by using the Japanese version of Patient Education Materials Assessment Tool for Printable Materials (PEMAT-P) [17,18]. In cases of disagreement, consensus was reached through discussion.

Ethical Considerations

This study was not reviewed by an ethics board because no human participants or interventions were involved.

Understandability and Actionability

The ease of understandability and actionability of the text on the website and the text generated by ChatGPT-4o were evaluated using the Japanese version of PEMAT-P [17,18]. The Japanese version of PEMAT-P comprises 23 items, and evaluates content, word choice and style, use of numbers, structure, layout and design, and use of visual materials. The final score for PEMAT-P ranges from 0% to 100%, with a higher score indicating that the text is easier to understand and easier to act on. The cutoff score for both ease of understanding and actionability is 70%.

Readability

In this study, the Japanese Readability Measurement System (jReadability) was used to quantitatively evaluate the readability of Japanese texts [19,20]. This measurement system calculates the difficulty of Japanese based on the average sentence length, word difficulty, grammatical part-of-speech ratio, and character type of each text. A higher score indicates that the text is relatively easy to read: 0.5-1.4, very difficult to read; 1.5-2.4,

XSL•FO
RenderX

difficult to read; 2.5-3.4, somewhat difficult to read; 3.5-4.4, neither difficult nor easy to read; 4.5-5.4, easy to read; and 5.5-6.4, very easy to read. For example, “very difficult” refers to a level where the skills required allow one to understand even highly specialized texts.

Credibility

To assess the reliability of texts on web pages, we used the benchmark criteria outlined by the Journal of the American Medical Association [21]. These criteria consist of authorship (authors and contributors with affiliations and relevant qualifications), attribution (references and sources with copyright information disclosed), timeliness (date of content publication and revision dates clearly stated), and disclosure (disclosure of site ownership along with sponsorship, advertising, warranties, and financial support).

Statistical Analyses

Statistical analyses were conducted using 2-sided *t* tests, chi-square tests, and Fisher exact tests to compare sentences from web pages with those generated by ChatGPT-4o. In addition, intraclass correlation coefficients (ICCs) were calculated to assess interrater reliability. A significance level of $P<.05$ was applied for all statistical tests. Data analysis was performed using SPSS Statistics for Windows (version 25.0; IBM Corp).

Results

Information Sources

Analysis was performed for 119 web pages from Google and 30 sentences generated by ChatGPT-4o. None of the sentences generated by ChatGPT-4o contained any obvious errors. The ICC was calculated to quantify the degree of agreement between items, with ICC=0.43 for PEMAT-P understandability and ICC=0.43 for actionability. The characteristics of the web pages are summarized in Table 1. For Japanese mpox-related web pages, those generated by the government were the most common (90/119, 75.6%). Web pages were last updated after 2021, with 51 (42.9%) pages updated in 2023 and 40 (33.6%) pages updated in 2024. For the JAMA benchmark criteria, 117 (98.3%) pages had disclosure, but only 31 (26.1%) had attribution.

Table 1. Characteristics of the web page search results (N=119).

	Values, n (%)
Source	
Government	90 (75.6)
Business	15 (12.6)
Academic organization	6 (5.0)
Nonprofit organization	5 (4.2)
Medical organization	3 (2.5)
Year of website update	
2021	2 (1.7)
2022	13 (10.9)
2023	51 (42.9)
2024	40 (33.6)
Unknown	13 (10.9)
Journal of the American Medical Association benchmark criteria	
Authorship	93 (78.2)
Attribution	31 (26.1)
Disclosure	117 (98.3)
Currency	105 (88.2)

Understandability and Actionability

The results of the comparisons between web page texts and sentences generated by ChatGPT-4o are shown in Table 2 and Figure 1. The proportion of PEMAT-P understandability scores ≥70% (as defined in the Methods section) was significantly higher for ChatGPT-4o texts (24/30, 80%; $P<.001$). Mean (SD) PEMAT-P scale scores for texts from ChatGPT-4o were significantly higher for understandability (77.1, SD 9.7; mean difference –10.3, 95% CI –14.7 to –5.9; $P<.001$) and lower for actionability (5.3, SD 9.0; mean difference 31.9, 95% CI 26.9-37.0; $P<.001$) than for texts from web pages.

Readability

Regarding the results for jReadability, the most common results for web pages were somewhat difficult (60/119, 50.4%) or difficult (55/119, 46.2%), while the most common result for ChatGPT-4o was somewhat difficult (22/30, 73%). The mean readability score for web page texts (2.4, SD 1.0) was significantly lower than that for ChatGPT-4o–generated texts (2.9, SD 0.4; mean difference –0.5, 95% CI –0.8 to –0.1; *P*=.009), while the difficulty level was significantly higher (*P*=.009). According to the jReadability classification system, the mean score for ChatGPT-4o–generated texts (2.9) corresponds to the "somewhat difficult to read" category, while the mean score for web page texts (2.4) falls into the "difficult to read" category. "Difficult to read" texts typically include complex or technical content, whereas "somewhat difficult to read" texts are generally understandable even if they are slightly technical, especially in everyday contexts.

Discussion

This study compares the comprehensibility, actionability, and readability of Japanese health education materials on mpox published online with that of AI-generated content from ChatGPT-4o. Our results suggest that AI-generated texts are generally easier to understand and written in simpler Japanese compared to traditional web-based materials. These findings are consistent with those reported in previous research [14,22,23].

AI-generated texts such as those from ChatGPT-4o offer the advantage of providing clearer and more straightforward information, which is critical in the context of public health emergencies. By reducing the cognitive load required to comprehend and act on health information, AI has the potential to improve health literacy and facilitate more effective communication with populations that may face barriers in accessing or understanding complex medical information. However, one key limitation of AI-generated content is the lack of visual aids, charts, and graphs that often accompany web-based texts, which can significantly enhance understanding. Incorporating multimedia elements such as images, diagrams, and graphs into AI-generated content could further improve the comprehensibility and practical application of health information, particularly for complex medical topics.

Regarding actionability, the results showed that web-based texts provided more explicit calls to action than AI-generated content. This difference may be due to the nature of the prompt used to generate AI content, which did not specifically encourage behavior-specific guidance. Research suggests that customized prompts such as asking AI to explain at a sixth-grade level can enhance clarity and actionability [23]. In this study, however, we intentionally used simple keyword-based prompts (eg, Tell me about mpox) to reflect realistic information-seeking behavior by general users. Given that the public understanding of mpox remains limited, particularly in Japan, we assumed that users would initiate queries with minimal phrasing. Assessing the quality of AI-generated materials in response to such basic prompts is important for evaluating the real-world utility of AI in public health education. To further support behavior-oriented communication, developing prompts that elicit more specific and actionable outputs warrants consideration. For instance, prompts such as "Explain mpox to someone with no medical background" or "List 3 actions I should take to avoid mpox" might enhance comprehensibility and actionability. Moreover, instead of expecting complete guidance in a single interaction, users could issue follow-up prompts like "What should I do if I think I might have mpox?" or "How can I talk to my partner about mpox prevention?" These examples are exploratory and suggest that more systematic investigation into prompt design will be essential for maximizing the practical utility of AI-generated health content. For AI-generated health information to be practically applicable and useful in public health contexts, future research should emphasize optimizing prompt use to ensure that the results not only provide information but also encourage preventive actions and healthy behaviors.

The readability analysis suggested that AI-generated texts were easier to read than web-based materials. This finding is important because readability plays a critical role in how effectively public health information can be understood and acted upon, particularly in times of crisis like the mpox outbreak. By maintaining lower levels of text complexity, AI-generated content can serve as a useful tool for delivering health education to broader audiences, including underserved populations.

This study is, to the best of our knowledge, the first to compare health education texts on mpox available on web pages and that available via AI chatbots. This is also the first study to evaluate the understandability, actionability, and writing difficulty of Japanese health education texts on mpox published online. Many searches for health education information related to mpox are likely conducted on the web and via AI chatbots because of ease of access and anonymity. For this reason, we believe evaluating the quality of information related to mpox is important.

Several limitations to this study must be kept in mind. First, AI chatbots sometimes generate inaccurate information; therefore, issues with the reliability of the resulting information need to be investigated. Second, this study used a simple prompt, "Please tell me about the keyword," and did not consider prompts aimed at reducing sentence difficulty, generating summaries, generating charts, or promoting prevention or health behaviors. Future research should consider prompts that increase comprehension and ease of action while reducing text difficulty. Third, because this was a cross-sectional study, only information available at the time of the survey was assessed. Web and ChatGPT-4o health education texts are constantly changing. For example, as the spread of mpox has increased, information available on the internet has been updated frequently. In addition, new versions of AI chatbots are released every few months, and the quality of the generated text has reportedly improved with each new version [23,24]. In this study, we used ChatGPT-4o (OpenAI) from August 20 to 30, 2024. Therefore, the findings reflect the performance of that specific version at that time. It is important to note that the results of this study merely represent a snapshot of the situation at the time of the evaluation. Additionally, the moderate interrater reliability observed (ICC=0.43) may be explained by differing

XSL•FO
RenderX

interpretations between the physician and epidemiologist who served as raters. For instance, in PEMAT item 4 (definition of medical terms), the physician assessed that definitions were present, whereas the epidemiologist judged that the explanations were insufficient due to the complexity of the terminology. In contrast, for item 21 (clear steps for actions), the epidemiologist found the materials actionable, while the physician considered the instructions inadequate. These discrepancies suggest that the raters' professional backgrounds influenced their assessments, highlighting a potential limitation in applying PEMAT across multidisciplinary evaluators. Finally, it should be noted that current AI models such as ChatGPT-4o cannot generate visual materials (eg, diagrams, illustrations) in response to general prompts such as "Tell me about mpox." Due to copyright and security limitations, they are also unable to automatically incorporate images from the internet. Therefore, for AI-generated materials to include visual aids, additional steps such as human editing or integration with external tools are required. Alternatively, providing trustworthy visuals from academic articles or official sources to the AI model and requesting explanations based on them may be a practical workaround in future applications.

AI-generated health education materials such as those from ChatGPT-4o appear easier to understand and read compared to traditional web-based content. However, visual aids and clear action-oriented guidance are lacking. These findings suggest that AI can improve how health information is shared with the public, particularly during health emergencies like the mpox outbreak. Nonetheless, more refinement is needed to ensure that the information provided is both actionable and comprehensive. One possible approach to addressing this limitation is prompt engineering, which involves designing questions that elicit more specific, behavior-oriented responses from AI. Additionally, fine-tuning the AI model using public health domain–specific data could help generate more tailored and context-appropriate health guidance.

Acknowledgments

This work was supported by the Japan Society for the Promotion of Science under KAKENHI grant JP 24K06389. From August 20 to August 30, 2024, web pages were searched using the Google search engine, and text related to mpox was generated using ChatGPT-4o (Open AI) artificial intelligence chatbot. The original ChatGPT transcripts are made available as Multimedia Appendix 1.

Abstract

Background: Choosing a transplant program impacts a patient's likelihood of receiving a kidney transplant. Most patients are unaware of the factors influencing their candidacy. As patients increasingly rely on online resources for health care decisions, this study quantifies the available online patient-level information on kidney transplant recipient (KTR) selection criteria across US kidney transplant centers.

Objective: We aimed to use natural language processing and a large language model to quantify the available online patient-level information regarding the guideline-recommended KTR selection criteria reported by US transplant centers.

Methods: A cross-sectional study using natural language processing and a large language model was conducted to review the websites of US kidney transplant centers from June to August 2024. Links were explored up to 3 levels deep, and information on 31 guideline-recommended KTR selection criteria was collected from each transplant center.

Results: A total of 255 US kidney transplant centers were analyzed, comprising 10,508 web pages and 9,113,753 words. Among the kidney transplant guideline–recommended KTR selection criteria, only 2.6% (206/7905) of the information was present on the transplant center web pages. Socioeconomic and behavioral criteria were mentioned more than those related to the patient's medical conditions and comorbidities. Of the 31 criteria, finances and health insurance was the most frequently mentioned, appearing in 25.5% (65/255) of the transplant centers. Other socioeconomic and behavioral criteria, such as family and social support systems, adherence, and psychosocial assessment, were addressed in less than 4% (9/255) of the transplant centers. No information was found on any web page for 45.2% (14/31) of the KTR selection criteria. Geographically, disparities in reporting were observed, with the South Atlantic division showing the highest number of distinct criteria, while New England had the fewest.

Conclusions: Most transplant center websites do not disclose patient-level KTR selection criteria online. The lack of transparency in the evaluation and listing process for kidney transplantation may limit patients in choosing their most suitable transplant center and successfully receiving a kidney transplant.

Introduction

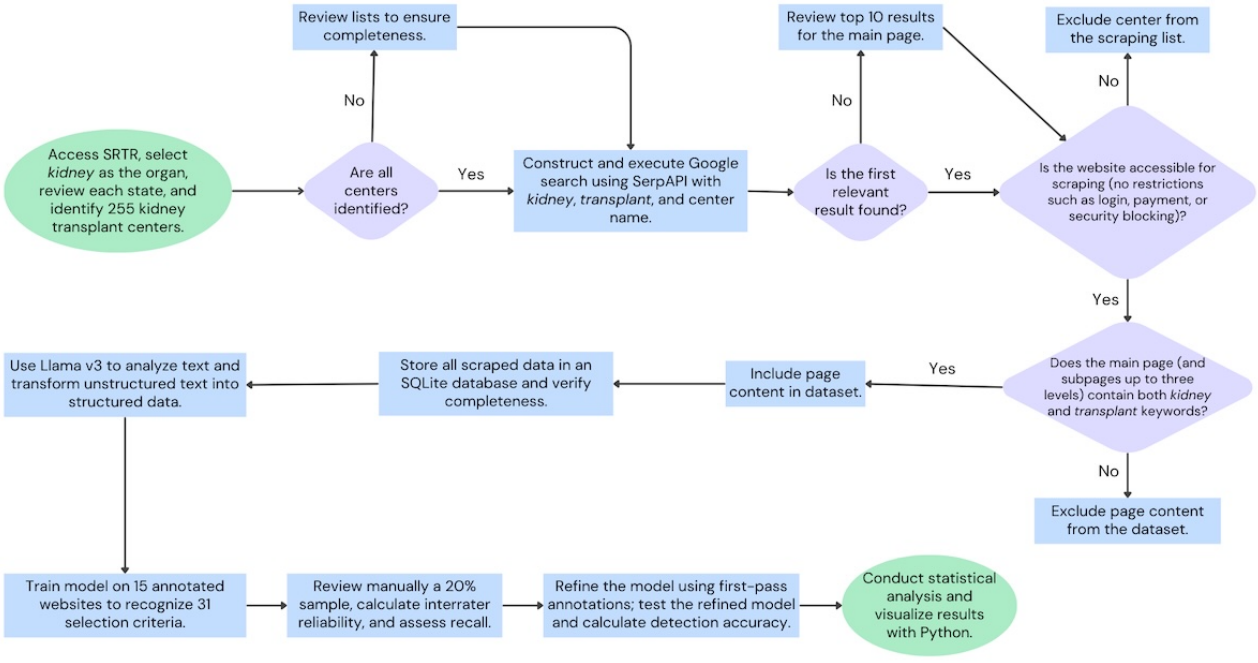
Background

Kidney transplantation is considered the gold standard treatment for patients with end-stage kidney disease [1-3]. However, to receive a kidney transplant, a patient must first be referred, evaluated, deemed a suitable candidate, and then listed at a transplant center [4,5]. Patients may not be fully aware of the factors that shape their candidacy for a kidney transplant or of the variation across centers in reliance on certain evaluation criteria [1,6]. Selecting a transplant program is a critical decision, with far-reaching implications that impact the success of receiving a transplant [5].

Reports from the Organ Procurement and Transplantation Network Ethics Committee on transparency in program selection; the National Academies of Sciences, Engineering, and Medicine on advancing equity in transplantation; and the Health Resources and Services Administration initiatives emphasize the importance of accessible information in supporting shared decision-making [7,8]. In addition to the recognized lack of transparency in available information, there is notable heterogeneity in the prewaitlisting practices and kidney transplant recipient (KTR) selection criteria reported by transplant centers [5,7,9-11]. These inconsistencies contribute to inefficiencies and inequities impacting waitlisting and eventual transplantation, especially considering that insurance plans may only cover a single transplant evaluation [7].

Despite the evolving landscape of policies aimed at increasing equity and access in the prewaitlist process, such as the Increasing Organ Transplant Access (IOTA) model, a critical information gap remains in quantifying the extent of the unavailable information regarding KTR selection criteria, which helps guide the construction of these policies [12]. Furthermore, in an era where patients increasingly use online resources for health care decision-making, accessible online patient-level KTR selection criteria information may aid patients in selecting their most suitable transplant program [13-16]. Recurrent themes have been expressed by patients regarding the difficulty in finding patient-centered information and the lack of transparency throughout the kidney transplant process, which hinder their ability to make informed decisions [17-19].

This Study



While the criteria for determining priority in the national organ allocation system are explicit, those for determining transplant candidacy at the transplant center level remain unclear for most patients. Fragmented data, an overwhelming volume of information across nationwide programs, and their various website links can be challenging for human evaluators to navigate. Moreover, the dynamic nature of online content further complicates the evaluation process. Therefore, using artificial intelligence (AI), specifically training a large language model (LLM), has emerged as a valuable tool to automate this analysis, making it comprehensive, scalable, and efficient.

In this study, we aimed to use natural language processing (NLP) and an LLM to quantify the available online patient-level information regarding guideline-recommended KTR selection criteria reported by US kidney transplant centers.

Methods

As a brief overview of the study's methods, we determined guideline-recommended KTR selection criteria [20], aggregated data from US kidney transplant center websites, and trained and refined an LLM to analyze the available information. The method sequence is illustrated in Figure 1.

Figure 1. Overview of data aggregation, scraping, cleaning, and analysis. SRTR: Scientific Registry of Transplant Recipients.

XSL•FO
RenderX

Ethical Considerations

A determination form confirming that the study did not involve human participants was approved by the Beth Israel Deaconess Medical Center Institutional Review Board.

Selection Criteria Definition

KTR selection criteria categories used in our analysis for the LLM were collected by consulting the Kidney Disease: Improving Global Outcomes Clinical Practice Guideline on the Evaluation and Management of Candidates for Kidney Transplantation [20]. This guideline is designed to aid decision-making and provides a framework for the KTR selection criteria, all of which were included in our list. In addition, to broaden the scope of possible selection criteria and assess the alignment between LLM and human review in identifying KTR selection criteria, we conducted a manual search of the 15 transplant center websites in the New England division. Frequently mentioned criteria not present in the Kidney Disease: Improving Global Outcomes guidelines were added (Table S1 in Multimedia Appendix 1).

Data Aggregation

We accessed the Scientific Registry of Transplant Recipients to compile a list of 255 US kidney transplant centers. Specifically, in the search bar, "kidney" was selected as the organ, and then each state was reviewed to include the associated transplant center or centers in our dataset.

To access the transplant centers' websites, we conducted an online search using Google [21] searches via SerpAPI (SerpApi, LLC) [22] with the keywords "kidney" and "transplant" along with the name of each kidney transplant center and selected the first organic result. We opted to use Google because it is the most common search engine, with an 82% market share worldwide [23]. To ensure a systematic approach, we used SerpAPI, a search engine tool designed to access results programmatically in a structured format [24]. When we refer to a *website*, it indicates the entire online domain associated with a specific kidney transplant center. In contrast, a *web page* refers to a single page within a website. Therefore, for each transplant center, there was one website and multiple web pages.

Each transplant center's first organic result was manually reviewed. If the results did not appear to represent the center's main website, the top 10 search results were examined to locate the correct main website. We included text from subpages that were linked to the main website, up to 3 levels in, and to ensure relevance, only pages containing both "kidney" and "transplant" were included in the dataset.

Centers that lacked a clearly identifiable website or appeared only in aggregator listings were excluded from the scraping process. Web pages that required a log in, asked for payment, or disallowed scraping were also excluded (Table S2 in Multimedia Appendix 1).

After defining the web pages to be included, we conducted data scraping for content aggregation. For this purpose, AngleSharp (AngleSharp.IO) [25] was the HTML parser, DotNetBrowser (TeamDev Ltd) [26] was the programmable browser emulator, UglyToad.PdfPig (UglyToad Software Ltd) [27] was used to parse PDFs, and SQLite [28] was used as the database.

NLP and LLM Analysis

NLP and LLMs enabled the interpretation and computerized *reading* of unstructured text and the transformation of the text into structured data for analysis. Llama (version 3; Meta Platforms Inc) [29] was used to conduct the LLM analysis. Initially, data from 15 manually annotated web pages were used for training the model to identify the 31 predefined KTR selection criteria in the scraped text from all the web pages included.

Model Testing

Table 1 provides an overview of the model performance metrics.

Table 1. Summary of large language model performance metrics during model validation.

Metric	Value	Description
Interrater reliability, %	97.8	Agreement between 2 human reviewers (BR and SC) on 20% of web pages
Recall (approximate), %	99.7	Less than 0.3% of relevant data were missed in the random validation sample
Sensitivity (first-pass model), %	97.6	Accurately identified KTR[a] selection criteria
Specificity (first-pass model), %	4.2	Low because of false positives (eg, mislabeling "donor" as financial donor)
False positive reduction after refinement, %	54	Improvement in accuracy after further model training
Detection within 95% CI, n/n (%)	23/31 (74)	Number of criteria with detection rates within 95% CI
Detection within 99% CI, n/n (%)	5/31 (16.1)	Number of criteria with detection rates within 99% CI
Criteria exceeding 99% CI, n/n (%)	3/31 (9.7)	GFR[b], dialysis, and finances and insurance categories exceeded expected detection

[a]KTR: kidney transplant recipient.

[b]GFR: glomerular filtration rate.

First Model Testing

A random sample of 20% of the web pages scraped from these first-pass LLM results was then hand-reviewed by 2 investigators (BR and SC). The interrater agreement was high, with 97.8% raw concordance; the corresponding chance-corrected coefficient (Cohen κ=0.39) indicated moderate reliability after accounting for the expected agreement by

XSL•FO
RenderX

chance. To facilitate collaborative review and structured comparison of LLM outputs, our team conducted annotation and verification using a shared cloud-based spreadsheet, allowing tabular alignment of criteria across centers and efficient resolution of discrepancies. Discrepancies were resolved through discussion. The human-reviewed sample was used as the ground truth. This first-pass model demonstrated a strong recall within the random sample, missing less than 0.3% of the relevant data. Although the model resulted in a high sensitivity (97.6%), it had an unacceptably low specificity (4.2%). Therefore, we continued to train the model to improve its performance.

Second Model Validation

The primary reason that the first-pass–trained version of the model had a high number of false positives was that it tended to misclassify word mentions as KTR selection criteria. For instance, mentioning diabetes on a website does not necessarily mean that it is a transplant criterion. Therefore, to refine the specificity of the model, the annotated sample from the first-pass training was used to further train the model.

Training the model using the additional hand-annotated data resulted in highly accurate estimates of the presence of the 31 criteria across the transplant centers' websites. Detection estimates were calculated with both 95% and 99% CIs. For 23 (74.2%) categories, detection rates fell within the 95% CI, while 5 (16.1%) categories met the 99% confidence level. However, 3 (9.7%) categories exceeded the upper bound of the 99% CI: glomerular filtration rate (by 35%), dialysis (by 18%), and finances and health insurance. A further refinement of the finances and health insurance category reduced false positives by 54%, largely because of the model's misinterpretation of the word "donor" as a financial donor rather than an organ donor.

In addition to assessing the overall availability of the kidney transplant center KTR selection criteria, we further examined the clarity and consistency of the criteria presented online by selecting 6 criteria and extracting 2 representative quotes for each, which were then compiled into Table S3 in Multimedia Appendix 1. This table was used to illustrate the heterogeneity and lack of clarity in how these criteria were described across the websites.

Statistical analysis was conducted using Python version 3.12 Matplotlib, Pandas, and Scikit-learn libraries. GeoPandas was used to map the centers based on the ZIP code, and geographic divisions were based on the US census divisions. Each division included a group of states.

Results

We identified 255 US kidney transplant centers. Of these, we successfully scraped 203 (79.6%) transplant center websites, exploring subpages up to 3 levels deep. The final dataset comprised 10,508 web pages and 9,113,753 words.

Criteria Mentions by Center

An analysis of publicly available websites revealed that most transplant centers included only a limited range of KTR selection criteria. Across the 255 US kidney transplant centers, we evaluated the presence of 31 guideline-recommended criteria per center, with 7905 expected mentions of the KTR selection criteria. Of these, only 206 (2.6%) KTR selection criteria were found, indicating that only a small fraction of the expected information was publicly available online. Moreover, among the 203 (79.6%) transplant center websites that were successfully scraped, most kidney transplant centers had minimal or no accessible information regarding their transplant criteria; 56.1% (143/255) of the centers did not provide any listing criteria information. A smaller number of centers provided limited information, with 53 (20.8%), 38 (14.9%), and 13 (5.0%) centers listing one, 2, and 3 criteria, respectively. Few centers included information about 4 or more criteria, with 4 (1.6%) and 4 (1.6%) centers listing 4 or more than 4 criteria, respectively. No center listed more than 6 criteria on their website.

Criteria Mentions by Category

Of all 31 KTR selection criteria included, 14 (45.2%) were not mentioned on any of the 203 transplant center websites analyzed. These included 2 criteria under the socioeconomic and behavioral category (homelessness or other unstable living conditions and support networks), 10 criteria related to medical conditions and comorbidities (diabetes, heart disease, neurocognitive disorder/dementia, hematologic disorders, multiple organ failure, and immunologic assessment), 1 laboratory value (creatinine clearance), and 1 functional status criterion (mobility), which was classified under the category of others.

Conversely, the most common category mentioned was socioeconomic and behavioral in 27.1% (69/255) of the centers (Table 2). Of note, this analysis focused solely on whether the KTR selection criteria were mentioned on transplant center websites, without evaluating the clarity, context, or depth of explanation. Specifically, finances and health insurance were mentioned at 25.5% (65/255) of centers, while a few centers considered other factors—2% (5/255) addressed family and/or social support system, 1.2% (3/255) listed adherence, and 0.4% (1/255) mentioned psychosocial assessments. Homelessness and support networks were not mentioned in any center. Medical conditions and comorbidities were addressed by 47 (18.4%) centers, mainly chronic kidney disease stage 15 (5.9%), life-threatening diseases 12 (4.7%), HIV 8 (3.1%), infection 5 (2.0%), frailty 5 (2.0%), drug or alcohol abuse 4 (1.6%), malignancy 4 (1.6%), smoking 3 (1.2%), and psychiatric illness 1 (0.4%). None of the centers mentioned diabetes, heart disease, peripheral vascular disease, bone or mineral disorders, liver disease, lung disease, neurocognitive disorders or dementia, hematologic disorders, multiple organ failure, or immunological assessments. For demographics and laboratory values, 45 (17.6%) centers assessed at least one criterion. Glomerular filtration rate was the most common (34/255, 13.3%), followed by age (10/255, 3.9%) and BMI (9/255, 3.5%).

Mobility	0 (0.0)	255 (100.0)

[a]CKD: chronic kidney disease.

[b]GFR: glomerular filtration rate.

When evaluating the availability of the KTR selection criteria for kidney transplant centers on patient-accessible websites, we compiled representative quotes to illustrate how the KTR selection criteria were presented online (Table S3 in Multimedia Appendix 1). These quotes highlight that, in addition to the fact that the KTR selection criteria were mentioned in only 2.6% (206/7905) of instances, many were unclear and inconsistently described.

XSL•FO
RenderX

Geographic Variation in Transparency

As shown in Table 3, the availability of distinct categories of information across the geographic divisions varied significantly; information gaps were evident across multiple geographic regions. The South Atlantic division (Delaware, Florida, Georgia, Maryland, North Carolina, South Carolina, Virginia, District of Columbia, West Virginia) and the East North Central division (Illinois, Indiana, Michigan, Ohio, Wisconsin) provided the highest percentage of distinct KTR selection criteria, with both divisions showing 41.9% (13/31) availability. In contrast, the West North Central (Iowa, Kansas, Minnesota, Missouri, Nebraska, North Dakota, South Dakota), East South Central (Alabama, Kentucky, Mississippi, Tennessee), and New England (Connecticut, Maine, Massachusetts, New Hampshire, Rhode Island, Vermont) divisions offered the least amount of information, each with only 16.1% (5/31) of the distinct criteria available. Other divisions, such as the Pacific (Alaska, California, Hawaii, Oregon, Washington) and Middle Atlantic (New Jersey, New York, Pennsylvania), displayed moderate information availability at 35.5% (11/31), while the Mountain division (Arizona, Colorado, Idaho, Montana, Nevada, New Mexico, Utah, Wyoming) followed closely with 32.3% (10/31). Despite having numerous centers, the West South-Central division (Arkansas, Louisiana, Oklahoma, Texas) had relatively low information availability, with only 25.8% (8/31) of the distinct criteria found (Table 3).

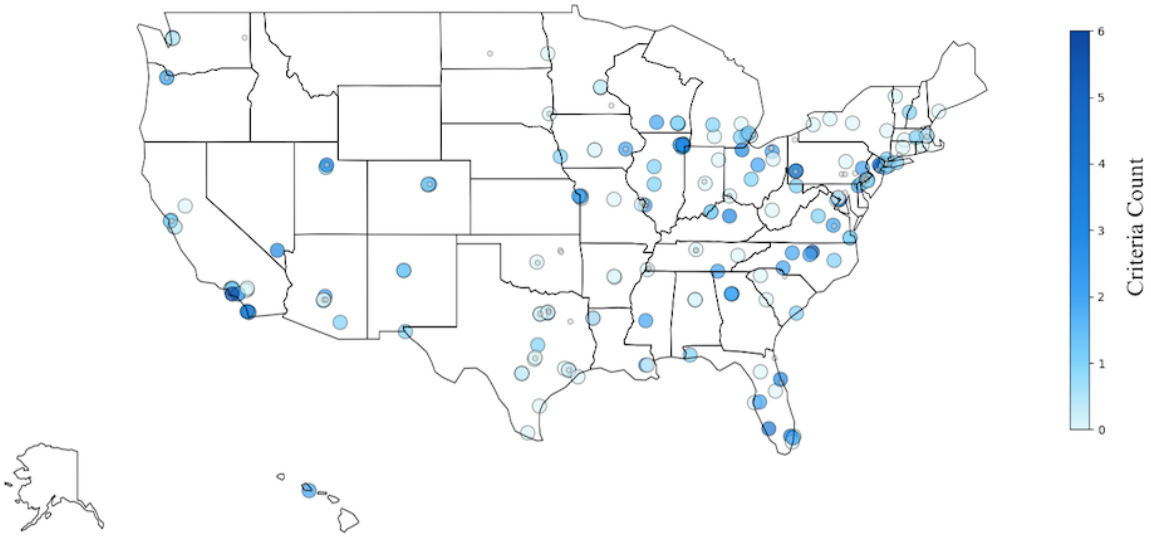
[a]This column illustrates the number of times the selection criteria were mentioned on the transplant center websites in a specific division.



[b]Indicates the number of unique selection criteria referenced on the web pages in that division.

States such as Idaho, Montana, and Wyoming, which are part of the Mountain division, do not have kidney transplant centers; therefore, they were not expected to have available KTR selection criteria. North and South Dakota typically rely on regional transplant programs, which may contribute to the lower availability of online KTR selection criteria observed in the West North Central division.

The geographic distribution of the individual kidney transplant centers across the US further highlights differences with transparency in reporting KTR selection criteria. A national map of the 255 kidney transplant centers shows each center color-coded by the number of KTR selection criteria mentioned on its website. The scale ranges from 0 to 6, where lighter shades indicate centers with no or few criteria reported, while darker shades represent centers providing more detailed information. Smaller gray markers correspond to centers without available information or those that did not pass initial filtering (Figure 2).

Figure 2. Geographic distribution of US kidney transplant centers by the number of kidney transplant recipient selection criteria mentioned on websites.

Discussion

Principal Findings

In this study, we evaluated patient-facing information regarding KTR selection criteria across the websites of US kidney transplant centers using AI and an LLM. Our findings revealed an unmet need for patients undergoing the kidney transplant prewaitlist process: most transplant center websites with online patient-facing information (7699/7905, 97.4%) did not contain KTR selection criteria, and among those that did, few included information about multiple criteria. More than half of the transplant centers (143/255, 56.1%) did not report any KTR selection criteria, limiting access to crucial patient information. Moreover, variation in the availability of KTR selection criteria information was observed across geographic divisions, with some regions providing more information than others.

These gaps in access to online patient-level information are especially important given the growing reliance on the internet as a tool for health care decision-making [30-32]. Patients are increasingly turning to online resources to guide their health care choices, and the lack of clear and consistent KTR selection criteria on transplant center websites can lead to confusion about their transplant candidacy or center-specific suitability [30,33]. This lack of access and transparency may undermine patients' and their families' autonomy in taking timely and informed decisions regarding their transplant care [7].

Although the lack of transparency in the KTR selection criteria is widely acknowledged [7], this study identified and quantified the gaps in the available information that can guide improvements. Policies such as the Presidential Executive Order on Advancing American Kidney Health and Centers for Medicare and Medicaid Services (CMS) initiatives increased transplant referrals and tied dialysis facility transplant rates to quality metrics [12,34]. However, to maximize the benefits of these efforts, policy adaptations, such as the IOTA model [12], which emphasized strategies that enhance transparency in the referral process, are important for improving equity and efficiency [19,35]. However, the transparency provisions initially proposed in the IOTA were ultimately eliminated. Patients often lack sufficient information about the transplantation process, which may lead them to seek evaluation at centers that are unlikely to list them, limiting their overall access to transplantation [36]. Transparency in program-specific KTR selection criteria would also benefit nephrologists, who play a crucial role in referring patients to transplant centers, and would enhance shared decision-making [4,19,37]. If nephrologists had access to the specific KTR selection criteria for each transplant center, they would have been better equipped to refer patients to the center most suited to their individual needs. Equally important is clarifying what type of information is most useful to patients. Insufficient information can hinder patient decision-making, and the information provided needs to be accurate, clear, and useful for patients. The transplant centers should clearly disclose their KTR selection criteria, ensuring that patients have the option to choose access to information, while still allowing them to disregard this information if they prefer. Such a format and content will also need refining based on stakeholder input.

Our findings aligned with prior research, which highlighted the challenges patients face in locating relevant information to choose a transplant center [17]. Moreover, significant variation in prewaitlisting practices and access to KTR selection criteria information across geographic regions and centers further complicates the decision-making process, as patients may encounter inconsistent or incomplete data depending on where they seek care [17,38,39]. However, this study was the first to provide a US national-level analysis quantifying the gaps in the availability of transplant center information on their websites. By shedding light on these barriers to accessing KTR selection criteria information, this study supported the recommendations of the Organ Procurement and Transplantation Network Ethics Committee for improving transparency in transplant program selection [7]. Access to and transparency in KTR selection

XSL•FO
RenderX

criteria can be assessed using frameworks such as Accountability for Reasonableness, which emphasizes fairness and equity in health care decision-making [40,41]. Furthermore, decisions about patient candidacy tend to be more acceptable to all parties when the process is perceived as transparent [42]. Further research is needed to examine how differences in online KTR selection criteria reporting between transplant centers can impact evaluation completion and listing practices.

Beyond the gap in online patient-level information, disparities also extend to the kidney transplant referral process itself [43]. Many patients referred for transplant evaluation do not complete the necessary steps, which may stem from unclear health care provider communication and misinformation [1]. Although platforms such as the Scientific Registry of Transplant Recipients provide important data on transplant center outcomes [44], they do not usually include details on the KTR selection criteria. This highlights the ongoing need for a more transparent and regulated pretransplant evaluation process, which is crucial for building trust throughout the transplant process [1,7,19,45].

Although transplant centers generally follow protocol-driven selection processes to assess the suitability of potential candidates [46], there is heterogeneity in how KTR selection criteria are shared with patients across centers. Although some disclose financial criteria (the most frequently mentioned), others do not. Medical factors, namely clinical cutoffs, are mentioned in less than one-fifth of the center websites. Few centers report lifestyle and psychosocial factors that are decisive in transplant candidacy [11,47]. Government agencies, such as the Health Resources and Services Administration and the National Academies of Sciences, Engineering, and Medicine, are advocating for strategies to clarify the kidney transplant prewaitlist process [8,48]. We suggest that mandatory and regulated disclosure of consistent KTR selection criteria across centers' online patient-level information could be a potential pathway to ensure more equitable access to kidney transplantation.

This study provides relevant insights into the transparency of KTR selection criteria information in a novel way using AI and NLP to facilitate broader-scale understanding. Previous research in nephrology has demonstrated that NLP is effective in identifying the presence or absence of qualitative data within large datasets, such as electronic health records [49]. However, with any AI-driven analysis, balancing sensitivity and specificity is challenging. Our model performed well overall, but it may have missed or inaccurately identified information in certain instances, as is common with AI-NLP approaches. Therefore, these results should be interpreted as an aggregate estimate of the available information rather than a definitive representation of every transplant center's criterion.

Many factors influence transplant eligibility, and standardizing thresholds can be challenging, particularly when certain patient conditions may make eligibility more nuanced, requiring a case-by-case assessment [50]. Selection criteria may vary across centers, which may reflect differences in their experiences, such as older age, life-threatening conditions, and higher BMI. These variations in thresholds can be valuable, as some centers are more permissive than others and may include patients who might otherwise be excluded. Despite this, transparency remains the main pillar to ensure that patients can identify appropriate programs efficiently.

Moreover, despite this complexity, the reporting of KTR selection criteria, including absolute contraindication, is valuable. These criteria could be presented with explanations, such as highlighting that certain conditions may be acceptable if optimized or corrected. Disclaimers emphasizing that the information serves as a guide to help patients navigate the system and choose the transplant center most suited to their needs could also be included. We believe that having online patient-level available criteria is crucial in helping patients and providers navigate the prewaitlist process and a priority in improving the transplant system overall by increasing their chance to complete a transplant evaluation successfully.

Finally, it is relevant to note that not all centers may keep their websites up to date, and the KTR selection criteria may be available to patients through other modalities, such as paper or patient portals. Nonetheless, these alternatives are not equally accessible to all patients and may further contribute to perceived inequities in the system. In future research, it would be valuable to assess how centers make this information available through paper or patient portals and how consistent it is. Transplant center websites may be primarily created for marketing purposes with varying input from medical physicians; therefore, collaboration between medical and administrative teams is crucial to improving the accuracy and utility of patient-level online resources, ensuring that the information provided is accessible and reliable. We also acknowledge that variation in information disclosure may be influenced by center-specific factors, such as size, staffing capacity, or institutional strategy. Although our analysis focuses on the patient perspective—assessing whether information is readily accessible—future research could examine how these organizational characteristics shape transparency practices across regions.

As illustrated by the representative quotes from online patient-level information, there is variability in how centers present their KTR selection criteria. Therefore, evaluating the quality and accuracy of the websites' content is warranted to examine specific differences across centers in online patient-level available information regarding KTR selection criteria. To better understand the heterogeneity between centers' reporting, the use of NLP could be refined to identify and analyze more nuanced aspects of the KTR selection criteria.

Conclusions

In summary, we found that 97.4% of online patient-level information regarding the KTR selection criteria was unavailable across centers in the United States. The extent of this lack of transparency profoundly limits patients in choosing their most suitable transplant center. Despite current federal initiatives, it remains a challenge to report specific selection criteria for KTR that could increase patients' access to information related to their candidacy. This fosters their autonomy and enables them to make informed decisions when choosing their transplant program, ultimately impacting their access to transplants.

Data Availability

The datasets generated or analyzed during this study are not publicly available due to the scale of the data collection, which involved scraping over 10,000 web pages and processing more than 9 million words, making it not feasible to release the full dataset. However, all data were obtained from publicly available online information given by the kidney transplant centers' websites, and our dataset is available from the corresponding author on reasonable request.

Abstract

Background: Online depression screening tools may increase uptake of evidence-based care and consequently lead to symptom reduction. However, results of the DISCOVER trial suggested no effect of automated results feedback compared with no feedback after online depression screening on depressive symptom reduction six months after screening. Interpersonal variation in symptom representation, health care needs, and treatment preferences may nonetheless have led to differential response to feedback mode on an individual level.

Objective: The aim of this study was to examine heterogeneity of treatment effects (HTE), that is, differential responses to two feedback modes (tailored or nontailored) versus no feedback (control) following online depression screening.

Methods: We used causal forests, a machine learning method that applies recursive partitioning to estimate conditional average treatment effects (CATEs). In this secondary data analysis of the DISCOVER trial, eligible participants screened positive for at least moderate depression severity but had not been diagnosed or treated for depression in the preceding year. The primary outcome was heterogeneity in depression severity change, over a and six-month follow up period, measured with the Patient Health Questionnaire-9. Analysis comprised exploration of average treatment effects (ATE), HTE, operationalized with the area under the targeting operator characteristic curve (AUTOC), and differences in ATE when allocating feedback based on predicted CATE. We extracted top predictors of depression severity change, given feedback and explored high-CATE covariate profiles. Prior to analysis, data was split into training and test sets (1:1) to minimize the risk of overfitting and evaluate predictions in held-out test data.

Results: Data from 946 participants of the DISCOVER trial without missing data were analyzed. We did not detect HTE; no versus nontailored feedback, AUTOC −0.48 (95% CI −1.62 to 0.67, *P*=.41); no versus tailored feedback, AUTOC 0.06 (95% CI −1.21 to 1.33, *P*=.93); and no versus any feedback, AUTOC −0.20 (95% CI −1.30 to 0.89, *P*=.72). There was no evidence of alteration to the ATE in the test set when allocating feedback (tailored or nontailored) based on the predicted CATE. By examining covariate profiles, we observed a potentially detrimental role of control beliefs, given feedback compared with no feedback.

Conclusions: We applied causal forests to describe higher-level interactions among a broad range of predictors to detect HTE. In absence of evidence for HTE, treatment prioritization based on trained models did not improve ATEs. We did not find evidence of harm or benefit from providing tailored or nontailored feedback after online depression screening regarding depression severity change after six months. Future studies may test whether screening alone prompts behavioral activation and downstream depression severity reduction, considering the observed uniform changes across groups.

Introduction

Online depression screening may foster early identification of individuals with depressive symptoms and reinforce help-seeking behavior [1,2]. However, recently published results of the DISCOVER trial (ClinicalTrials.gov, NCT04633096) suggested no effect of automated results feedback compared with no feedback after online depression screening on depressive symptom reduction six months after screening [1].

Randomized controlled trials (RCT) are the gold-standard method for evaluating intervention efficacy. Still, evidence-based medicine incorporates the notion of differential responses to interventions on a person-level, potentially masking harms or benefits at the group-level [3]. Thus, it is important to examine individual-level responses to feedback.

Machine-learning (ML) methods have previously been adapted to examine such heterogeneity of treatment effects (HTE) [4-6]. ML can circumvent the issue of multiple testing through cross-validation and by design, account for higher level interactions [7]. ML approaches to estimate HTE have been successfully applied in health care literature, especially in cardiology and psychiatry [5,8].

The aim of this paper was to investigate the presence of HTE in response to feedback (no feedback ie, control group vs nontailored or tailored, ie, intervention), following online depression screening. We tested for the presence of HTE, based on person-level characteristics at baseline, with heterogeneity in depression severity change at six months as the primary outcome. The efficacy of allocating feedback to individuals with more favorable predicted conditional treatment response was examined in exploratory analysis.

Methods

Study Sample and Design

DISCOVER is a three-armed RCT examining change in depression severity six months after online screening with tailored, nontailored, or no feedback (control). The study was advertised as a study on stress and psychological well-being [1]. Recruitment strategies involved print and online advertisements on social media platforms and in a nationwide online access survey panel in Germany [1]. Eligible participants were 18 years or older, proficient in German, and screened positive for at least moderate depression severity (Patient Health Questionnaire-9, PHQ-9 ≥10) [1]. Participants with missing data, or those with a diagnosis of or treatment for depression in the previous year were excluded.

Feedback comprised depression screening results, a recommendation to consult a mental health care professional or general practitioner, and further information regarding depression and related treatment based on national guidelines [1,9]. For the tailored feedback group, feedback was adapted according to participants' symptom profiles, treatment preferences, and available guideline-recommended options [1,9].

Ethical Considerations

Review and approval was provided by the Ethics Committee of the Hamburg Medical Chamber (PV7039) [9]. Participants provided online informed consent covering secondary data analyses [1]. Participants received a € 5 (US $5.85) voucher for compensation upon each completed follow-up. Data was deidentified prior to analysis.

Main Outcomes and Measures

The primary outcome was heterogeneity in depression severity change six months after online screening. Depression severity was measured with the PHQ-9 [10]. Predictors involved baseline depression (PHQ-9), anxiety (Generalized Anxiety Disorder Scale-7; GAD-7 [11]), and somatic symptom severity (Somatic Symptom Scale-8; SSS-8 [12]), health-related quality of life (EuroQoL-5 Dimension-5 Level visual analogue scale [EQ-5D-5 L VAS]) [13], illness beliefs (Brief Illness Perception Questionnaire; B-IPQ [14,15]), patient history, depression-related risk factors, and sociodemographic characteristics (Table S1 in Multimedia Appendix 1).

Statistical Analysis

Causal Forests (CF) [5,6] have previously been used to investigate HTE [8] (Box S1 in Multimedia Appendix 1). CFs estimate conditional average treatment effects (CATE), which approximate individual-level treatment effects (ITE). ITE cannot be inferred directly since only one potential outcome is realized per participant. Thus, CATE are more granular than average treatment effects (ATE) but less granular than ITE.

Two CFs were trained based on either training (tau-forest) or test data (eval-forest), with a random split (1:1). CFs were trained with 2000 trees, a sample fraction of 0.5, a minimum node size of 5, and mtry = 30. ATE and CATE were computed by contrasting intervention (nontailored [1], tailored [2], or any [1/2] feedback) to no feedback (control) with depression severity change as the outcome and a propensity score for treatment allocation (P=.50) [4,5].

To assess the presence of HTE discretely, tau-forest predictions of CATE for the test data were grouped into quartiles. Then, ATE was estimated in each quartile using the eval-forest. To assess the presence of HTE continuously, we computed the area under the targeting operator characteristic curve (AUTOC) and tested for the presence of HTE with a significance test for AUTOC (H_1:AUTOC≠0) [4]. Significance of AUTOC was tested two-sided, with bootstrapped standard errors (n=200 bootstrap replicates).

For a comprehensive overview of model evaluation and sample code, see Box S2 in Multimedia Appendix 1, Sverdrup, Petukhova [4] and Klee [16]. Analyses were conducted using R (version 4.3.1; R Foundation for Statistical Computing) using the *grf* package [17].

Results

Baseline Characteristics

After visual inspection of missingness patterns, 19 participants were removed, assuming missingness at random (Table S2 in

XSL•FO
RenderX

Multimedia Appendix 1). In total, 946 participants were eligible for analysis. Participants were aged 18 to 79 years, mean 37.20 (SD 13.98) (Table 1).

Table . Baseline characteristics of participants in the analytic data set (N=946).

Characteristic	No feedback (n=318)	Nontailored feedback (n=313)	*P* value[a]	Tailored feedback (n=315)	*P* value[a]
Age in years, mean (SD)	36.4 (13.7)	38.2 (13.8)	.11	37.0 (14.4)	.62
Gender, n (%)			.85[b]		.73[b]
Women	232 (73.0)	222 (70.9)	—	221 (70.2)	—
Men	83 (26.1)	88 (28.1)	—	91 (28.9)	—
Other	3 (0.9)	3 (1.0)	—	3 (1.0)	—
Education, n (%)			.66		.55
<10 years	55 (17.3)	59 (18.8)	—	47 (14.9)	—
≥10 years	94 (29.6)	99 (31.6)	—	104 (33.0)	—
University entrance qualification	169 (53.1)	155 (49.5)	—	164 (52.1)	—
Depression severity (PHQ-9[c]), mean (SD)	14.8 (4.03)	14.7 (4.09)	.78	14.8 (3.82)	.94
Somatic symptom severity (SSS-8[d]), mean (SD)	14.6 (5.23)	14.5 (5.13)	.90	14.3 (5.32)	.57
Anxiety severity (GAD-7[e]), mean (SD)	12.0 (4.32)	12.5 (4.23)	.19	12.0 (4.29)	.94

[a]*P* values for pairwise comparisons with the 'no feedback' group. Continuous characteristics were compared with Student's *t*-test, categorical characteristics were compared with χ^2 tests.

[b]χ^2 approximation may be incorrect due to small cell size. Analysis based on men and women only replicated findings (*P*=.63 for nontailored feedback vs no feedback, *P*=.48 for tailored feedback vs no feedback).

[c]PHQ-9=Patient Health Questionnaire-9.

[d]SSS-8=Somatic Symptom Scale-8.

[e]GAD-7=Generalized Anxiety Disorder Scale-7.

Average Treatment Effect

We did not find evidence of non-zero ATE in either tau- or eval-forests, suggesting no benefit of providing any form of feedback compared with the control (no feedback) (Table 2).

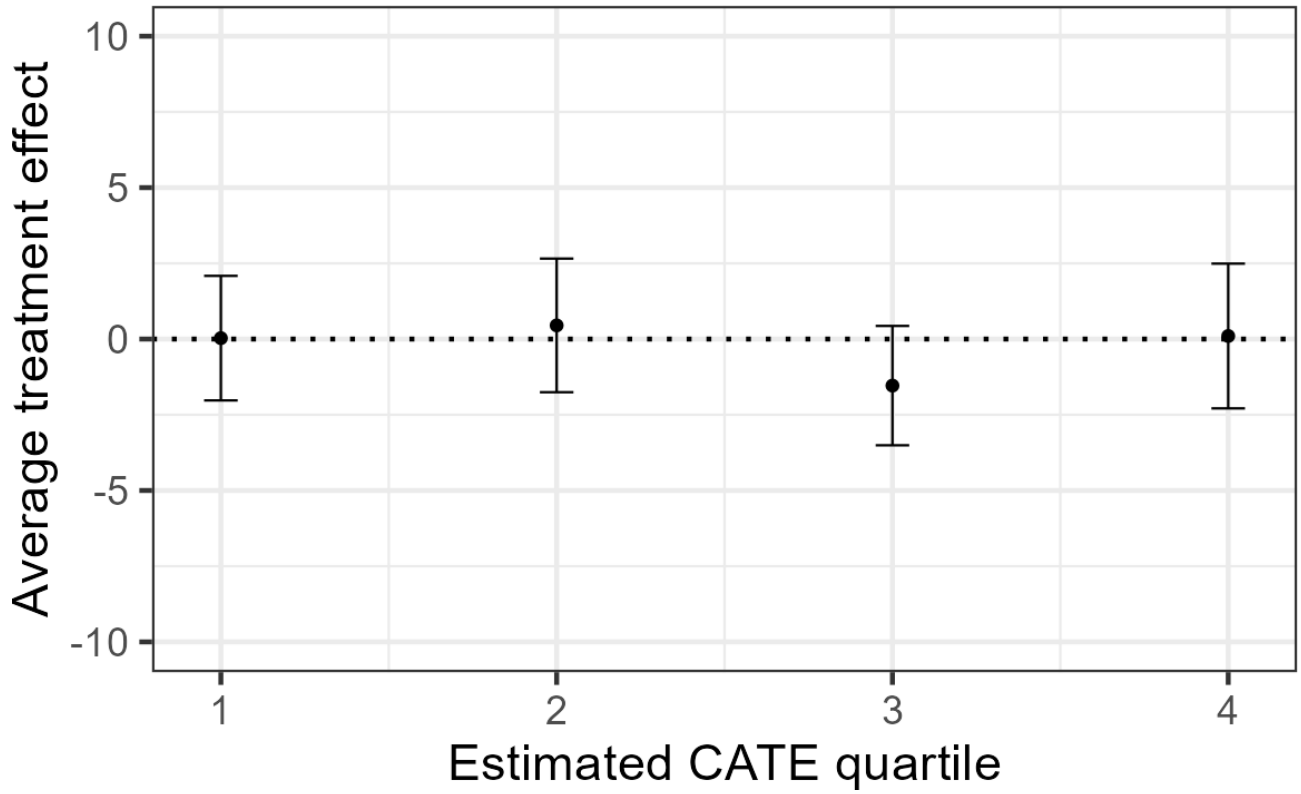
Table . Average treatment effects for pairwise comparison of feedback conditions.

Comparison	Tau-forest[a]	Eval-forest[b]
	ATE[c] (SE)	ATE (SE)
No feedback versus nontailored feedback	0.04 (0.54)	−0.24 (0.55)
No feedback versus tailored feedback	−0.38 (0.57)	−0.16 (0.57)
No feedback versus any feedback	0.07 (0.48)	−0.48 (0.49)

[a]Tau-forest is based on training data.

[b]Eval-forest is based on test data.

[c]ATE: Average treatment effect.



Heterogeneity in Treatment Effects

There was no evidence of HTE when comparing nontailored (Figure 1) or any feedback with control (Figure S4 in Multimedia Appendix 1). However, there was a lower (ie, more favorable) ATE when comparing tailored feedback with control among participants with predicted CATE in the second most

XSL•FO
RenderX

favorable quartile regarding depression severity change (Figure S1 in Multimedia Appendix 1).

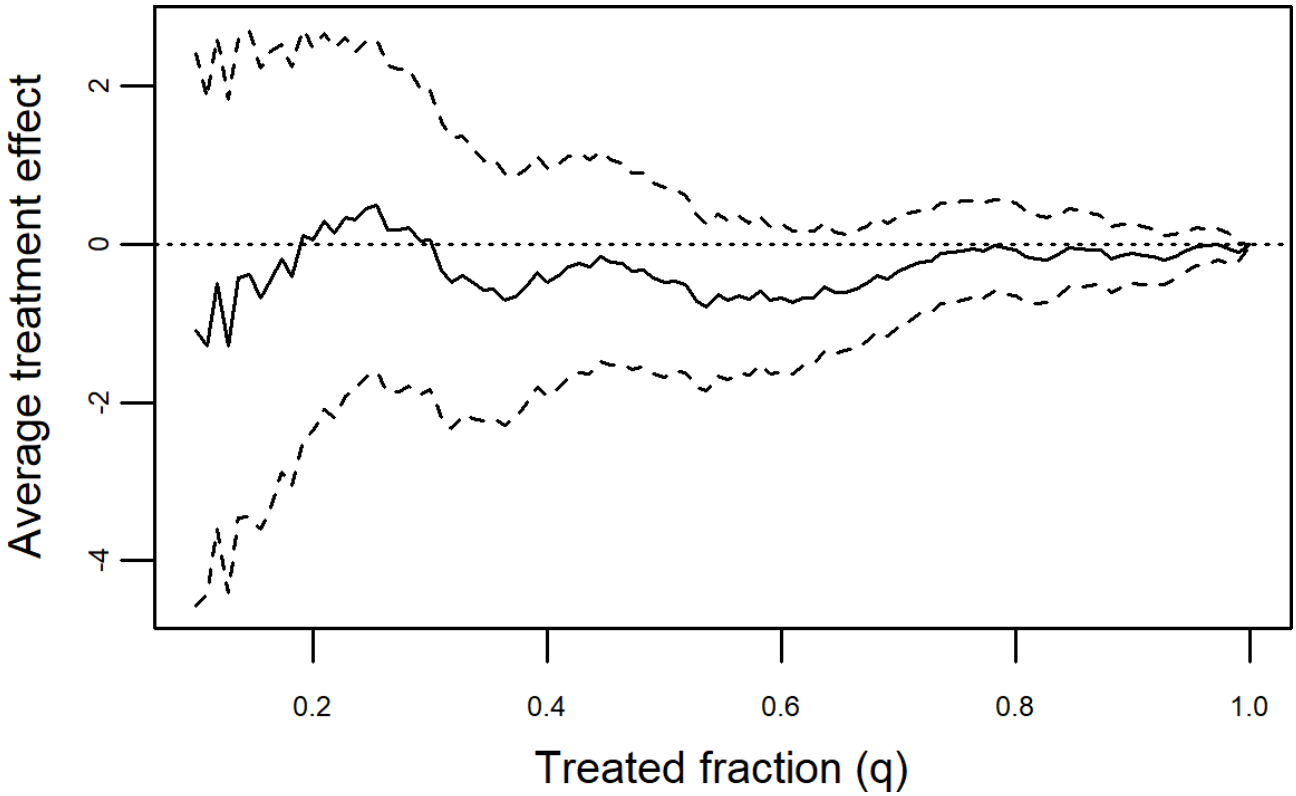


Figure 1. Average treatment effects in participant groups reflecting quartiles of predicted CATE from lowest (L) to highest (R). CATE was predicted in test data with the tau-forest. ATE was estimated within quartiles with the evaluation forest (based on test data). Positive values indicate less favorable ATE. ATE: average treatment effect; CATE: conditional average treatment effect.

AUTOC estimates (Figures S2 and S5 in Multimedia Appendix 1) did not suggest the presence of HTE in any comparison: AUTOC −0.48 95% CI −1.62 to 0.67, *P*=.41, nontailored; AUTOC 0.06, 95% CI −1.21 to 1.33, *P*=.93 tailored; AUTOC −0.20 (95% CI −1.30 to 0.89, *P*=.72 any feedback vs control). Allocating feedback based on predicted CATE did not substantially alter ATE (Figure 2). This is consistent with the near-zero AUTOC estimates, and indicates limited potential for altering the effects of feedback mode regarding depression severity change through targeted allocation.

XSL•FO
RenderX

Figure 2. Targeting operator characteristic curve plot. The dashed lines are pointwise 95% confidence intervals conditional on the estimated CATE function, (ie, the tau-forest based on the training data). The y-lab illustrates the benefit of providing feedback only to a fraction of participants based on their CATE (ie, treatment priority score), over treating everyone (difference in average treatment effects; ie, PHQ-9 change six months after screening). The x lab illustrates the fraction treated from highest (L) to lowest (R) CATE. Positive values indicate less favorable ATE. ATE: average treatment effect; CATE: conditional average treatment effect.

Top Predictors of Harm or Benefit From Treatment

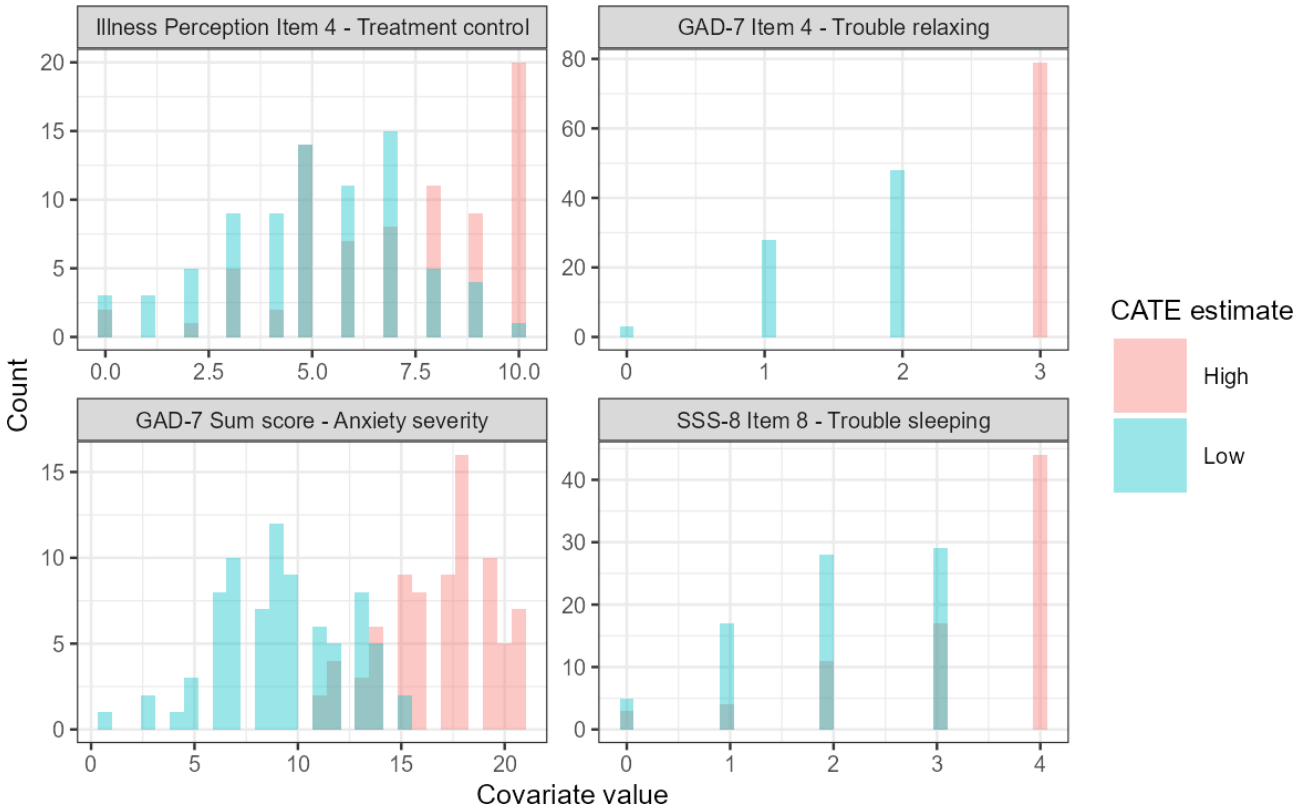
The most important predictors of the tau-forest (comparing nontailored feedback with control) were items assessing depression–related treatment control belief (B-IPQ), trouble relaxing (GAD-7), anxiety severity (GAD-7) and trouble sleeping (SSS-8). For tailored feedback compared with control, items denoting age, somatic symptom (SSS-8) and anxiety (GAD-7) severity and depression-related treatment control belief (B-IPQ) were most important. For any feedback compared with control, illness beliefs (B-IPQ) were most important: treatment and personal control, concern, and emotional response.

Sensitivity Analyses

Higher treatment control (nontailored feedback vs control) and personal control beliefs (any feedback vs control) were the only predictors significantly associated with a linear approximation of CATE (Table 3 and Tables S3 and S4 in Multimedia Appendix 1). Both predictors were associated with less favorable CATE estimates, suggesting less favorable depression severity change at follow-up, given feedback.

XSL•FO
RenderX

Table . Best linear projection for top predictors of the causal forest with training data.



Term	Estimate	SE	*P* value
GAD-7[a] Item 4: How frequent did you feel impaired by the following symptoms during the past 2 weeks? – Trouble relaxing (0 not at all to 3 almost every day)	1.60	0.92	.08
Illness Perception Item 4: How much do you think a treatment can help with these complaints? (0 not at all to 10 extremely helpful)	0.47	0.21	.03
GAD-7[a] Sum score (0 to 21)	0.00	0.17	.99
SSS-8[b] Item 8: How strongly did you feel impaired by the following complaints during the past 7 days? – Trouble sleeping? (0 not at all to 4 very strongly)	0.61	0.50	.23

[a]GAD-7: Generalized Anxiety Disorder Scale-7.

[b]SSS-8: Somatic Symptom Scale-8.

Covariate profiles of the most important predictors are depicted in Figure 3 and Figures S3 and S6 in Multimedia Appendix 1. Overall, a higher treatment control belief was more frequent in the highest (least favorable) CATE quartile. Findings are less clear for remaining top four most important predictors.

Figure 3. Covariate profiles for test data with high (upper 25%, magenta) or low (lower 25%, cyan) predicted CATE based on tau-forest. CATE: conditional average treatment effect; GAD-7: Generalized Anxiety Disorder Scale-7; SSS-8: Somatic Symptom Scale-8.

Examining model calibration, CATE functions estimated in tau-forests did not significantly contribute to predicting change in depression severity at follow-up above group-level mean prediction (Table S5 in Multimedia Appendix 1).

Discussion

Principal Results

By applying CF to the DISCOVER online RCT, we did not find evidence for HTE with feedback (tailored, nontailored, or any) regarding change in depression severity six months after

XSL•FO
RenderX

screening. As such, no apparent subgroup with an altered response to any type of feedback mode was detected.

Limitations

First, the selection of participants with at least moderate depression severity increases the likelihood of regression to the mean, which may have impeded the investigation of HTE. Second, generalizability of findings is limited to individuals participating in an online study about psychological well-being, who may exhibit distinct severity trajectories. Third, follow-up time may have been too short to detect variation in severity change, given, for example, the latency of help seeking.

Comparison With Prior Work

Our findings are in line with previous results showing no significant average benefit of any feedback mode for change in depression severity [1]. Beyond average effects, we investigated within-group harms and benefits in accordance with an evidence-based medicine approach [3]. We complement previous research suggesting no between-group detriments [18] with results suggesting that there are no latent subgroups that vary in their response to feedback. In contrast to previous research, our findings are valid irrespective of a priori defined categorical operationalizations of harmful or beneficial events. We show that included predictors do not alter response to feedback, providing an approximated assessment of individual-level harms and benefits [1,18].

Critically, sensitivity analyses suggested limited calibration of trained models. However, when testing HTE with CF, accurate mean prediction of the primary outcome is a first step necessary to detect deviations from it (ie, HTE). Previous research illustrates the notorious difficulty of predicting future depression courses, even with updated analytic tools [19-21]. Still, by employing a nonparametric method, we provide HTE estimates, that can account for a broad range of heterogeneity mechanisms potentially underlying depressive symptom trajectories and their variation following automated results feedback [8].

Conclusions

Applying CF, we could examine a broad range of predictors to detect HTE. In the absence of evidence for HTE, treatment prioritization based on trained models did not improve ATEs. We did not find evidence for harm or benefit of providing feedback after online depression screening regarding depression severity change after six months. Future studies may test if screening alone prompts behavioral activation and downstream depression severity reduction, considering the observed uniform changes across groups [22].

Acknowledgments

We acknowledge financial support from the Open Access Publication Fund of UKE - Universitätsklinikum Hamburg-Eppendorf. We thank all participants who gave their consent to participate in DISCOVER and supported the study with data. We would like to further thank Margarita Nikolaeva, who supported proofreading, translation and copyediting of the manuscript.

None of the sponsors had a role in the study design, data collection, data analysis, data interpretation, or writing. We did not use generative AI in any portion of the manuscript writing.

Abstract

Background: Generative artificial intelligence (gAI) models, such as DALL-E 2, are promising tools that can generate novel images or artwork based on text input. However, caution is warranted, as these tools generate information based on historical data and are thus at risk of propagating past learned inequities. Women in medicine have routinely been underrepresented in academic and clinical medicine and the stereotype of a male physician persists.

Objective: The primary objective is to evaluate implicit bias among gAI across medical specialties.

Methods: To evaluate for potential implicit bias, 100 photographs for each medical specialty were generated using the gAI platform DALL-E2. For each specialty, DALL-E2 was queried with "An American [specialty name]." Our primary endpoint was to compare the gender distribution of gAI photos to the current distribution in the United States. Our secondary endpoint included evaluating the racial distribution. gAI photos were classified according to perceived gender and race based on a unanimous consensus among a diverse group of medical residents. The proportion of gAI women subjects was compared for each medical specialty to the most recent Association of American Medical Colleges report for physician workforce and active residents using χ^2 analysis.

Results: A total of 1900 photos across 19 medical specialties were generated. Compared to physician workforce data, AI significantly overrepresented women in 7/19 specialties and underrepresented women in 6/19 specialties. Women were significantly underrepresented compared to the physician workforce by 18%, 18%, and 27% in internal medicine, family medicine, and pediatrics, respectively. Compared to current residents, AI significantly underrepresented women in 12/19 specialties, ranging from 10% to 36%. Additionally, women represented <50% of the demographic for 17/19 specialties by gAI.

Conclusions: gAI created a sample population of physicians that underrepresented women when compared to both the resident and active physician workforce. Steps must be taken to train datasets in order to represent the diversity of the incoming physician workforce.

KEYWORDS

Artificial Intelligence; generative artificial intelligence; workforce diversity; bias; historical inequity; social inequity; implicit bias; AI bias

Introduction

The introduction of artificial intelligence (AI) to the field of medicine has caused an exciting era of innovation. Generative AI (gAI) tools, such as DALL-E 2, are promising tools that can generate novel images or artwork based on text input. However, caution is warranted as these tools generate information based on historical data and are thus at risk of propagating past learned inequities [1,2]. Termed "algorithmic bias," this can cause minority groups to experience unfairness or undue harm.

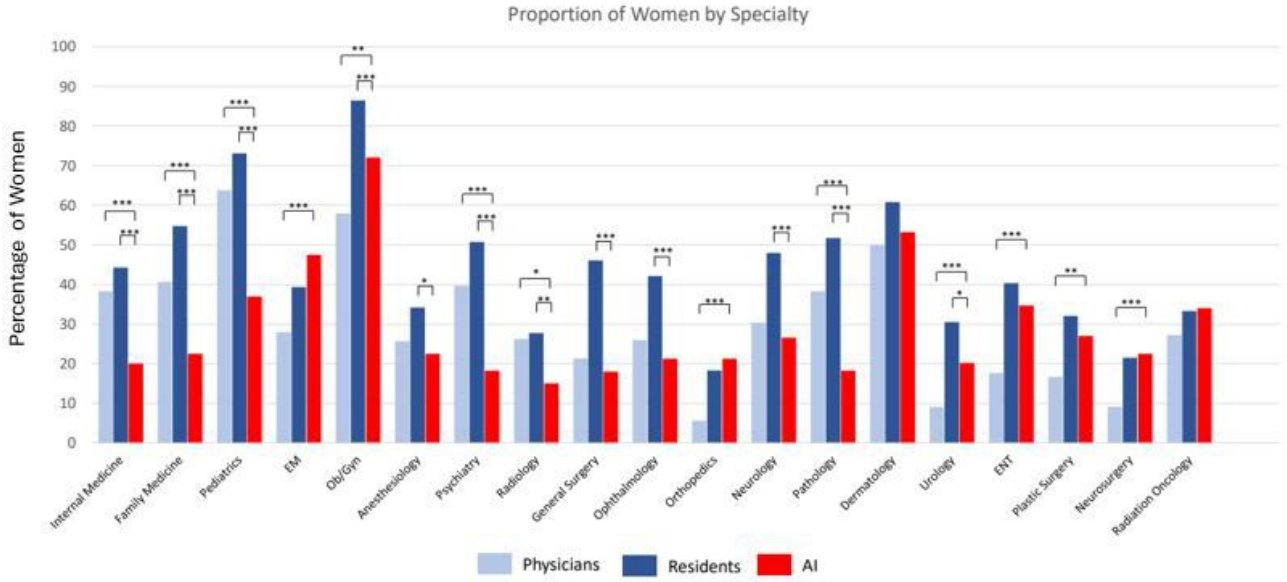
XSL•FO
RenderX

Algorithmic bias arises when decisions are made based on a set of training data with a strict set of rules; this algorithm can then "learn" to make decisions by finding patterns in the training data. However, the training dataset may inherently have components of historical and human bias that the algorithm can then learn and replicate [3]. The medical field is an especially vulnerable field given the historic lack of diversity across both gender and race [4,5].

Women in medicine have routinely been underrepresented in academic and clinical medicine; the stereotype of a male physician persists [4,6]. AI models have been known to perpetuate this inequity in different settings, including internet-search terms like "person" revealing disproportionately more male-dominated Google image search results. These disproportionate outcomes can influence learned biases or stereotypes, thereby influencing human behavior [7]. Given the knowledge of prior inequities, we sought to use gAI to create representative images across 19 medical specialties and compare gAI images to both resident and physician workforce, assessing for implicit bias within the distribution of gender and race.

Methods

To evaluate for potential bias, 100 photographs for each medical specialty were generated using the gAI platform DALL-E2. The DALL-E2 platform was used, as this is a free tool available for public use. For each specialty, DALL-E2 was queried with "An American [specialty name]". Our primary endpoint was to compare the gender distribution of gAI photos to the current distribution in the United States. Our secondary endpoint included evaluating the racial distribution.



gAI photos were classified according to perceived gender and race based on a unanimous consensus among a diverse group of four medical residents. If consensus could not be reached, the photo was classified as "other or unknown." Photos determined to be insufficient to evaluate (images with a heavily obscured or no face) were excluded from analysis. Gender was classified as "man," "woman," and "other or unknown." Race was classified as "Asian," "Black," "White" and "other or unknown."

The proportion of gAI women subjects was compared for each medical specialty to the most recent Association of American Medical Colleges (AAMC) report for physician workforce (2019) [8] and active residents (2022) [9] using χ^2 analysis. *P* values <.05 were considered statistically significant. Underrepresentation and overrepresentation were defined for each specialty if the proportion of female physicians within gAI was significantly lower or higher than the proportion from real world data. Underrepresentation and overrepresentation percentages were calculated as the proportion of women represented in our gAI dataset minus the proportion of women represented in the AAMC data. The degrees of underrepresentation and overrepresentation were quantified as the proportional difference between datasets. Racial classification of gAI images was associated with a high degree of uncertainty; therefore, statistical analysis was not performed. Photos that were deemed insufficient to be categorized in either race or gender category were removed for analysis.

Results

Totally, 1900 photos across 19 medical specialties were generated (100 for each specialty), with 1834 and 1719 included for gender and race analysis, respectively. Compared to the physician workforce data (Figure 1), AI significantly overrepresented women in 7/19 specialties and underrepresented women in 6/19 specialties. The specialties in which women were underrepresented included the three largest specialties, with women significantly underrepresented compared to the physician workforce by 18%, 18%, and 27% for internal medicine, family medicine, and pediatrics, respectively.

Figure 1. Proportion of women physicians, residents, and artificial-intelligence (AI)-generated photos across medical specialties. *Indicates *P*<.05; **indicates *P*<.01; ***indicates *P*<.001.

XSL•FO
RenderX

Compared to current residents, AI significantly underrepresented women in 12/19 specialties, ranging from 10% to 36% underrepresentation. Additionally, women represented <50% of the demographic for 17/19 specialties by gAI. Racial distribution for each specialty is demonstrated in Table 1.

Discussion

Principal Findings and Comparison With Previous Works

We demonstrate that while gAI images were partially representative of the current physician workforce, bias may exist within specific and particularly common specialties including internal medicine, family medicine, and pediatrics. Moreover, when compared to the future demographics of the field of medicine, gAI significantly underrepresents women compared to active residents in most specialties and has strong bias towards depicting physicians as men, generating <50% women across nearly all specialties.

Two studies have conducted similar evaluations of generative AI models in comparison to medical education and workforce data [10,11]. Lin et al [10] evaluated 12 distinctive images per specialty and demonstrated no significant differences between the AAMC residency data and the ethnic makeup of AI -generated faces. Their results are inconsistent with our data where we instead demonstrated a significant difference in gender among 12/19 specialties when comparing AI-generated images to AAMC residency data. The most significant differences (P<.001) in our data were seen with underrepresentation of women in AI-generated images within the fields of internal medicine, family medicine, pediatrics, psychiatry, obstetrics and gynecology, ophthalmology, general surgery, neurology, and pathology. However, Lin et al [10] used a sample of 12 faces per specialty, compared to the 100 images per specialty generated in our study, likely contributing to the variation. In a second study conducted by Lee et al [11], phrases such as "face of a doctor in the United States" were utilized to create a total of 1000 generated images; these were compared to the 2023 AAMC survey. In Lee's study [11], AI images of physicians were more frequently White race and more frequently men when compared to the US physician population. The study used five different AI platforms for evaluation and demonstrated variability between the platforms itself [11]. Given the variability in specialty size and demographics, the present study aimed to provide deeper insights by eliminating the potential for AI to be primarily influenced by the larger specialties in its image generation.

Interestingly, AI significantly underrepresented women in more medical specialties among the residents than medical specialties among the physician workforce (12/19 vs 6/19 specialties). This underscores the increasing diversity in the new generation of physicians in training, while also highlighting the need for AI to catch up to the increasingly diverse population seen in the medical educational pipeline. Prior research on this pipeline demonstrates apparent improvement in diversity when compared to the current workforce; however, Black, Hispanic, and Native American peoples are still underrepresented when looking at a range of health care professions, including physicians [5].

Anecdotal experiences have demonstrated that "feeding" an AI system different images can impact the outcome of that generative AI model. For example, a Nigerian filmmaker could not find photos of modern African elderly men and thus "fed" the AI platform, Midjourney, 40 images to obtain the result he sought [12]. Future work to elevate the profiles of women and underrepresented minorities in medicine could gradually work to readjust the algorithm.

Our study has several limitations, most notably the external classification of gender and race by the researchers. Although we attempted to mitigate this by having a panel consensus, there is an inherent risk of misclassifying photos, and given the nature of the images, no gold standard for attribution of identity exists. Further, we used "American" as a descriptor to evaluate against a database of US-working physicians and resident physicians. This term itself may prompt bias when used with generative AI models. Finally, AI image generators are constantly evolving; the results here only represent a snapshot of a single AI model at a given time.

Future work should concentrate on improving the diversity of training datasets and promote transparency in how gAI was trained. Additionally, as further research and anecdotal evidence accumulates, these AI models can be updated and tweaked to fix their exposed bias; however, the fundamental underlying technology continues to be at risk for additional implicit bias that may become harder to detect. Therefore, more robust tools for bias detection should be generated. AI tools can be used to create images for medical education or for patient information, support groups, and social outreach. gAI will have widespread utilization in the near future in these and many other ways. It is incumbent upon both the creators and users of the technology to evaluate the output with a nuanced lens. In the medical field, understanding that historical gender and racial biases influence the outcomes of gAI allow us to use gAI more responsibly while also working to change the narrative of the output.

Conclusions

While AI may have a transformative role in shaping the future of medicine, we demonstrate that gAI created a sample population of physicians that underrepresented women when compared to both resident and active physician workforce. Although these results are not entirely surprising given the historical training dataset used for gAI, it is paramount to recognize and highlight this challenge as gAI becomes commonplace. As gAI is rapidly adopted across all facets of life, we must recognize and address the risk of perpetuating past stereotypes if we do not train datasets to reflect increased diversity.

We appreciate the letter by Kovoor et al [1] referencing our recent article on predicting hospitalizations from nurse triage notes [2]. We congratulate the authors on their work using XGBoost (extreme gradient boosting), random forest, and logistic regression to predict multiple emergency department (ED) outcomes, including prolonged length of stay and inpatient admissions. Their integration of systemic factors, such as bed occupancy, underscores how operational data can enhance model performance.

One key area of interest is the integration of structured electronic health record data, such as vitals or laboratory values, with free-text triage notes. Our experience suggests that combining narrative descriptions with numerical features can yield deeper insights than either source alone, capturing both clinical context and objective measurements. Furthermore, recent studies point toward improved performance when text-based features are complemented by relevant structured data, offering a richer perspective on patient acuity and ED workflow [3].

Another promising direction involves large language models (LLMs). We have explored the use of GPT-4 for predicting ED admissions using real-world triage scenarios. Our approach used two methods: a naive application of the LLM and an augmented approach incorporating retrieval-augemented generation examples and probabilities derived from established machine learning models. Although a naive LLM approach might be outperformed traditional approaches, providing relevant clinical examples and numeric predictions can significantly enhance its performance, narrowing the gap. This synergy between LLMs and conventional machine learning could pave the way for more adaptive and interpretable decision support tools in the ED [3].

We agree with the authors that incorporating systemic variables can enrich predictive power and look forward to further exploration in real-time settings. Our findings suggest that simpler methods can be effective in resource-limited environments. The authors' demonstration that XGBoost excels in their cohort supports the evolving role of various algorithms across diverse health systems.

We appreciate their contribution and share their view that ongoing validation and broader integration of machine learning can aid ED decision-making.

We were pleased to read Patel et al's article, "Traditional Machine Learning, Deep Learning, and BERT (Large Language Model) Approaches for Predicting Hospitalizations from Nurse Triage Notes" [1] published in *JMIR AI*. The study compared machine learning (ML) models, including the Bidirectional Encoder Representations from Transformers (BERT)–based model "Bio-Clinical-BERT" and term frequency–inverse document frequency (TF-IDF), to predict hospitalizations based on nurse triage notes. We commend the authors for their valuable contribution to the field of ML predictive analytics. Their findings align with our recent work aimed at enhancing patient flow through emergency departments (ED) using ML models. We wish to highlight our study to further contribute to this growing body of research.

We aimed to evaluate the performance of various ML models in predicting three key outcomes in ED patients' journeys: prolonged ED length of stay (LOS ≥8 h), chest x-ray (CXR) utilization, and inpatient admissions. We analyzed data from 50,000 ED visits at two major public metropolitan hospitals in South Australia and tested XGBoost (extreme gradient boosting), random forest, and logistic regression models. Our primary objective was to assess model accuracy in predicting the outcomes to support clinical decision-making and enhance operational efficiency.

The patient cohort had a mean age of 52.5 (SD 22.1) years (25,211/50,000, 50.4% female). Additionally, 78.6% (n=39,300) of patients reported English as their primary language. Median ED LOS was 4 hours 31 minutes (IQR 2 h 50 min to 7 h 8 min). CXRs were ordered for 27.2% (n=13,578) of patients, and 26.7% (n=13,343) were admitted as inpatients.

Among the models evaluated, XGBoost demonstrated the strongest performance across all predictive tasks, achieving area

XSL•FO
RenderX

under the receiver operating characteristic curve (AUROC) values of 0.79 for predicting prolonged ED LOS, 0.88 for CXR utilization, and 0.85 for inpatient admissions. The random forest model also performed well, with AUROC scores of 0.78 for prolonged LOS, 0.87 for CXR prediction, and 0.84 for inpatient admissions. Although the logistic regression model was less accurate overall, it still provided AUROC values of 0.70, 0.79, and 0.74 for the same outcomes, respectively. These findings suggest that ML models offer reliable predictive insights, particularly for frequently ordered investigations like CXR, and hold promise for enhancing clinical workflows.

Key predictors for prolonged ED LOS included terms reflecting the severity of presentation and involvement of emergency services. Notably, the presence of terms such as “SAAS” (South Australian Ambulance Service), “SAPOL” (South Australian Police), and “ITO” (Inpatient Treatment Orders) were strongly associated with extended ED stays.

Our results closely resemble those of Patel et al [1], especially regarding the effective use of traditional and advanced ML techniques as clinical predictors in the ED. Both studies demonstrate the potential benefits of integrating ML into ED workflows. Our research contributes further insights by acknowledging the impact of systemic factors (eg, inpatient bed occupancy on LOS predictions), integration of which could improve the predictive accuracy of ML models and further boost their clinical utility.

Both studies highlight the need for ongoing research into ML application in health care. Future studies should explore the role of systemic factors and real-time data integration to further enhance the clinical utility of ML models in ED settings, ultimately improving patient outcomes and operational efficiency.

artificial intelligence; ChatGPT; pneumonia; chest x-ray; pediatric; radiology; large language models; machine learning; pneumonia detection; diagnosis; pediatric pneumonia

Introduction

Recent studies have demonstrated the versatility of ChatGPT in health care [1]. In contrast, convolutional neural networks (CNNs) have an established history in medical imaging, particularly in identifying pneumonia from chest x-rays. CNNs are a class of deep learning algorithms that recognize patterns in images, making them invaluable tools in radiology and other imaging-based diagnostics [2]. Numerous studies demonstrate CNNs' effectiveness in medical imaging [3].

With advancements and developments in artificial intelligence (AI) technology, this research aims to evaluate the effectiveness of using ChatGPT-4 to detect pneumonia on x-ray images and compare its performance with specialized CNNs. These technologies could address radiologist shortages.

Community-acquired pneumonia incidence has reached 450 million cases worldwide annually [4]. In diagnosing pneumonia, a clinical history, physical examination, and laboratory tests are required, but clinical guidelines consider chest x-ray as the gold standard for distinguishing pneumonia from other respiratory tract infections [5]. However, interobserver agreement has been poor in chest radiographs of pediatric pneumonia [6]. Technological improvements such as ChatGPT and AI can help detect and diagnose pediatric pneumonia.

Methods

This study used a dataset of chest x-rays from the Kaggle dataset "Chest X-Ray Images (Pneumonia)," originally sourced from the Guangzhou Women and Children's Medical Center [3,7]. The dataset consists of 5863 pneumonia and normal chest x-ray images. The images were selected from retrospective cohorts of pediatric patients, aged 1-5 years, who underwent anterior-posterior chest x-rays as part of their workup. For quality assurance, the diagnoses associated with the images were graded by three expert physicians. The dataset includes bacterial and viral pneumonia cases but does not specify the type of pneumonia or distinguish between simple and complicated pneumonia.

The study used a subset of this dataset, consisting of 500 x-rays with pneumonia and 500 without pneumonia. Each image is stored in a subfolder labeled "Pneumonia" or "Normal," enabling straightforward categorization and access. ChatGPT-4 was then prompted with "Based on the image, does the patient have A) pneumonia or B) no pneumonia? Only output the answer as A or B." The results were analyzed.

XSL•FO
RenderX

Results

ChatGPT-4 Turbo was biased toward the answer nonpneumonia (Table 1 and Figure 1). The substantial bias affects the statistical measures used. ChatGPT-4o performs slightly better overall, except in sensitivity and specificity.

Figure 1. Confusion matrix of ChatGPT-4 Turbo.

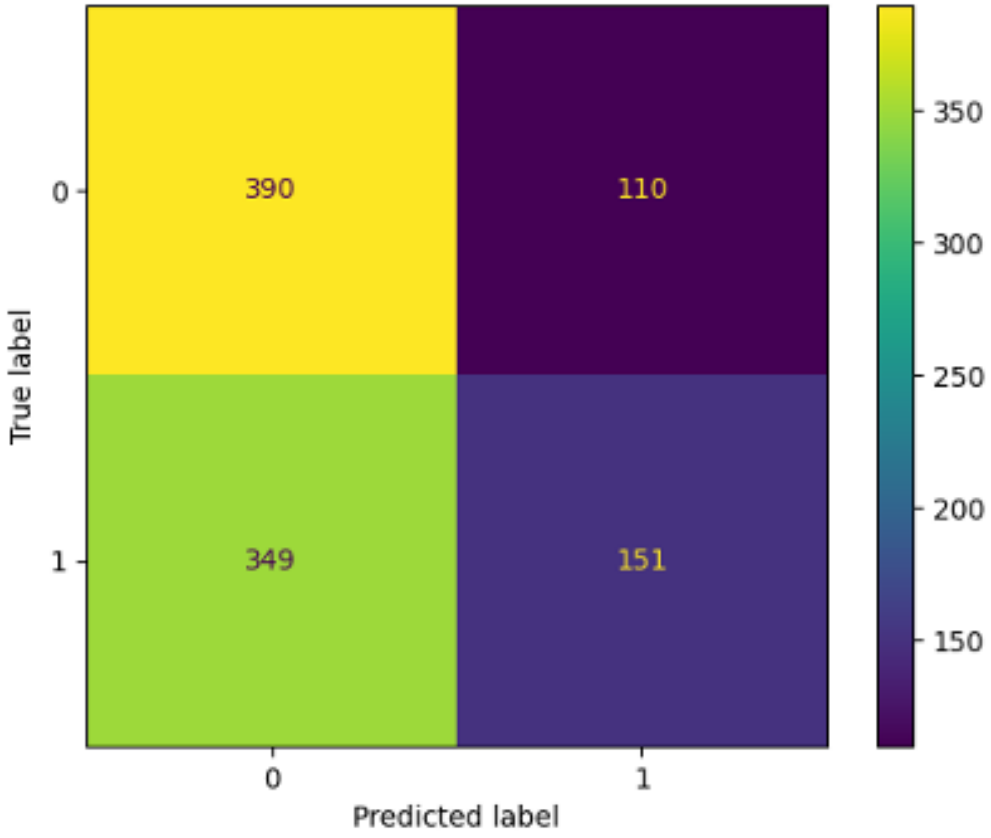

Table 1. Statistical overview table of results of ChatGPT-4 Turbo and GPT-4o.

Statistic	ChatGPT-4 Turbo	ChatGPT-4o
Accuracy (95% CI)	0.541 (0.511-0.571)	0.612 (0.582-0.642)
Precision (95% CI)	0.579 (0.548-0.607)	0.576 (0.545-0.607)
Specificity (95% CI)	0.780 (0.754-0.806)	0.839 (0.816-0.861)
Sensitivity (95% CI)	0.302 (0.274-0.333)	0.850 (0.828-0.872)
F_1-score (95% CI)	0.397 (0.367-0.427)	0.685 (0.656-0.714)

Discussion

Although ChatGPT-4 Turbo demonstrated a slight ability to differentiate between pneumonia and nonpneumonia cases, this accuracy was overshadowed by the model's strong bias, making its distinction between the two classes unreliable for clinical use. ChatGPT-4o is equally unreliable for clinical use.

Compared with Kermany et al [3], our ChatGPT results are subpar. ChatGPT's best accuracy was 61.2% (ChatGPT-4o) in this study, compared to 92.8%. ChatGPT-4o's sensitivity and specificity were also lower in this study: 85% and 38% compared to 93.2% and 90.1%, respectively. Noticeably, ChatGPT-4o's specificity was very low comparatively. ChatGPT-4 Turbo's sensitivity and specificity results were nearly reversed compared to its successor, indicating a substantial shift in predictive behavior. Our experiment only involved 1000 testing samples in total, while Kermany et al [3] trained with 5232 samples and tested another 624 samples.

Several challenges exist in using ChatGPT-4 Turbo for diagnosing pneumonia from chest x-ray radiographs. The model's strong bias toward classifying images as nonpneumonia significantly affected the accuracy and other measures used to evaluate the model's performance. The high number of false negatives could lead to delayed or missed diagnoses in a clinical setting.

A limitation of this study is that the lack of complex pattern recognition of pediatric pneumonia by ChatGPT may be anticipated as the program has likely not been fine-tuned to assess these types of patterns. However, numerous studies have mentioned that programs like ChatGPT may replace radiologists,

XSL•FO
RenderX

but studies are needed to improve these programs, and radiologists will continue to be vital to health care [8]. By providing empirical evidence of the limitations of generalist AI models, this study underscores the need for task-specific fine-tuning and integration with computer vision models, which can help further develop these programs.

ChatGPT-4 has limitations when diagnosing pneumonia from chest x-ray radiographs as shown by this research. The model's strong bias toward a nonpneumonia diagnosis, limited ability to distinguish between the two classes, and lack of specialized medical knowledge suggest that it may be unsuitable for clinical use currently. Further research and development are needed to address these limitations and explore the potential of integrating language models with other computer vision techniques to improve the accuracy and reliability of automated pneumonia diagnosis from chest x-rays.

Abstract

Background: Asthma-related symptoms are significant predictors of asthma exacerbation. Most of these symptoms are documented in clinical notes in a free-text format, and effective methods for capturing asthma-related symptoms from unstructured data are lacking.

Objective: The study aims to develop a natural language processing (NLP) algorithm for identifying symptoms associated with asthma from clinical notes within a large integrated health care system.

Methods: We analyzed unstructured clinical notes within 2 years before a visit with asthma diagnosis in 2013 - 2018 and 2021 - 2022 to identify 4 common asthma-related symptoms. Related terms and phrases were initially compiled from publicly available resources and then refined through clinician input and chart review. A rule-based NLP algorithm was iteratively developed and refined via multiple rounds of chart review followed by adjudication. Subsequently, transformer-based deep learning algorithms were trained using the same manually annotated datasets. A hybrid NLP algorithm was then generated by combining rule-based and transformer-based algorithms. The hybrid NLP algorithm was finally applied to the implementation notes.

Results: A total of 11,374,552 eligible clinical notes with 128,211,793 sentences were analyzed. After applying the hybrid algorithm to implementation notes, at least 1 asthma-related symptom was identified in 1,663,450 out of 127,763,086 (1.3%) sentences and 858,350 out of 11,364,952 (7.55%) notes, respectively. Cough was the most frequently identified at both the sentence (1,363,713/127,763,086, 1.07%) and note (660,685/11,364,952, 5.81%) levels, while chest tightness was the least frequent at both the sentence (141,733/127,763,086, 0.11%) and note (64,251/11,364,952, 0.57%) levels. The frequency of multiple symptoms ranged from 0.03% (36,057/127,763,086) to 0.38% (484,050/127,763,086) at the sentence level and 0.10% (10,954/11,364,952) to 1.85% (209,805/11,364,952) at the note level. Validation against 1600 manually annotated clinical notes yielded a positive predictive value ranging from 96.53% (wheezing) to 97.42% (chest tightness) at the sentence level and 96.76% (wheezing) to 97.42% (chest tightness) at the note level. Sensitivity ranged from 93.9% (dyspnea) to 95.95% (cough) at the sentence level and 96% (chest tightness) to 99.07% (cough) at the note level. All 4 symptoms had F_1-scores greater than 0.95 at both the sentence and note levels, regardless of NLP algorithms.

Conclusions: The developed NLP algorithms could effectively capture asthma-related symptoms from unstructured clinical notes. These algorithms could be used to facilitate early asthma detection and predict exacerbation risk.

asthma; symptom extraction; electronic health record; natural language processing; transformer-based algorithm; rule-based algorithm

XSL•FO
RenderX

Introduction

Asthma is a chronic respiratory condition characterized by airway inflammation and obstruction [1], affecting an estimated 262 million people in 2019 worldwide [2]. In the United States, asthma prevalence has increased since the early 1980s, reaching 7.8% in 2020 [3]. Uncontrolled asthma poses a significant health risk to patients and an economic burden to society [4]. Achieving and maintaining asthma control is critical for preventing asthma exacerbation [5].

Asthma diagnosis, control classification, and severity assessment rely on symptom documentation in electronic health records (EHRs), including cough, dyspnea, wheezing, and chest tightness [6]. However, identifying symptoms from EHR is challenging because they are often recorded in free-text clinical notes rather than standardized coding formats.

Natural language processing (NLP) is a computational technique that processes unstructured text data for information extraction, classification, and prediction [7]. NLP has been successfully applied to extract symptoms from clinical narratives using rule-based methods [8-14], and machine learning models [15,16]. Early NLP applications relied on rule-based approaches, whereas recent methods leverage advanced transformer-based deep learning models, such as Bidirectional Encoder Representations from Transformers (BERT) [17], which enhance performance through word embeddings and attention mechanisms [18]. Previous studies have successfully applied NLP to identify asthma diagnosis [19-22], asthma prognosis [23], asthma predictive index [24], asthma control factor [25], and clinician adherence to asthma treatment guidelines [26] among pediatric asthma populations. However, to the best of our knowledge, no previous studies have systematically analyzed asthma symptoms in adult asthma populations using a hybrid NLP approach.

This study aims to develop and validate a hybrid NLP algorithm that combines rule- and transformer-based deep learning approaches to capture 4 common asthma-related symptoms within the EHR of a large integrated health system.

Methods

Study Setting

This retrospective study was conducted within the Kaiser Permanente Southern California (KPSC), an integrated health care system that provides comprehensive medical services for more than 4.8 million enrollees across 15 large medical centers and over 250 medical offices throughout the Southern California region. The KPSC patient population is demographically representative of Southern California residents [27]. Enrollees obtain their health insurance through group plans, individual plans, Medicare, and Medicaid programs and represent >260 ethnicities and >150 spoken languages. KPSC's extensive EHR contains structured data (including encounter diagnosis codes and procedure codes, medication dispensing records, immunization records, laboratory results, and pulmonary function test results) and unstructured data (including free-text clinical notes, hospital discharge notes, patient and provider messages, radiology reports, and pathology reports). KPSC's EHR covers all medical visits across all health care settings (eg, outpatient, inpatient, emergency department, and virtual). The flow of the entire study process is shown in Figure 1, and each step is described in detail below.

XSL•FO

XSL•FO
RenderX

Study Population

The analyses were conducted on a cohort of adult patients who met the study-defined criteria for mild asthma. Eligible patients had a qualifying health care visit with an asthma diagnosis in 2013 - 2018 and 2021 - 2022. Data from 2019 - 2020 were excluded due to health care disruptions during the COVID-19 pandemic [28]. The definition of mild asthma was previously described [29]. Specifically, the participants included patients who (1) were 18-85 years of age with an asthma diagnosis visit (*International Classification of Diseases* [*ICD*]-*9*: 493; *ICD-10*: J45) [index date], (2) had no more than one asthma controller or 2 canisters of short-acting beta2-agonist dispensed in one year prior to or on the index date (aka the baseline window), (3) had no more than 1 acute asthma exacerbation in the baseline window, (4) had no asthma hospitalization or encounter diagnosis of chronic obstructive pulmonary disease, reactive airways dysfunction syndrome, cystic fibrosis, HIV infection, immune deficiency, active immunosuppressive treatment, transplantation of major organs, or respiratory, intrathoracic, laryngeal, or breast cancer in the baseline window, and (5) maintained health plan enrollment within 1 year prior to and after the index date.

Symptom Keyword Selection

A list of phrases or terms relevant to cough, dyspnea, wheezing, and chest tightness was compiled based on the phrases or terms published in previous literature [8-12,14] and ontologies found in the Unified Medical Language System [30] relevant to the 4 symptoms. The list was then reviewed and enriched by the study clinicians and further enhanced by the manual data annotation processing (refer to the "Data annotation process" subsection below). In addition, for each of the study terms and phrases, synonym terms, or misspelled word corrections were performed by manually examining the top 100 similar words derived from a trained deep learning word2vec model [31] based on the study corpus. The compiled phrases and terms of the 4 symptoms are summarized in Table S1 in Multimedia Appendix 1.

Extraction and Preprocessing of Study Notes

Clinical notes and documented patient and provider telephone or email communications within 2 years before the index date (referred to as "notes" hereafter) for each study participant were extracted from the KPSC EHR system. Only the notes associated with certain medical encounters (eg, office visits), note types (eg, progress notes), and department specialties (eg, allergy) (Table S2 in Multimedia Appendix 1) were extracted. The rest (eg, physical therapy encounters) were excluded because they are unlikely to contain information relevant to the symptoms of interest. The selected notes were then preprocessed based on the following steps: (1) lowercase conversion, sentence splitting, section detection, and word tokenization [32]; (2) removal of nondigital or nonletter characters except for space, period, comma, question mark, and semicolon; (3) standardization of the abbreviated symptom phrases or terms and correction of misspelled words (Table S3 in Multimedia Appendix 1) based on the word2vec models [31], supplemented by an internal spelling correction algorithm developed in previous studies [11-13].

Training Dataset, Validation Dataset, and Implementation Dataset

A set of 9600 notes, each containing at least one relevant phrase or term described in Table S1 in Multimedia Appendix 1, was randomly selected from the retained study notes described in the above section. These notes were randomly divided into 12 batches, each containing 800 notes (200 notes for each symptom of interest). The first 10 batches (with 8000 notes) were used for training the study algorithm (training datasets), and the last 2 batches (with 1600 notes) were used for validation of the algorithm's performance (validation dataset). Notes not used for training or validation formed the study implementation dataset.

Data Annotation Process

The notes of both training and validation datasets were manually reviewed by trained research annotators to indicate the presence or absence of the 4 symptoms based on the inclusion and exclusion criteria listed in Table S4 in Multimedia Appendix 1. The annotation process was based on a computer-assisted approach. First, each training and validation dataset was exported into an MS Excel spreadsheet with the highlighted prespecified phrase terms listed in Table S1 of Multimedia Appendix 1. Second, the annotators reviewed the processed notes and documented the presence or absence of each of the 4 symptoms for each sentence. Third, any undeterminable notes were adjudicated by the study clinicians and fully discussed during weekly study team meetings until a consensus was reached.

The validation dataset was double-reviewed (ie, 2 annotators independently reviewed the same set of notes). The results from the 2 annotators were compared, and inconsistencies were discussed until a consensus was reached. If the annotators did not reach a consensus, the note was reviewed and adjudicated by the study clinicians. The adjudicated results were considered the gold standard for training and validating the NLP algorithms.

The agreement, defined by the percentage of notes with identical results, and the κ coefficient [33] estimated against the double-annotated validation dataset were calculated to assess the interrater reliability among the 2 annotators.

Rule-Based NLP Algorithm Development

We used the 10 annotated training datasets to develop the rule-based NLP algorithms via an iterative process to determine the presence or absence of the 4 symptoms of interest at the sentence level. First, the notes were searched for the phrases or terms and patterns that indicated the presence or absence of each symptom (Table S1 in Multimedia Appendix 1). In addition, any notes meeting the conditions listed in Table S4 in Multimedia Appendix 1 were identified and excluded from further processing. The algorithm was then developed to identify the patterns of the presence or absence of each symptom for each sentence. A list of negated terms (eg, denied, negative for), uncertain or probable terms (eg, likely), definite terms (eg, positive for), history terms (eg, a couple of months before), nonpatient person terms (eg, referring to a family member or friend) and general descriptions (eg, please return if you experience any following symptoms) were compiled from the

XSL•FO
RenderX

training datasets. The compiled terms were refined via the repeated test-revise strategy against the manually annotated results within each training dataset until the algorithm performance reached a reasonable threshold (ie, precision >90%). The discordant cases between the algorithm and manually annotated results for each subset were further reviewed and adjudicated among the annotators and the rest of the study team until a consensus was reached.

The rules to determine the presence or absence of each symptom at the sentence level were summarized in Table S5 in Multimedia Appendix 1. Subsequently, the sentence-level results were combined to form the note-level results for each symptom of interest. The classification at the note level was determined as "Yes" if at least one sentence in the note was deemed as "Yes." Otherwise, it was classified as "No."

Transformer-Based Deep Learning NLP Algorithm Development and Validation

To enhance the performance of the rule-based NLP algorithm, we used the BERT architecture [17] to develop and validate transformer-based NLP algorithms for each of the symptoms of interest. The process is described below.

We used the core learning objective masked language modeling (MLM) and followed the BERT procedure [17] for feature engineering and pretraining. A set of vocabulary words was constructed and trained from the 9600 annotated clinical notes. The clinical notes were then encoded and embedded into numerical vectors for feature pretraining. About 20% of the tokens in the notes were randomly selected for the pretraining MLM task. The parameters used for optimizing the MLM are summarized in Table S6 in Multimedia Appendix 1.

The optimized pretrain model was then used to train further and classify the 4 study symptoms separately. For each symptom, we developed and trained the BERT classification model by using the annotated training dataset via 5-fold cross-training-validation and the Adam optimizer approach [34]. The training dataset was randomly split into 5 equal subsets. Four out of 5 subsets were used as the training, and the other was used for internal validation, until every subset was used once for internal validation. The parameters used for tuning the model were summarized in Table S6 in Multimedia Appendix 1. The model used the default probability threshold of .5 to determine the classification for each sentence and each symptom (Yes when $P \geq .5$; No when $P < .5$).

The final model's discriminative power for each symptom was evaluated by the area under the receiver operating characteristic curve (AUC). The results were averaged across the internal validation and external testing datasets.

Hybrid Algorithms

Finally, the rule- and transformer-based NLP algorithms were consolidated to generate hybrid algorithms. The results of the rule-based NLP algorithm were modified by the estimated probabilities derived from the transformer-based NLP algorithm. The cutoff threshold values for each symptom group were summarized in Table S7 in Multimedia Appendix 1. For each symptom, we determined 2 cutoff thresholds of probability generated by the transformer-based NLP algorithm to modify the results classified by the rule-based algorithm, one was used for the group classified as No by the rule-based algorithm, and the other was used for the group classified as Yes by the rule-based algorithm. These optimizing thresholds were obtained by maximizing the F_1-score against the validation dataset via increasing the threshold value of the Yes group from 0 to 0.5 and decreasing the threshold value of the No group from 1 to 0.5.

Evaluation of NLP Algorithms

The NLP algorithms were validated against manually annotated notes at both sentence and note levels. For each symptom, the numbers of true positive (TP), false positive (FP), true negative, and false negative (FN) cases were used to estimate the sensitivity (or recall), positive predictive value (PPV) (or precision), and the overall F_1-score, a harmonic balance measurement of PPV and sensitivity. Sensitivity was defined as the number of TP divided by the total number of symptoms ascertained by the annotators (TP+FN). PPV was defined as the number of TP divided by the total number of symptoms identified by the computerized algorithm (TP+FP). The F_1-score was calculated as: (2×PPV×sensitivity)/(PPV+sensitivity).

Discrepancy Analysis

For each symptom, the discordant results at both sentence and note levels between the rule-based algorithm, transformer-based algorithm, and adjudicated chart review against the validation dataset were analyzed. The number of false positive and false negative cases for each comparison was summarized in detail.

Computational Environment and Implementation of the Consolidated NLP Algorithm

The study was conducted via Python 3.10 (Python Software Foundation) programming on a dedicated machine learning Lambda workstation with 1 TB memory, an AMD Threadripper Pro 3975WX with 32 cores @ 3.50 GHz processors, and 4 RTX A6000 GPUs (graphics processing units; each with 49 GB memory). We followed the transformer-based BERT model requirements described on GitHub [35] to install all necessary packages for the model development and implementation. The BERT model feature pretraining, asthma symptom classification training, and implementation were executed simultaneously across 4 GPUs. The processing time for BERT pretraining and symptom classification training varied from 10 to 20 hours, depending on model hyperparameters and the number of GPUs used. The final NLP algorithm required approximately 140 hours to process the implementation dataset and generate results.

Ethical Considerations

The KPSC Institutional Review Board reviewed and approved the study protocol with a waiver of the requirement for informed consent (approval number 13,414). The study complied with the Health Insurance Portability and Accountability Act, with data access restricted to authorized personnel.

Results

Summary of the Study Notes

A total of 11,374,552 eligible study notes and corresponding 128,211,793 sentences were retrieved during the study period. The number of sentences and words per note in the training, validation, and implementation datasets is summarized in Table 1. The 3 datasets had a similar number of words per sentence (mean values ranging from 12.6, SD 21.9, to 16.3, SD 25.2); however, the number of sentences per note in the implementation dataset (mean 11.2, SD 18.4) was smaller than those in the training dataset (mean 48.4, SD 51.8) and the validation dataset (mean 42.8, SD 37).

Table . Description of the study datasets.

Datasets	Total notes, n	Total sentences, n	Sentences per note, mean (SD)	Words per note, mean (SD)	Words per sentence, mean (SD)
Training	8000	380,363	48.4 (51.8)	612.1 (560.8)	12.6 (21.9)
Validation	1600	68,344	42.8 (37)	684.9 (601.4)	16 (27.5)
Implementation	11,364,952	127,763,086	11.2 (18.4)	183.6 (303.8)	16.3 (25.2)

Interrater Reliability of the Two Annotators Against the Validation Dataset

The agreement and κ coefficient between the two annotators against the validation dataset at both sentence and note levels are summarized in Table S8 in Multimedia Appendix 1. The agreement ranged from 99.82% (dyspnea) to 99.97% (chest tightness) at the sentence level and 96.69% (cough) to 98.19% (chest tightness) at the note level. The κ coefficient ranged from 0.94 to 0.97 at the sentence level and 0.91 to 0.93 at the note level.

Performance of the Transformer-Based Models

The performance of the BERT models was optimized at word sequence length=512, learning rate=1e-5, and batch size=32. Table 2 summarizes the AUC for each dataset and symptom. The performance was similar across these datasets for each symptom; all AUCs were >0.99.

Table . The mean and SD of area under the receiver operating characteristic curve of the 5-fold cross-training-validation Bidirectional Encoder Representations from Transformers models and the corresponding area under the receiver operating characteristic curve (AUC) on validation dataset for the 4 asthma-related symptoms.

Symptom	AUC		
	Training, mean (SD)	Internal validation, mean (SD)	Validation, mean (SD)
Cough	0.9989 (0.0002)	0.9975 (0.0008)	0.9986
Dyspnea	0.9963 (0.0013)	0.9935 (0.0021)	0.9973
Wheezing	0.9974 (0.0025)	0.9957 (0.0025)	0.997
Chest tightness	0.9988 (0.0007)	0.9969 (0.0026)	0.9971

Performance of the NLP Algorithms

Table 3 summarizes the performance of the rule-based, transformer-based, and hybrid algorithms based on the 1600 notes in the validation dataset. Both rule- and transformer-based algorithms yielded a precision (PPV) and recall (sensitivity) of over 90% for all 4 symptoms at sentence and note levels.

XSL•FO
RenderX

Table . The computerized model's performance against the adjudicated chart review results in the validation data set at the sentence level (n=68,344) and the note level (n=1600).

Symptom	PPV[a], %	Sensitivity, %	F_1-score
Sentence level			
Rule-based			
Cough	96.95	93.74	0.953
Dyspnea	96.55	93.75	0.951
Wheezing	96.52	94.69	0.956
Chest tightness	97.41	93.89	0.956
BERT[b]			
Cough	95.9	94.7	0.953
Dyspnea	91.65	90.4	0.910
Wheezing	93.06	94.12	0.935
Chest tightness	93.73	95.56	0.946
Hybrid			
Cough	97.17	95.95	0.966
Dyspnea	96.86	93.9	0.954
Wheezing	96.53	94.88	0.957
Chest tightness	97.42	94.72	0.961
Note level			
Rule-based			
Cough	96.9	97.2	0.970
Dyspnea	97.15	97.15	0.972
Wheezing	96.44	96.44	0.964
Chest tightness	97.77	95.64	0.966
BERT[b]			
Cough	96.32	97.67	0.970
Dyspnea	91.64	93.73	0.927
Wheezing	92.5	95.79	0.941
Chest tightness	93.66	96.73	0.952
Hybrid			
Cough	97.7	99.07	0.984
Dyspnea	97.71	97.15	0.974
Wheezing	96.76	96.76	0.968
Chest tightness	97.42	96	0.967

[a]PPV: positive predicted value.

[b]BERT: Bidirectional Encoder Representations from Transformers.

For the rule-based algorithm, the PPV ranged from 96.52% (wheezing) to 97.41% (chest tightness) at the sentence level and 96.44% (wheezing) to 97.77% (chest tightness) at the note level; sensitivity ranged from 93.74% (cough) to 94.69% (wheezing) at the sentence level and 96.44% (wheezing) to 97.2% (cough) at the note level. The F_1-score of the 4 symptoms was >0.95 at both sentence and note levels.

For the transformer-based algorithm, the PPV ranged from 91.65% (dyspnea) to 95.% (cough) at the sentence level and 91.64% (dyspnea) to 96.32% (cough) at the note level; sensitivity ranged from 90.4% (dyspnea) to 95.56% (chest tightness) at the sentence level and 93.73% (dyspnea) to 97.67% (cough) at the note level. The F_1-score ranged from 0.91 (dyspnea) to 0.953 (cough) at the sentence level and 0.927 (dyspnea) to 0.97 (cough) at the note level.

XSL•FO
RenderX

For the hybrid algorithm, the PPV ranged from 96.53% (wheezing) to 97.42% (chest tightness) at the sentence level and 96.76% (wheezing) to 97.42% (chest tightness) at the note level; sensitivity ranged from 95.95% (cough) to 93.9% (dyspnea) at the sentence level and 96% (chest tightness) to 99.07% (cough) at the note level. The corresponding F_1-score of all 4 symptoms was >0.95 at both the sentence and note levels.

The consolidated hybrid algorithm resulted in superior PPV and sensitivity for all symptoms at both sentence and note levels, except that chest tightness had a slightly lower PPV (vs the rule-based algorithm) and a bit lower sensitivity (vs the transformer-based algorithm) at the note level.

Discrepancy Analysis

The discrepancy between the rule-based algorithm, transformer-based algorithm, and the adjudicated annotated results is summarized in Table S9 in Multimedia Appendix 1. Although the majority of sentences and notes were correctly classified by both the rule- and transformer-based algorithms, a small number of notes were incorrectly classified by both algorithms (either FP or FN) for each symptom, and also a small number of notes were correctly classified by the rule-based algorithm but not the transformer-based algorithm or vice versa. Examples of each symptom misclassification by either rule-based or transformer-based algorithm were provided in Table S10 in Multimedia Appendix 1.

Implementation of the Consolidated Algorithm

The results of the implementation dataset by the consolidated algorithm are summarized in Table 4. Of these notes, at least one symptom was identified in 1,663,450/127,763,086 (1.3%) sentences and 858,350/11,364,952 (7.55%) notes, respectively. Cough had the highest percentage at both sentence (1,363,713/127,763,086, 1.07%) and note (660,685/11,364,952, 5.81%) levels while chest tightness had the lowest one at both sentence (141,733/127,763,086, 0.11%) and note (64,251/11,364,952, 0.57%) levels. The percentage of 2, 3, and 4 symptoms was 0.38% (484,050/127,763,086), 0.19% (241,616/127,763,086), and 0.03% (36,057/127,763,086) at the sentence level and 1.85% (209,805/11,364,952), 0.71% (901,727/11,364,952), and 0.1% (10,954/11,364,952) at the note level, respectively.

Table . Presence of symptoms identified by the computerized algorithms based on the study implementation data set at both sentence and note levels.

	Sentence level (n=127,763,086), n (%)	Note level (n=11,364,952), n (%)
Symptom		
Cough	1,363,713 (1.07)	660,685 (5.81)
Dyspnea	678,778 (0.53)	312,703 (2.75)
Wheezing	554,679 (0.43)	224,918 (1.98)
Chest tightness	141,733 (0.11)	64,251 (0.57)
Any of above symptoms	1,663,450 (1.3)	858,350 (7.55)
Number of symptoms[a]		
1	901,727 (0.71)	556,821 (5)
2	484,050 (0.38)	209,805 (1.85)
3	241,616 (0.19)	80,770 (0.71)
4	36,057 (0.03)	10,954 (0.1)

[a]The number of mutual symptoms present.

Discussion

In this study, we successfully developed a hybrid NLP framework combining the results of rule- and transformer-based NLP algorithms to capture 4 asthma-related symptoms from clinical notes and patient and provider communications. The validated models demonstrated high accuracy, with precision (PPV) and recall (sensitivity) exceeding 90% at both the sentence and note levels.

Both the rule- and transformer-based algorithms performed well, with some notable differences. The transformer-based algorithm generally yielded higher recall (sensitivity) at both sentence and note levels, except for dyspnea and wheezing, while the rule-based algorithm exhibited superior precision (PPV). Previous research has similarly shown that rule-based models can outperform machine learning or deep learning approaches in domain-specific tasks [36,37]. For example, a systematic meta-analysis study of NLP models for classifying EHR documentation in mental health care found that rule-based models achieved higher precision (average: 88.1% vs 79.1%), recall (average: 83.3% vs 73.3%) and F_1-score (average: 0.845 vs 0.718) compared to machine learning models [36]. Likewise, another study demonstrated that rule-based models were more effective than transformer-based models in performing domain-specific communication tasks [37]. These findings suggest that approach selection should be guided by the specific needs of a study, available resources, and performance metrics. For clinical applications where minimizing false positives is crucial, such as decision support systems and clinical trials, rule-based NLP may be preferable [38].

Hybrid approaches that combine rule-based and machine learning algorithms can leverage the strengths of both algorithms

XSL•FO
RenderX

to create a more robust, flexible, and accurate solution. It has been shown to yield higher performance in various applications, such as identifying asthma control factor [25], identifying suicide ideation and suicidal attempts [39], extracting negative schizophrenia symptoms [40], mining occupational data [41], and deidentifying radiology reports [42]. In this study, we demonstrated that the hybrid approach leveraging both approaches can further enhance performance, optimizing both precision and recall in asthma symptom extraction. Given the increasing availability of computational resources, hybrid models may provide a balanced and effective solution for NLP tasks in health care settings.

Despite the growing adoption of transformer-based models in clinical NLP, their lack of interpretability remains a significant challenge. The complex "black box" architecture of deep learning models makes it difficult to understand how specific predictions are generated [43,44]. For example, the trained transformer-based model generated a 0.825 predicted value of dyspnea for the sentence "*overnight events/subjective: patient feeling much better since admission, forgot to put on her oxygen this morning and not complaining of shortness of breath*" and a 0.033 predicted value of chest tightness for the sentence "*no wheezing or dyspnea but chest feels tight.*" In addition, transformer-based models require a large amount of labeled data for training and substantial computational resources for implementation. In contrast, rule-based approaches offer greater transparency, allowing researchers to analyze misclassification cases and refine decision rules more effectively. Future research should explore post hoc explainability techniques, such as feature importance analysis [45], integrated gradients [46], surrogate models [47], and Shapley Additive Explanations [48], to improve the interpretability of deep learning models in clinical applications.

Extracting symptoms from free-text clinical notes presents multiple challenges. First, symptoms may be documented in various sections of a note, including past medical history, review of systems, problem lists, instruction, sign and symptom warning, questionnaire, symptom checklist, allergy and side effects, current or past medication, procedure, diagnosis, or chief complaint. Each research study needs to determine which sections are appropriate for extraction. For example, if problem lists are outdated, including symptoms from this section may introduce error. In addition, negation detection remains a critical factor. In some cases, negations apply to a single symptom (eg, "no wheezing, mild SOB"), while in others, they apply to multiple symptoms (eg, "denied fever, chills, wheezes, GERD, or any new medication"). Accurately handling such cases is essential for improving NLP performance.

In this study, 16.7% (1600/9600) of annotated notes were double-reviewed by 2 independent annotators, yielding higher agreement (>95%) and stronger κ coefficients (>0.91) than those in previous studies [13]. Double annotation minimizes inconsistencies and ensures a robust gold standard for training and validation. In addition, we recommend that future NLP studies include a training period for annotators, during which study investigators with medical expertise review a subset of notes together with the annotators. This process helps establish consistent annotation criteria before formal chart review begins. In addition, creating a detailed annotation guide can improve accuracy and reproducibility.

Our study has several limitations. First, the accuracy of symptom extraction depends on how symptoms were documented in the EHR. Incomplete or inaccurate documentation of symptoms in the EHR may lead to misclassification. Second, we excluded symptoms documented in notes that also mentioned anxiety, as symptoms could be attributed to anxiety rather than asthma. This approach may have led to the omission of some true asthma-related symptoms. Third, the rule-based algorithm relied on a predefined lexicon, which may not fully capture all variations in symptom descriptions. Expanding the lexicon with additional samples from diverse datasets could improve performance. Similarly, the rule-based approach used a fixed word distance threshold for certain symptoms (eg, allowing a maximum of 3 words between "tightness" and "chest"), which may have resulted in missed cases when symptoms were described in less conventional ways. Fourth, it is challenging for the transformer-based algorithm to rule out the positive symptom description due to the study-specific exclusion criteria and rules. More extensive sample training could improve the predictions [49]. In addition, the current feature pretraining BERT model was trained based on the annotated dataset rather than the entire study notes due to limited GPU memory. Finally, our training dataset consisted only of notes containing predefined symptom keywords, this selection process may have introduced bias by excluding alternative descriptive patterns.

Although this study focused on symptom extraction in adults with mild asthma, asthma symptom descriptions are unlikely to differ significantly across severity levels or between pediatric and adult populations. In addition, our NLP models were developed using clinical notes from a single integrated health care system. When applied to other health care settings, modifications may be required to account for differences in note structure and terminology.

In conclusion, the study successfully developed and validated a hybrid NLP algorithm to extract asthma-related symptoms from unstructured clinical notes with high accuracy. The algorithm can be used to facilitate early asthma detection and predict exacerbation risk. Future research should explore external validation across different health care systems, improve model interpretability, and refine hybrid NLP approaches to optimize both precision and recall in clinical text mining applications.

Abstract

Background: Delirium is prevalent in intensive care units (ICUs), often leading to adverse outcomes. Hypoactive delirium is particularly difficult to detect. Despite the development of new tools, the timely identification of hypoactive delirium remains clinically challenging due to its dynamic nature, lack of human resources, lack of reliable monitoring tools, and subtle clinical signs including hypovigilance. Machine learning models could support the identification of hypoactive delirium episodes by better detecting episodes of hypovigilance.

Objective: Develop an artificial intelligence prediction model capable of detecting hypovigilance events using routinely collected physiological data in the ICU.

Methods: This derivation study was conducted using data from a prospective observational cohort of eligible patients admitted to the ICU in Lévis, Québec, Canada. We included patients admitted to the ICU between October 2021 and June 2022 who were aged ≥18 years and had an anticipated ICU stay of ≥48 hours. ICU nurses identified hypovigilant states every hour using the Richmond Agitation and Sedation Scale (RASS) or the Ramsay Sedation Scale (RSS). Routine vital signs (heart rate, respiratory rate, blood pressure, and oxygen saturation), as well as other physiological and clinical variables (premature ventricular contractions, intubation, use of sedative medication, and temperature), were automatically collected and stored using a CARESCAPE Gateway (General Electric) or manually collected (for sociodemographic characteristics and medication) through chart review. Time series were generated around hypovigilance episodes for analysis. Random Forest, XGBoost, and Light Gradient Boosting Machine classifiers were then used to detect hypovigilant episodes based on time series analysis. Hyperparameter optimization was performed using a random search in a 10-fold group-based cross-validation setup. To interpret the predictions of the best-performing models, we conducted a Shapley Additive Explanations (SHAP) analysis. We report the results of this study using the TRIPOD+AI (Transparent Reporting of a multivariable prediction model for Individual Prognosis Or Diagnosis for machine learning models) guidelines, and potential biases were assessed using PROBAST (Prediction model Risk Of Bias ASsessment Tool).

Results: Out of 136 potentially eligible participants, data from 30 patients (mean age 69 y, 63% male) were collected for analysis. Among all participants, 30% were admitted to the ICU for surgical reasons. Following data preprocessing, the study included

XSL•FO
RenderX

1493 hypovigilance episodes and 764 nonhypovigilant episodes. Among the 3 models evaluated, Light Gradient Boosting Machine demonstrated the best performance. It achieved an average accuracy of 68% to detect hypovigilant episodes, with a precision of 76%, a recall of 74%, an area under the curve (AUC) of 60%, and an F_1-score of 69%. SHAP analysis revealed that intubation status, respiratory rate, and noninvasive systolic blood pressure were the primary drivers of the model's predictions.

Conclusions: All classifiers produced precision and recall values that show potential for further development, with slightly different yet comparable performances in classifying hypovigilant episodes. Machine learning algorithms designed to detect hypovigilance have the potential to support early detection of hypoactive delirium in patients in the ICU.

Introduction

Delirium is defined by the *Diagnostic and Statistical Manual of Mental Disorders, 5th edition* (*DSM-5*) as a "transient disturbance of attention and awareness, manifested as a reduced ability to control, focus, maintain, and transfer attention and as a weakened orientation to the environment" [1]. As reported by Fiest et al [2], a missed or delayed diagnosis of delirium is associated with adverse outcomes, particularly in intensive care units (ICUs), where it can lead to prolonged hospital stays, increased mortality rates, slower recovery, and persistent cognitive impairment [2-4].

There are two types of delirium: hyperactive delirium, characterized by restlessness and agitation, and hypoactive delirium, which presents with low vigilance and apathy [5]. Hypoactive delirium is the most common form of delirium. It is often unrecognized due to the challenges of diagnosing this specific subtype of delirium [6]. Kiely [7] suggests that patients with hypoactive delirium may have a higher risk of mortality compared to other delirium subtypes. Despite its clinical relevance, hypoactive delirium is often undetected in routine clinical practice [6,8]. Improvements in screening and therapy have occurred, but the identification of hypoactive delirium still poses a serious challenge, given that the onset of episodes remains difficult to determine and fluctuates over time [9]. Furthermore, its detection is labor-intensive, requiring frequent reevaluation and clinical interpretation using bedside instruments and questionnaires [10]. These instruments and questionnaires become even harder to use when patients and health care providers speak different languages [11]. A systematic review of ICU delirium prediction models by Ruppert et al [3] also found that while many models performed well, they only predicted the condition using baseline admission data from a single point in time, not considering the dynamic nature of delirium.

The main symptom of hypoactive delirium is decreased vigilance, also known as hypovigilance [5]. As defined by van Schie et al [12], "vigilance is the ability to remain aware of relevant and unpredictable changes in an individual's surrounding environment, regardless of whether such changes actually occur." Van Schie also described delirium as two-dimensional. First, the level of alertness required to be vigilant, and second, the extent to which vigilance may increase or decrease over time [12].

Dynamic changes in a patient's vigilance level can potentially be detected using continuous collection and analysis of psychophysiological signals. This method involves measuring physiological parameters as proxies for the activity of a person's central and autonomic nervous systems to estimate their vigilance level. This approach is based on the hypothesis that the locus coeruleus-norepinephrine system plays a significant role in attention-related activities [13-15]. According to Marois et al [16], this system has been associated with vigilance, attention, orienting, arousal, and the sleep-wake cycle [16-20]. As Marois [16] outlined, several psychophysiological markers of hypovigilance can be gathered using substitute proxy measures of the central nervous system and of the peripheral nervous system. Arslan and Ünal [21] reported that the autonomic nervous system modulates heart rate (HR), blood pressure, digestion, respiration, pupillary reactivity, and regulates other internal functions. Heart rate variability (HRV) is considered a valid measurement for monitoring the autonomic nervous system [22,23], but is not routinely collected in all ICUs.

International guidelines advocate for sedatives and analgesics to ensure patient comfort during painful events [24]. However, when used to induce coma for mechanical ventilation, sedative and analgesic medications such as benzodiazepines and opioids place patients at high risk for delirium [25,26]. According to Riker and Fraser [27], sedative and analgesic therapy is also related to several important side effects, including hypotension, bradycardia and other dysrhythmias, and sepsis. At least one published delirium prediction model includes the use of benzodiazepines and antipsychotics as predictors [3].

Marois et al [16] and Oken et al [28] stated that prediction models using artificial intelligence (AI) have been developed to quantify hypovigilance using psychobehavioral correlates of vigilance in laboratory settings, but real-world examples are lacking. The same scoping review identified 21 psychophysiological models of hypovigilance detection, in which almost all relied on at least one of the following signals, targeting both central and autonomic nervous systems: electrocardiography, photoplethysmography, electroencephalography, electrooculography, and eye tracking

XSL•FO
RenderX

[16]. While sensitive, these systems are resource-intensive and hard to use in dynamic environments such as the ICU.

Despite the clinical need for new diagnostic tools, there is still a lack of consensus regarding the most accurate tool to use in clinical practice. There are also significant barriers to the widespread use of more sophisticated diagnostic modalities, such as electroencephalography, in clinical settings due to poor signal quality [16], specialized and costly equipment requirements [29], and patient discomfort associated with extended wear [30]. These factors hinder the adoption of these sensors in routine health care settings. Moreover, other emerging sensors capable of monitoring HRV are not universally incorporated into ICU monitors and are not part of routine data collection.

Patients admitted to the ICU are assessed hourly by critical care nurses to determine their level of vigilance. This assessment is necessary because the condition of patients in the ICU often fluctuates. Current delirium prediction models rely on static baseline data taken at admission, which fail to capture the fluctuating nature of vigilance over time [3]. Moreover, vigilance detection models developed in lab environments lack real-world clinical validation [16]. Clinical real-world settings, such as ICUs, can provide a reliable data collection environment where patients often experience frequent episodes of hypovigilance. Further research is needed to identify effective detection methods for patients in the ICU, including but not limited to the use of automated hypovigilance assessment tools that could be reliably used on a large scale by nonexperts and that could be used in all patients regardless of the language they speak [31]. AI technologies offer a novel modality to support the detection of hypovigilance. The development of a reliable tool capable of monitoring vigilance represents an initial step in the creation of a tool that can accurately diagnose delirium. The objective of this project was to derive an AI-driven prediction model able to continuously detect recurrent episodes of hypovigilance using routinely collected physiological markers in the ICU.

Methods

Design and Setting

We conducted a derivation study using data collected from a prospective observational cohort study carried out in the ICU at the Hôtel-Dieu de Lévis Hospital. Its research protocol was not published or registered in a clinical trials registry. We report our findings using the Transparent Reporting of a multivariable prediction model for Individual Prognosis Or Diagnosis for machine learning models (TRIPOD+AI) guidelines [32,33] (checklist provided in Checklist 1). We also used the Prediction model Risk Of Bias Assessment Tool (PROBAST) to identify potential biases [34] (Multimedia Appendix 1). The code and datasets generated to support preprocessing and training the models are available for download from a Zenodo repository [35].

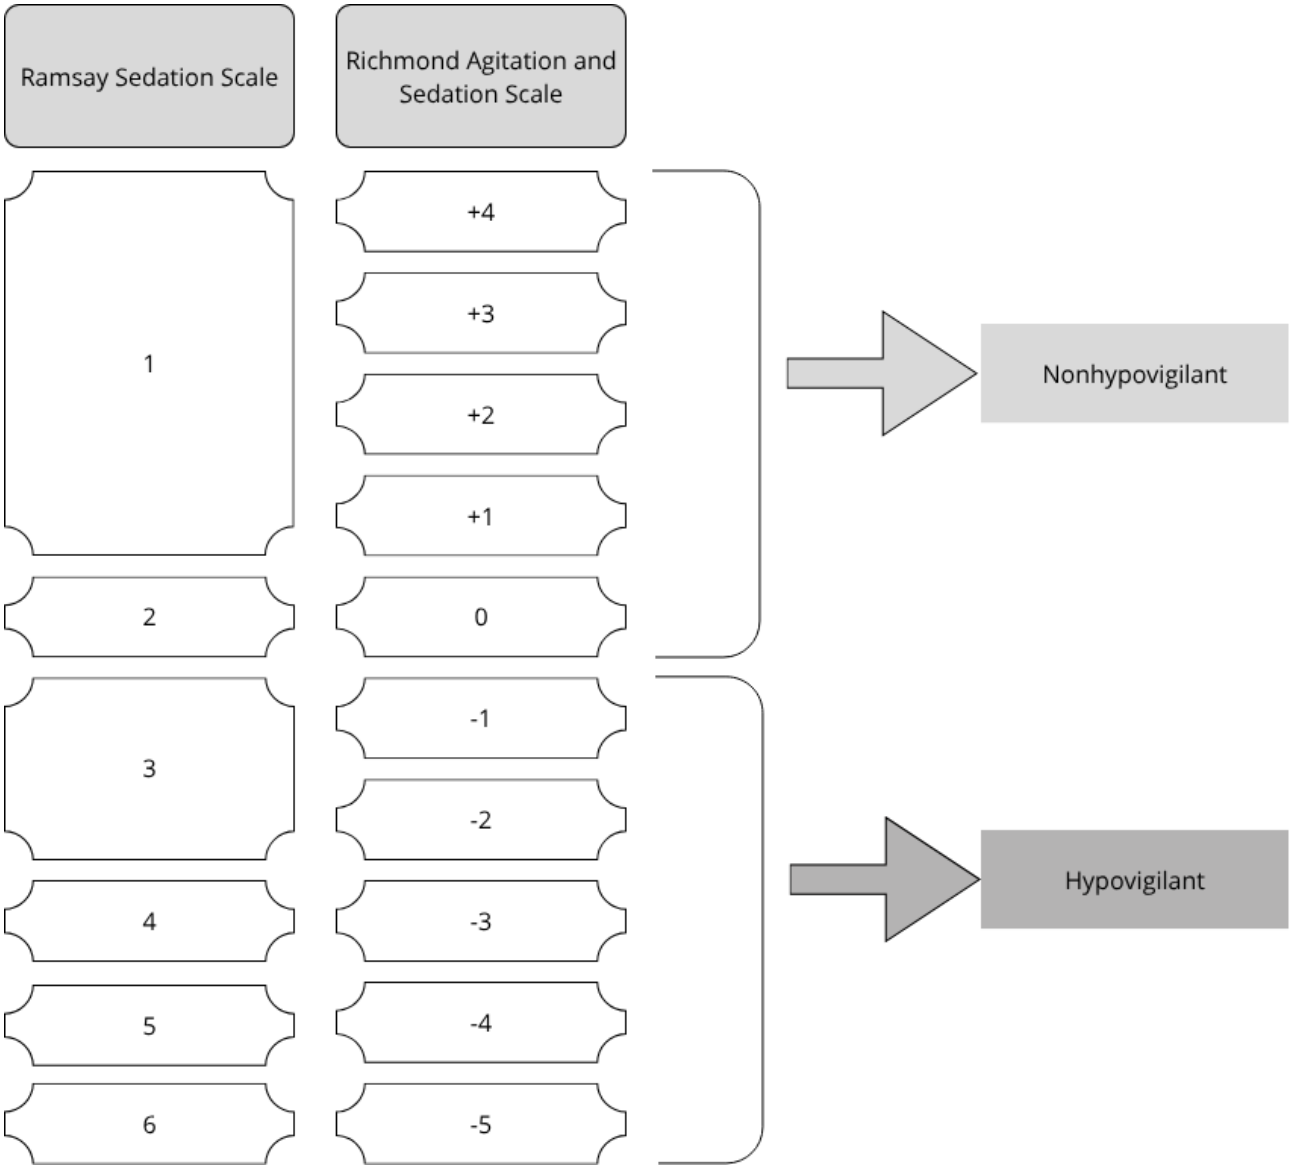
Participants

Eligible patients were admitted to the Hôtel-Dieu de Lévis Hospital ICU between October 2021 and June 2022. Inclusion criteria were (1) age ≥18 years and (2) an anticipated ICU stay of ≥48 hours from admission. We did not include patients anticipated to stay <48 hours because these patients are often elective patients in the postoperative period undergoing surgeries that require short observation periods in the ICU (eg, simple thoracic surgeries) and carry a much lower risk of developing episodes of hypovigilance during their ICU stay.

Exclusion criteria were (1) inability to obtain informed consent (from patients themselves or their substitute decision-makers), (2) inability to communicate in English or French, (3) neurodegenerative diseases (eg, Alzheimer disease), and (4) unavailability of the data collection device. We excluded patients unable to communicate in English or French or with cognitive disorders, as they would potentially not be capable of answering our study questionnaires, potentially biasing our outcome measure based on the capacity of individuals to interact with bedside nurses. Patients who presented in the ICU when the data collection device was unavailable (eg, due to maintenance or system failure) were not included because no data collection was possible during these periods. We also stopped collecting data for participants who stayed >5 days in the ICU because we wanted to maximize the number of patients included in our study. If we had included data from patients who stayed more than 5 days, all of our team's human resources would have been spent collecting data on a smaller and less diverse number of patients.

Data Collection

Despite the inability to blind bedside nurses to the predicted outcome (hypovigilance), they were unaware of the ongoing project. In addition, all vital signs used as predictors were automatically collected by the General Electric (GE) CARESCAPE Gateway, eliminating any potential for information bias.



Event Identification

Intensive care nurses assessed patients' levels of vigilance using 2 scales. Bedside ICU nurses completed hourly assessments of the patient's vigilance using the Richmond Agitation and Sedation Scale (RASS) [36] or the Ramsay Sedation Scale (RSS) [37,38]. RASS is a 10-point scale that assesses sedation and agitation based on criteria that evaluate the patient's response to verbal stimulation. The RSS categorizes sedation levels across 6 states and is widely used in clinical settings [21]. While the RASS is standard for patients who are intubated, the RSS is used when participants are not intubated. There is a strong correlation between the 2 scales, which demonstrates good interrater reliability [39]. Following the study by Mistraletti et al [24], we identified hypovigilant episodes when RASS scores were <0, indicating a drowsy to unarousable state, and RSS scores >2, signifying a drowsy to unarousable condition. These specific criteria served as the basis for labeling vigilance states as episodes of hypovigilance versus nonhypovigilance (Figure 1).

We did not capture the sociodemographic characteristics of the nurses who conducted the RASS and RSS assessments. Vital signs were automatically captured by the GE CARESCAPE Gateway.

XSL•FO
RenderX

Figure 1. Labeling process to identify episodes of hypovigilance using the corresponding Ramsay Sedation Scale and Richmond Agitation and Sedation Scale.

Clinical Information

At enrollment, we collected participant data on age, sex, height, and comorbidities. We also collected information on the type of admission (medical vs. surgical), history of depression, need for ventilatory support, and need for intubation. We documented whether any intravenously administered sedative or analgesic agents (eg, midazolam, propofol, hydromorphone, or fentanyl) were being administered at the time of vigilance assessment by bedside nurses. Use of intravenous sedation and analgesia was extracted from nursing notes as a binary variable (presence or absence of one of these medications). Multiple medications could be administered simultaneously.

When patients were admitted to the ICU, we also collected data on (1) the Glasgow Coma Scale (GCS) to measure patients' level of consciousness, ranging from 3 to 15, with lower scores indicating more severe deficits [40,41]; (2) participants' baseline functional capabilities using the Pfeffer Functional Activities Questionnaire (FAQ) [42]; and (3) the Clinical Frailty Scale (CFS) to evaluate the baseline frailty status of participants with scores ranging from 1 (very fit) to 9 (terminally ill) [43]. These questionnaires are described in Multimedia Appendix 2. These tools were used to describe the population included in our cohort, but were not integrated into our AI algorithm.

Physiological Time Series Collection

We used a GE CARESCAPE Gateway (GE HealthCare) to streamline and automate continuous data collection. Gateway data was extracted and securely stored in a comma-separated values format on local servers. Vital signs and physiological markers were continuously monitored and recorded at one-minute intervals, allowing for the exploration of indicators associated with hypovigilant episodes. Bedside vital signs and data automatically recorded via the gateway included HR, respiratory rate (RR), premature ventricular complex count, oxygen saturation, body temperature (when an internal body temperature probe was used), invasive arterial blood pressure, and noninvasive blood pressure (Table 1). Intubation was automatically derived from the presence of inhaled CO_2 while intubated (CO_2-IN) or exhaled CO_2 while intubated (CO_2-EX;

XSL•FO
RenderX

Table 1). Occasionally, more than one timestamp's worth of data was gathered by the gateway. To ensure data consistency, we systematically removed all duplicate lines.

Table . Bedside vital signs and data recorded with the General Electric CARESCAPE Gateway.

Feature	Description	Unit
HR	Heart rate	Beats per minute (bpm)
RR	Respiration rate	Breaths per minute (bpm)
SpO_2-%	Oxygen saturation	Percentage (%)
SpO_2-R	Pulse oximeter pulse rate	Beats per minute (bpm)
NBP-D	Noninvasive diastolic blood pressure	millimeters of mercury (mm Hg)
NBP-M	Noninvasive mean blood pressure	mm Hg
NBP-S	Noninvasive systolic blood pressure	mm Hg
PVC	Premature ventricular complex count	Events per minute
AR-D	Arterial line diastolic pressure	mm Hg
AR-S	Arterial line systolic pressure	mm Hg
AR-M	Arterial line mean pressure	mm Hg
AR-R	Arterial line pulse rate	Beats per minute (bpm)
CO_2-EX	Exhaled CO_2 while intubated	mm Hg
CO_2-IN	Inhaled CO_2 while intubated	mm Hg
Temperature	Rectal temperature	Degrees Celsius (°C)

Time Series Selection

Time series of sequential changes in vigilance states were generated by selecting physiological measurement data within a 5-minute window before and after each hypovigilant or nonhypovigilant episode, resulting in an 11-point time series spanning 11 minutes (Figure 2). RASS and RSS assessments were made hourly; if two measurement points were the same, the condition was considered constant throughout the hour. When two consecutive vigilance levels were different, no assumptions were made for the time points between these two vigilance assessments. The decision to use an 11-minute window in each time series aimed to maximize clinical relevance, better characterize state changes, and optimize the classification capacity of our AI models.

Figure 2 illustrates the 2 simple rules we followed to label episodes of hypovigilance before and after the hourly vigilance assessments determined by bedside nurses. Labels (hypovigilant vs nonhypovigilant) were automatically assigned for each separate vigilance state as determined by bedside nurses. Additional imputed labels were assigned to time points before and after each hourly vigilance assessment performed by the nurses based on two simple rules. The first rule determined if two labels were within 60 minutes of each other. If two consecutive vigilance assessments were made ≤60 minutes apart, we proceeded to the second rule. If the assessments' labels were >60 minutes apart, we did not add any new labels for new hypovigilance episodes. The second rule determined if the consecutive vigilance states (and associated labels) were identical. If they were identical, we added labels at 5-minute intervals for each episode of hypovigilance or nonhypovigilance between the original labels, based on the value of the vigilance state at both boundaries. If they were not identical, we did not add additional episodes of hypovigilance or nonhypovigilance between the consecutive discordant labels, because determining the moment when the state changed from hypovigilant to nonhypovigilant (or vice versa) was not documented by bedside nurses and was impossible to determine retrospectively. For example, in case 1, no additional labels were added because the consecutive labels differed. In case 2, labels were added at 5-minute intervals when the consecutive labels were identical and less than 60 minutes apart. However, in case 3, no additional labels were added because the consecutive states remained the same but were separated by more than 60 minutes. This approach preserved the temporal structure integrity of our model.

Time Series Preprocessing

Missing Values and Data Cleaning

We used a backward- and forward-filling strategy to address missing values in the vital signs time series [44]. Backward filling involves filling in missing values in a dataset by using preceding data values to complete the gaps. In other words, missing values were filled based on available data preceding them in the time series [44]. In some cases, backward filing was impossible due to the lack of available previous data. In such cases, forward filling was performed. Forward filling involves using future values to fill in missing data [44].

Real-world data is also inevitably contaminated with noise, artifacts, and unreliability due to patient movement, sensor unavailability, or electrical interference. We deliberately chose to analyze all of the data, knowing that it may present noise and artifacts, using robust machine learning techniques instead of relying solely on cleaned datasets for traditional statistical analysis. We aimed to develop a model that is not only representative of real-world conditions but also capable of generalizing to diverse clinical scenarios. By adopting a machine learning approach, we could effectively learn from the inherent variability in the data and sensor availability, including occasional artifacts, rather than eliminating them entirely. Excessive data cleaning and artifact removal may result in a model that performs well in a controlled setting but fails to translate effectively in real-world applications. Our methodology emphasizes the importance of building resilience in our models to account for the inevitable noise present in ICU data.

Features Extraction

Since the objective of this project was to derive an AI algorithm capable of continuously detecting recurrent episodes of hypovigilance using routinely collected physiological markers in the ICU, we focused our development on physiological features that could be automatically captured by the GE CARESCAPE Gateway. As features for our model, we extracted the first-, second-, and third-order derivatives for each participant's temporal data stream to observe global variations or trends across all patient observations. The first derivative represents the rate of change over time. For example, it allows for the identification of rapidly increasing or decreasing blood pressure. The second derivative refers to the acceleration of the rate of change, for example, how the slope of a vital signs curve evolves over time [45]. A positive second derivative might suggest an acceleration in blood pressure increase, while a negative second derivative could indicate an acceleration in blood pressure decrease. The third derivative captures variation in acceleration, that is, the rate at which the acceleration changes [46]. This third derivative can be useful for detecting unusual changes. By using derivatives, we aimed to capture subtle physiological changes over time that might otherwise go unnoticed.

We also observed that some features (arterial line diastolic pressure, arterial line mean pressure, arterial line pulse rate, arterial line systolic pressure, temperature, CO_2-EX, and CO_2-IN) were missing for >40% of participants. This can be explained because these sensors were only used in certain critically ill patients when indicated. The presence of these features in certain patients reflects that a patient is critically ill and needs more invasive life support (eg, intubation, mechanical ventilation, and sedation) or invasive monitoring (eg, arterial blood pressure catheter or internal temperature probe). CO_2-EX and CO_2-IN are features only available when a patient is intubated. The presence of a temperature measurement captured by the GE CARESCAPE Gateway is only available when an internal temperature probe is used. Variables measured by an arterial line (arterial line diastolic pressure, arterial line mean pressure, arterial line pulse rate, and arterial line systolic pressure) are only available when an arterial line is installed. To mitigate potential bias in our classifier due to missing variables in less ill patients, we replaced these features with Boolean (presence or absence) variables indicating whether an arterial line was present, the patient was intubated, or an internal body temperature probe was used. This approach enhances the generalizability of our findings by accurately representing typical ICU practices.

This approach enhances the generalizability of our findings by accurately representing typical ICU practices.

Features Selection

Our objective was to identify significant differences between the two vigilance states (hypovigilant vs nonhypovigilant) with a non-normal distribution of the data. We elected to reduce the feature space by only selecting features that were significantly different between the two states, on average. To this end, we performed Mann-Whitney *U* tests [47] on the distribution of the features. The dataset was divided into training and test sets (refer to Figure 3), and the Mann-Whitney *U* test was performed separately on each set. Only the variables that were statistically significant within a particular set were included in the respective model trained on that set. As a result, multiple models were generated, each using a subset of the variables found to be significant in their respective sets. This approach ensured that the models were tuned to capture the most relevant features for predicting hypovigilance states, considering the variability observed across sets during the cross-validation process. To provide statistics on the selected features, we counted the number of times a variable was found to be significant across sets.

Machine Learning Models

We used 3 distinct AI models for detecting hypovigilance events: Random forest (RF) from the Python Scikit-learn library [48], Extreme Gradient Boosting (XGBoost) from the XGBoost library [49], and the Light Gradient Boosting Machine (LightGBM) classifier from the LightGBM library [50]. We chose these classifiers because RF and XGBoost were used in prior studies to identify delirium and hypovigilance [28]. LightGBM was also used because of its previous application in other ICU databases, such as the Medical Information Mart for Intensive Care III database [51].

RF is a real-time classification algorithm that excels in capturing nonlinear relationships, making it applicable to domains such as clinical outcome prediction [52]. It is composed of a set of data structures characterized by decisions (branches), called trees, with each tree depending on random variables. It creates a forest from a group of decision trees trained using the bagging method. The key notion behind the bagging method is the combination of multiple learning models to improve overall sensitivity [52]. XGBoost uses gradient-based decision trees. It is tailored for classification and regression modeling of tabular datasets [49]. As described by Qian et al [51], the LightGBM classifier uses iterative training to obtain the most advantageous identification model. Qian et al [51] explained that LightGBM uses a gradient-boosting framework using a tree-based learning algorithm to reduce computation time.

Data Splitting and Hyperparameters Search

To preserve patient data and account for the limited number of patients in our dataset, we used a 10-fold, group-based cross-validation strategy. The data were partitioned into groups of random size at the patient level. This approach ensured that all within-patient-related information was retained during model evaluation, making models more robust to new participants.

To enhance the performance of our 3 AI classifiers, we used the random search technique for hyperparameter tuning for each split. This technique is widely recognized for its computational efficiency compared to traditional grid search methods, as it requires less computational time [53].

In Figure 3, the model was trained and evaluated using group cross-validation. The data were split at the patient level into training and testing subsets for each fold of the cross-validation, with varying group sizes ranging from one to several patients. Across all folds, the Mann-Whitney U test was performed to select only the significant features in each model. Performance metrics (accuracy, precision, and recall) were computed on the testing subset during each fold.

Performance Evaluation

The performance metrics included average accuracy, which measured the proportion of correct predictions made by the model across all iterations of the cross-validation process; precision, which assessed the proportion of true positive predictions among all positive predictions, providing insight into the ability of the model to make precise classifications; and average recall (sensitivity), which evaluated the capability of the model to correctly identify positive instances from the entire dataset. In addition, we computed the average area under the curve (AUC), which serves as a measure of the model's ability to distinguish between positive and negative classes, and the average F_1-score, which provides a balanced assessment by considering both precision and recall. These metrics collectively indicate the overall performance of our model in classification tasks. We also generated calibration curves for the 3 different classifiers using one representative model from the cross-validation process.

To interpret the predictions of our best-performing models, we conducted a Shapley Additive Explanations (SHAP) analysis [54]. For this analysis, we selected one of the top-performing models identified during 10-fold group-based cross-validation and retrained it on the entire dataset of 30 participants. The resulting SHAP values provided insight into each feature's contribution to the model's output, although the exact feature importance may vary between individual model.

Sensitivity Analyses

We also aimed to evaluate the impact of including the medication variable (use of sedatives or analgesics) on the performance of our models. We therefore performed 2 main sets of sensitivity analyses: one excluding and the other including the medication variable as a variable of interest.

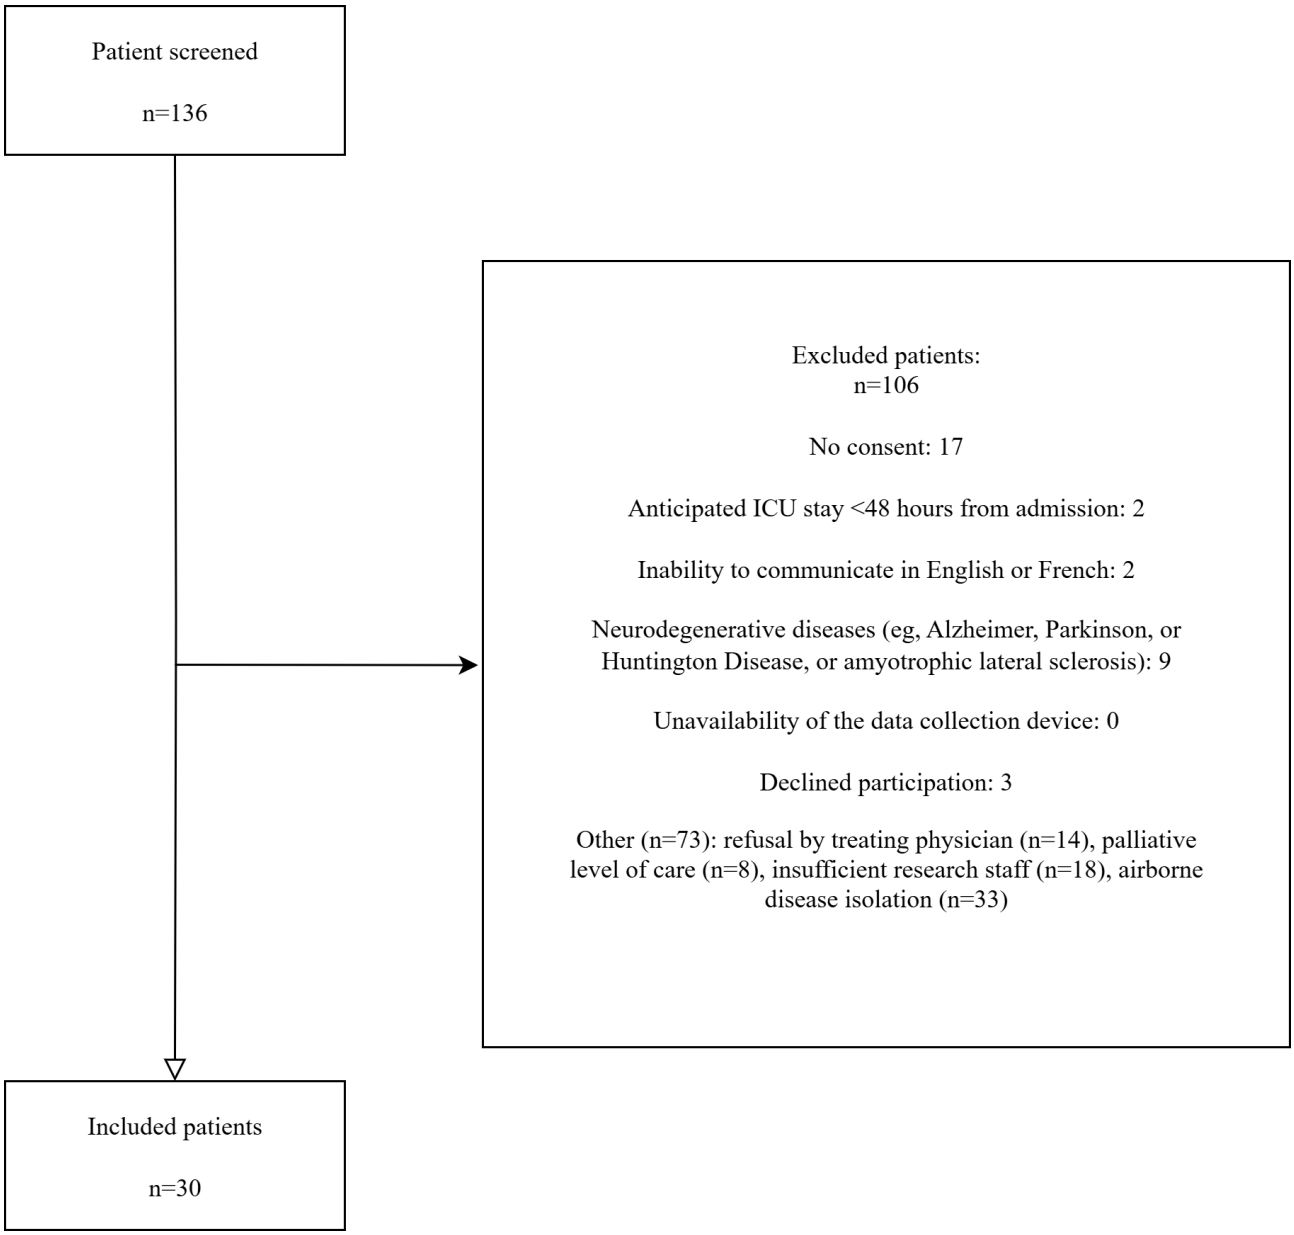
Patient and Public Involvement

Patients and the public were not involved in the design, conduct, reporting, or dissemination plans of this research.

Ethical Considerations



The study was approved by the research ethics committee of the Centre intégré de santé et de services sociaux de Chaudière-Appalaches (2021 - 771).

Results

Patient Characteristics

Among 136 patients considered for inclusion in our cohort, 30 were eligible (Figure 4). These 30 patients experienced a total of 1493 hypovigilant episodes and 764 nonhypovigilant episodes. Two participants did not have any hypovigilant episodes. As shown in Table 2, participants in our cohort were aged 69 years (mean), male (63%), admitted to the ICU for surgical (30%) or medical (70%) reasons, and mostly intubated, receiving intravenous sedation-analgesia medication (70%).

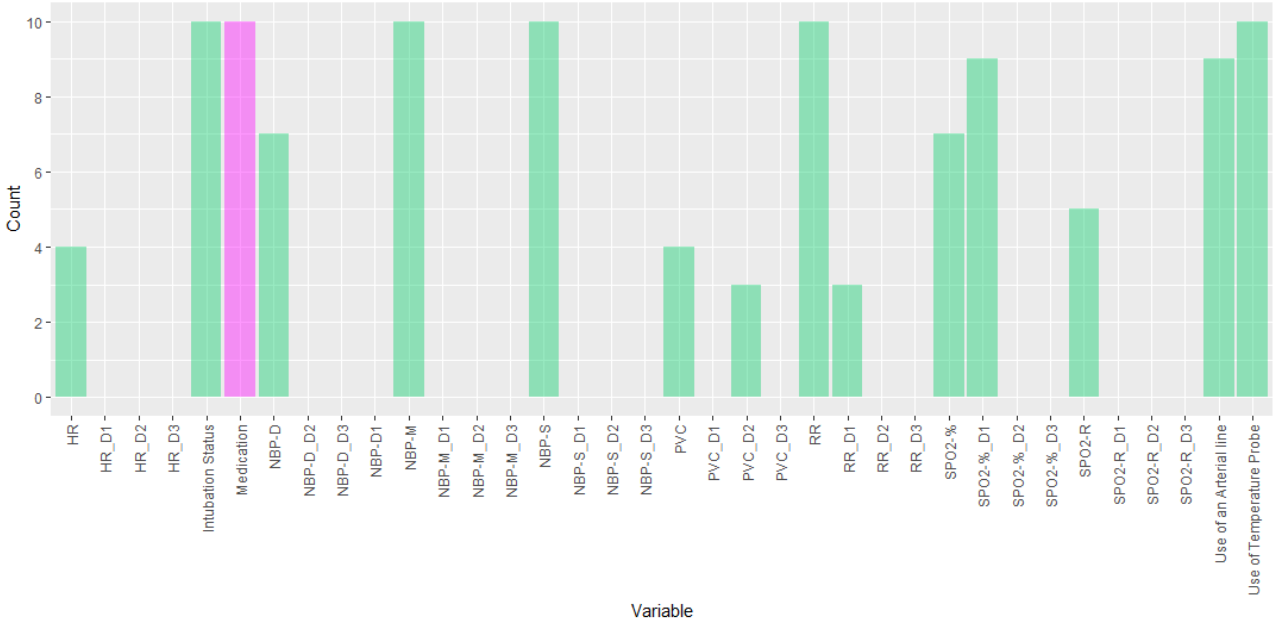

Figure 5 illustrates the frequency of significant features identified through the Mann-Whitney *U* test conducted during the LightGBM cross-validation. This is consistent across all classifiers, as they all used the same groups. Green bars represent features identified as significant across the 10-fold cross-validation procedure using the base model without the inclusion of the medication variable. The purple bar indicates the addition of the medication variable, which was consistently selected as a significant feature across all folds. The first, second, and third derivatives are labeled as "_D1," "_D2," and "_D3," respectively.

Variables that were consistently significant across multiple folds were intubation, noninvasive mean blood pressure, noninvasive systolic blood pressure, RR, and the presence of an internal body temperature probe. Other key features were also frequently found significant included the presence of an arterial line, noninvasive diastolic blood pressure, premature ventricular complex count (PVC) count, the second derivative of PVC count (PVC_D2), the first derivative of RR (RR_D1), oxygen

XSL•FO
RenderX

saturation (SpO_2-%), and HR determined by the pulse oximeter pulse rate. These features exhibited varying degrees of importance across cross-validation folds, suggesting their potential relevance in detecting hypovigilance episodes. Notably, the use of intravenous sedation and analgesia medication variable was significant in 10 instances, highlighting its importance in our models. In addition, only the following derivatives were significant in our feature analysis: PVC_D2, RR_D1, and SpO_2_D1.

Figure 5. Significant features in the models. Green bars represent features identified as significant across the 10-fold cross-validation procedure using the base model without the inclusion of the medication variable. The purple bar indicates the addition of the medication variable, which was consistently selected as a significant feature across all folds.

Classification Results

The classification results of the three AI classifiers—XGBoost, RF, and LightGBM—along with an additional set of the 3 models incorporating the sedative or analgesic medication variable, are presented in Table 3.

For the models excluding the sedative or analgesic medication variable, the LightGBM model demonstrated the highest average accuracy, average precision, average recall, average AUC, and average F_1-score. Furthermore, it exhibited an average recall of 74% (SD 18%) and an average precision of 76% (SD 11%). XGBoost followed as the second-best classifier with an average recall of 73% (SD 18%) and an average precision of 75% (SD 10%). When the sedative or analgesic medication variable was incorporated, LightGBM remained the top-performing classifier, closely followed by XGBoost and RF. Their performances are relatively similar, except in terms of average recall, where both XGBoost and LightGBM achieved 70% and 71%, respectively, and RF achieved 64%.

Table . Classification performance metrics for our 3 artificial intelligence models.

Model	Average accuracy, mean (SD)	Average precision, mean (SD)	Average recall, mean (SD)	Average AUC[a], mean (SD)	Average F_1-score, mean (SD)
Models without incorporating the sedative or analgesic medication variable					
XGBoost[b]	0.66 (0.11)	0.75 (0.10)	0.73 (0.18)	0.58 (0.09)	0.68 (0.10)
Random forest	0.67 (0.15)	0.76 (0.11)	0.68 (0.22)	0.60 (0.12)	0.69 (0.12)
LightGBM[c]	0.68 (0.12)	0.76 (0.11)	0.74 (0.18)	0.60 (0.12)	0.69 (0.11)
Models with the incorporation of the sedative or analgesic medication variable					
XGBoost	0.70 (0.15)	0.76 (0.13)	0.70 (0.19)	0.62 (0.14)	0.72 (0.14)
Random Forest	0.71 (0.15)	0.77 (0.13)	0.64 (0.25)	0.63 (0.13)	0.72 (0.15)
LightGBM	0.70 (0.15)	0.76 (0.13)	0.71 (0.21)	0.62 (0.12)	0.72 (0.14)

Feature Importance

To better understand which physiological parameters most influenced the model's prediction of hypovigilance, we computed SHAP values for the features used in our LightGBM classifier. The analysis revealed that intubation status, noninvasive systolic blood pressure, and RR were the most influential predictors. A detailed SHAP summary plot is provided in the Multimedia Appendix 3. For this specific model, the first derivative of oxygen saturation (SpO_2-%_D1) also had an impact. This indicates that the rate of change in oxygen saturation appears to be more informative in assessing vigilance than the absolute oxygen saturation level itself. No other derivatives influenced the model presented.

Figure 6 presents calibration curves comparing 3 classifier models. The black dotted diagonal line represents ideal calibration, where predicted probabilities perfectly align with observed event frequencies. Deviations above the diagonal indicate overestimation of probabilities (overconfidence), and deviations below indicate underestimation (underconfidence). In this specific test fold, the RF model (line with squares) displayed the most substantial deviations, indicating the least accurate calibration among the classifiers. The XGBoost model (line with circles) exhibited improved calibration, albeit with some residual discrepancies. The LightGBM model (line with triangles) demonstrated the closest approximation to perfect calibration. It is important to note that the cross-validation procedure resulted in 30 distinct models, and this figure illustrates only 3 representative examples. Although this study's primary objective was to evaluate predictive performance, future research should prioritize calibration techniques to optimize probability estimates in the final selected model.

Figure 6. Calibration curves comparison. LightGBM: Light Gradient Boosting Machine; XGBoost: Extreme Gradient Boosting.

Discussion

Principal Findings

This study aimed to develop an AI model to identify hypovigilance episodes in patients using data from a single ICU. Our results demonstrate that the differentiation of episodes of hypovigilance from nonhypovigilance episodes is possible with 3 different classifiers using routinely acquired clinical ICU data. While most researchers agree that an AUC below 0.6 indicates poor performance, there is less consensus on how to classify higher values [55]. AUC values between 0.7 and 0.8, for example, have been inconsistently described as poor, moderate, fair, or even good. We acknowledge that the performance statistics of our AI models, ranging in the poor to moderate range (AUCs of 0.58-0.63), preclude any clinical application at this time.

XSL•FO
RenderX

The LightGBM classifier showed slightly better results than XGBoost and RF across multiple evaluation criteria. However, all the classifiers showed significant variability in correctly identifying true positives across different folds of the cross-validation process. The high SD of our results may be due to differences in participant characteristics or class imbalances during training. A precision score of 76%, with a SD of 11%, indicates the ability to correctly identify true positives among all positive results across different folds. LightGBM classifiers generally outperformed both XGBoost and RF in terms of average accuracy, precision, recall, AUC, and F_1-score. These results demonstrate the need for further refinement and prospective, external validation with larger datasets. The XGBoost algorithm achieved a recall rate of 73% and an average precision rate of 75%. A screening tool needs to be sensitive and have a high recall [56]. Our average recall rate of 74% indicates we still need to decrease the number of false negatives generated by our model, because missing an episode of hypovigilance in the ICU could have serious consequences. Our sensitivity analysis revealed a clear improvement in model performance with the inclusion of medication data about the use of intravenous sedatives and analgesics, which correlated with the occurrence of hypovigilant episodes. This suggests the importance of incorporating other time-dependent concurrent contextual data into a predictive model developed to continuously monitor for the risk of hypovigilance.

Although our models do not demonstrate performance characteristics to support current clinical application, they collectively demonstrate promise for potential future refinement and research. Despite these limitations, our models remain superior to random chance and offer the opportunity to inform future studies on patients whose level of vigilance is at risk of fluctuating in the ICU. Future studies on this subject need to ascertain whether performance can be enhanced over time, including the calibration of a future model to optimize probability estimates. Any AI tool that enhances patient care, particularly for those who are most vulnerable in the ICU, is worthy of further investigation and validation if conducted ethically and with respect for equity, patient privacy, high-quality standards, and transparent data reporting.

Comparison With Prior Work

The majority of research on hypovigilance has previously been conducted in laboratory settings, which offer a highly regulated setting but might not accurately reflect real-world ICU situations [16]. Also, the field of vigilance is often poorly defined, which makes it hard to compare our results to the existing literature [28]. The existing vigilance research is mostly focused on driving and flight simulations, during which operators do experience hypovigilance, but it may not present the same as in patients in the ICU [16].

Although our study did not focus on the detection of delirium, we did study how to detect hypovigilance, which is an important component of hypoactive delirium. Comparable delirium prediction models, which also use noninvasive features, show similar or slightly better performances. For example, a model developed in South Korea by Oh et al [57], using automatically collected variables including HRV, achieved a slightly better-balanced accuracy of 70%, with a maximum accuracy of 71.5%. Despite its lower performance, our model still shows promise considering that we derived our algorithm on a smaller dataset without HRV data. These results are also in line with other delirium studies using electroencephalography and electrocardiography [58].

To improve the accuracy of future delirium diagnostic and prediction models, we considered the dynamic nature of a patient's condition and incorporated real-time data into our models that centered only on the detection of hypovigilance and not delirium [3]. A future enhanced and more accurate automated model could potentially offer real-time patient monitoring throughout their ICU stay. Such a model could use data that are generally accessible across all ICUs. As mentioned by Marois et al [16], the variability of the baseline "gold standard" in hypovigilance prediction models is a significant challenge. Different studies use diverse gold standards, some lacking prior validation. To address this, our study used 2 validated sedation scales (RSS and RASS) in a clinical setting, incorporating a validated gold standard to enhance the labeling process of hypovigilant episodes.

Strengths

Our study has several strengths. First, by conducting our research in a real-world ICU setting and using simple and routinely collected vital signs and physiological markers used in ICUs around the world, we ensured that our findings are relevant and transferable to similar health care settings. In addition, we used rigorous data collection methods using an automated vital sign data collection system. This ensured the consistency and accuracy of our dataset, minimizing the risk of classification bias. Our data collection and classification methods are entirely noninvasive and exclude procedures such as blood tests or electroencephalography, thereby increasing the integration potential into AI-based decision support systems. Given that no baseline sociodemographic variables such as age, sex, past medical history, or other clinical variables were included in our model, our first model without the intravenous sedative or analgesic medication variable could stand alone without any human-collected data. Another strength of our model is that our AI-derived detection model based on automatically collected vital signs is agnostic to language, which makes it more equitable for patients who speak languages different from their health care providers, and in settings where hypovigilance and delirium are assessed using detection tools that depend on understanding the language being used.

Our study analyzed numerous episodes of hypovigilance and nonhypovigilance in patients in the ICU. These episodes often lasted for extended periods, making them suitable for detailed analysis. The regular assessments of vigilance by experienced nurses using the RASS or RSS provided a rich dataset for training machine learning models. The expertise and familiarity of the bedside nurses with these standard assessment tools contributed to the reliability and credibility of our outcome measures.

Our study also took advantage of the routine use of intravenous sedatives and analgesics in the ICU, such as propofol,

XSL•FO
RenderX

hydromorphone, fentanyl, and midazolam, that induce prolonged states of deep sedation. This provided valuable opportunities to detect episodes of hypovigilance, allowing us to refine our model and improve its effectiveness in identifying clinically relevant conditions. Identification of hypovigilance has important implications for health care settings in screening persons at risk of delirium. Delirium screening is a time-consuming task that requires completing multicomponent screening tools such as the Confusion Assessment Method for the ICU. Motivated by the growing sophistication of AI models in the medical domain, our project investigated the possibility of using machine learning to enhance the screening capacity of hypovigilance in the context of nursing shortages. This potentially represents a viable path toward improving patient outcomes and decreasing the workload of health care professionals [59]. The creation of AI algorithms capable of detecting early onset of hypovigilant episodes may allow clinicians to apply timely delirium treatments or mitigation measures, thereby enhancing the outcomes of patients in the ICU.

Limitations

We used the PROBAST checklist to assess the risk of bias in our models (Multimedia Appendix 1) [34]. Based on this assessment, we identified several limitations to our study. First, our study recruited a small cohort of 30 participants and only used data collected for the first 5 days of their ICU stay. Data collection was limited to 5 days because we wanted to maximize the number of patients included in the study. If we had included data from patients during their entire ICU stay, we would have risked biasing our results with some patients who can stay up to several months in the ICU. In such cases, human resources would have been spent on collecting data for fewer patients, thus threatening the external validity of our study. Moreover, obtaining consent for studies in critical care settings can be difficult because substitute decision-makers are not always available. Even though we had a small number of individual participants, each participant underwent hourly, 24-hour vigilance assessments. In addition, the GE CARESCAPE Gateway recorded vital signs at 1-minute intervals, yielding a substantial amount of data for each participant. To address the limitation associated with the small size of our cohort, we used a 10-fold group cross-validation approach. Future studies that include a larger sample in other ICUs will help identify new patterns in physiological marker fluctuations that will help identify hypovigilant states. The cross-validation method used to evaluate the performance of our model across multiple patient groups helped us make full use of our small dataset. The cross-validation strategy also helped identify stable and reliable model performance metrics, minimizing overfitting risk and providing more accurate estimates of the true performance of our model on the entire patient dataset. The wide SDs of our performance metrics are attributed to our small dataset. Nonetheless, our models showed moderate discriminative power, surpassing chance, which suggests a hopeful path for future refinement and improvement. Future studies will need to include a greater number of participants to allow stratification based on comorbidities and detect within-class trends. This effort would require a deep learning approach to deal with the high number of potential interaction terms between different comorbidities and the risk of hypovigilance. Moreover, a larger sample size would allow a future AI model to produce a more powerful and better-calibrated model capable of predicting discrete ordinal outcomes (eg, discriminating between a RASS of 0 vs –1 [drowsy] vs –2 [light sedation] or –3 [moderate sedation]).

A second limitation comes from the fact that our models were built using physiological data captured at low frequency, using 1-minute intervals. Low-frequency data collection limited our ability to capture the subtle changes in high-frequency variations that could be manifested in the transition from nonhypovigilant to hypovigilant states, such as changes in HRV. HRV would have been a valuable characteristic, as shown in other contexts [16], but we could not collect this data with our current GE CARESCAPE Gateway setup. To address this lack of HRV, we investigated the use of the derivatives of the HR variable in our study to measure the rate of change of HR in our model, as well as the use of other cardiac measures such as PVC count as a surrogate for heart irritability and sympathetic nervous system activation [60]. Despite this effort, we did not find a relationship between the derivatives of the HR and the occurrence of hypovigilance. We did find, however, that the rate of change of oxygenation saturation (first derivative of SpO_2%) did predict hypovigilance, which may have some biological plausibility because lower saturation leads to lower brain tissue oxygenation [61].

Third, while other more sophisticated hypovigilance detection models incorporate continuous electroencephalography data [28], this was not possible in our study. Few ICUs have access to continuous electroencephalography monitoring simultaneously for all their patients, underscoring the importance of developing a model that does not rely on these rarely available sensors to ensure its generalizability to many settings. Hence, our approach enables the detection of hypovigilance in a broader context, where electroencephalography may not be readily available.

Fourth, our exclusion of patients with cognitive deficits limits the external validity of our findings. Any future refinements of our AI model will need to include these high-risk populations who are increasingly becoming frequent patients in the ICU [62]. Despite this limitation, our study adds evidence about the feasibility of conducting a privacy-compliant and ethically responsible AI study with vulnerable patients in the ICU that holds promise to improve the quality of patient care in the ICU.

Finally, we did not include patient comorbidities or elements from the medical history in our model development. Including these additional features could have potentially resulted in a superior model, but the decision was made to exclude them because our objective was to develop an automated tool that would minimize the burden on busy clinicians and rely only on features automatically captured by the GE CARESCAPE Gateway. Despite this, we did explore whether using data about sedative and analgesic medication administered would improve the performance of our model, even if medication administration is manually documented by bedside nurses in patients' charts. Future studies will have to explore how to automatically capture and integrate data about the administration of psychoactive

XSL•FO
RenderX

medications, their administration route, their exact time of administration, and their interaction with any preexisting comorbidities. Other potential candidate predictor variables could also be included to enhance the performance of future AI models, such as the time of the day [63] or ambient noise level in the room [64].

Conclusion

We developed an automatic machine learning algorithm to detect hypovigilance in patients in the ICU using routine and easily captured physiological parameters. The classifiers presented in this study demonstrated that hypovigilance could be distinguished from nonhypovigilance cases with poor-to-modest results. Our models exhibited potential for future improvement. Our study adds to the increasing evidence about the potential of machine learning algorithms in real-world clinical settings and identifies avenues for future research to enhance the detection of hypovigilance and improve patient outcomes.

Acknowledgments

We would like to thank the research team at the Centre de recherche intégrée pour un système apprenant en santé et services sociaux du Centre intégré de santé et de services sociaux de Chaudière-Appalaches for their help in implementing this project. We also express our gratitude to Pascal Smith, Emilie Côté, Stéphane Turcotte, Jean-François Gagnon, Maxime Huot-Lavoie, Laurie Couture, and Bao Tran Tran for their valuable contributions to this project. Special thanks to Nathalie Germain for her assistance during the writing process.

This study was funded by a MITACS grant and a NSERC CREATE Program training award for Raphaelle Giguère. Thales Research and Technology provided an unrestricted grant to acquire the GE CARESCAPE Gateway. The Fondation de l'Hôtel-Dieu de Lévis provided an operating grant. Patrick M Archambault held a Fonds de recherche du Québec – Santé Clinical Scholar Award during this project. No funding organization influenced the interpretation or reporting of the results.

Authors' Contributions

PA, SD, PD, and RG were in charge of funding acquisition. RG received financial support from the Hôtel-Dieu de Lévis, and PD received funding through the NSERC CREATE program (SDRDS). PA and SD obtained additional funding for the study. WW, RG, MNH, PA, and SD contributed to the conceptualization, methodology, and investigation. RG and VN were responsible for data curation, analysis, software development, and data visualization. PA, SD, and PD supervised the project and were also RG's master's thesis supervisors. RG prepared the original draft of the manuscript.

Abstract

Background: A major challenge in using electronic health records (EHR) is the inconsistency of patient follow-up, resulting in right-censored outcomes. This becomes particularly problematic in long-horizon event predictions, such as autism and attention-deficit/hyperactivity disorder (ADHD) diagnoses, where a significant number of patients are lost to follow-up before the outcome can be observed. Consequently, fully supervised methods such as binary classification (BC), which are trained to predict observed diagnoses, are substantially affected by the probability of sufficient follow-up, leading to biased results.

Objective: This empirical analysis aims to characterize BC's inherent limitations for long-horizon diagnosis prediction from EHR; and quantify the benefits of a specific time-to-event (TTE) approach, the discrete-time neural network (DTNN).

Methods: Records within the Duke University Health System EHR were analyzed, extracting features such as *ICD-10* (*International Classification of Diseases, Tenth Revision*) diagnosis codes, medications, laboratories, and procedures. We compared a DTNN to 3 BC approaches and a deep Cox proportional hazards model across 4 clinical conditions to examine distributional patterns across various subgroups. Time-varying area under the receiving operating characteristic curve (AUC_t) and time-varying average precision (AP_t) were our primary evaluation metrics.

Results: TTE models consistently had comparable or higher AUC_t and AP_t than BC for all conditions. At clinically relevant operating time points, the area under the receiving operating characteristic curve (AUC) values for $DTNN_{YOB\leq2020}$ (year-of-birth) and $DCPH_{YOB\leq2020}$ (deep Cox proportional hazard) were 0.70 (95% CI 0.66 - 0.77) and 0.72 (95% CI 0.66 - 0.78) at t=5 for autism, 0.72 (95% CI 0.65 - 0.76) and 0.68 (95% CI 0.62 - 0.74) at t=7 for ADHD, 0.72 (95% CI 0.70 - 0.75) and 0.71 (95% CI 0.69 - 0.74) at t=1 for recurrent otitis media, and 0.74 (95% CI 0.68 - 0.82) and 0.71 (95% CI 0.63 - 0.77) at t=1 for food allergy, compared to 0.6 (95% CI 0.55 - 0.66), 0.47 (95% CI 0.40 - 0.54), 0.73 (95% CI 0.70 - 0.75), and 0.77 (95% CI 0.71 - 0.82) for $BC_{YOB\leq2020}$, respectively. The probabilities predicted by BC models were positively correlated with censoring times, particularly for autism and ADHD prediction. Filtering strategies based on YOB or length of follow-up only partially corrected these biases. In subgroup analyses, only DTNN predicted diagnosis probabilities that accurately reflect actual clinical prevalence and temporal trends.

Conclusions: BC models substantially underpredicted diagnosis likelihood and inappropriately assigned lower probability scores to individuals with earlier censoring. Common filtering strategies did not adequately address this limitation. TTE approaches, particularly DTNN, effectively mitigated bias from the censoring distribution, resulting in superior discrimination and calibration performance and more accurate prediction of clinical prevalence. Machine learning practitioners should recognize the limitations of BC for long-horizon diagnosis prediction and adopt TTE approaches. The DTNN in particular is well-suited to mitigate the effects of right-censoring and maximize prediction performance in this setting.

Introduction

Electronic health records (EHR) are a rich source of data that can be used to develop effective clinical prediction models to improve patient care [1]. However, a major challenge is that patients have inconsistent follow-ups, leading to right-censored outcomes, and follow-up length typically depends on observed covariates. This challenge is exacerbated in long-horizon event prediction, such as prediction of an autism and attention-deficit/hyperactivity disorder (ADHD) diagnosis early in life, because many patients are lost to follow-up before the outcome can be observed. Consequently, the probability of observing a diagnosis depends not only on the probability of diagnosis but also on the probability of sufficient follow-up (ie, the probability that diagnosis occurs before censoring). As a result, binary classification (BC) models trained to predict observed diagnoses are substantially affected by the probability of sufficient follow-up unless filtering strategies are carefully applied [2].

A common filtering strategy to mitigate this effect is to exclude all individuals with insufficient follow-up. However, this is not feasible for many long-term prediction tasks. For example, sufficient follow-up for ADHD would extend into adolescence and adulthood; therefore, this criterion would preclude the development of early ADHD prediction models. Even in cases where such a criterion is feasible, it can significantly reduce the sample size available for learning and introduce systematic biases [3], as it tends to exclude subpopulations with shorter follow-up, including disadvantaged groups.

Time-to-event (TTE; ie, survival analysis) methods are the natural alternative, as they are designed for right-censored outcomes. Various versions of classification trees and random forests [4,5], Bayesian networks [6,7], Cox proportional hazards regression [8] and neural networks [9,10] have been applied to survival data with mixed success, and have been adapted to the EHR setting [11]. Deep learning [12] models such as DeepSurv [13] or deep Cox proportional hazards (DCPHs), which follow the Cox proportional hazards framework but uses a neural network to predict the log-hazard ratio, have become popular for EHR prediction tasks. Neural network-based TTE approaches are advantageous because they can efficiently process large, unstructured, high-dimensional inputs and capture complex nonlinear relationships between features and outcomes.

However, common TTE approaches also have limitations relevant to long-horizon diagnosis prediction. Unlike in survival analysis, the event of interest never occurs in most patients, and typically we are more concerned with predicting diagnosis probability than predicting diagnosis timing. Consequently, approaches that predict the probability of diagnosis separately from its timing [14] are well-suited for long-horizon diagnosis prediction, whereas DCPH and other approaches that assume relative likelihood does not change over time are less appropriate. These considerations motivate our current work to use a discrete-time neural network (DTNN), which combines the benefits of BC and TTE approaches.

First, the DTNN offers significant flexibility. Specifically, it does not assume a particular parametric form for the event time density, and in particular, allows the effect of covariates on risk to vary across the time horizon. Second, the DTNN predicts the probability of no-event within the time horizon, which is useful in diagnosis prediction where the event of interest may often not occur. For these reasons, we have found DTNN to be advantageous in our work.

In this paper, we examine the advantages of the DTNN approach compared to BC and DCPH across 4 long-horizon, EHR-based event prediction tasks. We hypothesize that the DTNN approach will yield higher discrimination performance and more accurate likelihood predictions compared to BC even after common filtering strategies are applied due to the inability of BC to disentangle the probability of diagnosis from that of insufficient follow-up. We further hypothesize that DTNN performance will be higher than DCPH, and DTNN predictions will better reflect real-world clinical prevalence and patterns. The code for our work is available online [15].

Methods

Ethical Considerations

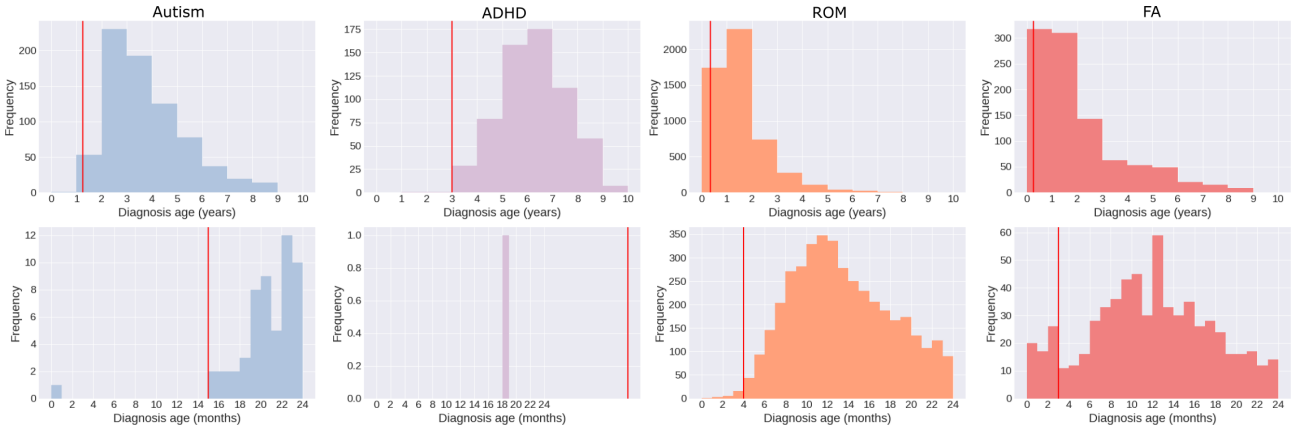
All study procedures were approved by the Duke Health Institutional Review Board (Pro00111224) and comply with institutional policies and federal regulations. A waiver of participant consent was approved due to the minimal risk posed by study procedures and the infeasibility of obtaining consent in a large retrospective cohort. No compensation was provided to the participants. Identifiers were omitted during analysis, which was executed within the Duke PACE (Protected Analytics Computing Environment), a highly secure virtual network space designed for protected health information.

Cohort Identification

Analyses were based on inpatient and outpatient encounters within the Duke University Health System (DUHS), a large academic medical center based in Durham, NC. DUHS provides care to approximately 85% of children in Durham and surrounding Durham County, which has a diverse population with varying demographic and socioeconomic status [16]. Records were extracted from the current (2014 - 2023) DUHS EHR, which is based on the platform developed by Epic.

Study inclusion criteria were the following: (1) date of birth between January 1, 2014 and October 29, 2022; and (2) ≥1 visit within the DUHS before aging 30 days. DUHS encounters between January 1, 2014 and June 2, 2023 were extracted for individuals meeting these criteria. See Figure S1 in Multimedia Appendix 1 for the distribution of year of birth for this identified cohort.

Diagnosis Identification



We focused on 4 clinical diagnoses: autism spectrum disorder (autism), ADHD, recurrent otitis media (ROM), and food allergy (FA). We used computable phenotypes previously established within DUHS [17] or formulated in consultation with clinicians. The classification criteria are provided in Tables S1 and S2 in Multimedia Appendix 1.

RenderX

Experimental Setup

BC models predicting observed diagnoses are significantly influenced by adequate follow-up probabilities, requiring meticulous filtering strategies. We first conducted baseline experiments to establish the performance of BC models with and without exclusion criteria based on year-of-birth (YOB) or follow-up length. Correspondingly, we have 3 models trained on different cohort subsets, which are denoted as $BC_{YOB\leq2020}$, $BC_{YOB\leq2018}$, and $BC_{t\geq5}$ (where t denotes follow-up length). The upper limit of the dataset for the prediction tasks was capped at 2020 due to the rarity of autism and ADHD diagnoses before the age of 2 years (Figure 1). For subset YOB ≤2018, we excluded all children who were age younger than 5 years at the end of our observation window to limit effects of early censoring on model predictions. For subset $t\geq5$, we excluded all children with <5 years of follow-up as a more aggressive measure; note that this subset overlaps the subset YOB≤2018. Next, we introduced 2 TTE models, namely $DTNN_{YOB\leq2020}$ and $DCPH_{YOB\leq2020}$, and evaluated their performance against the 3 BC approaches. To summarize, we explored the effect of each setup when training the corresponding model to predict each of the 4 conditions, yielding 20 models in total.

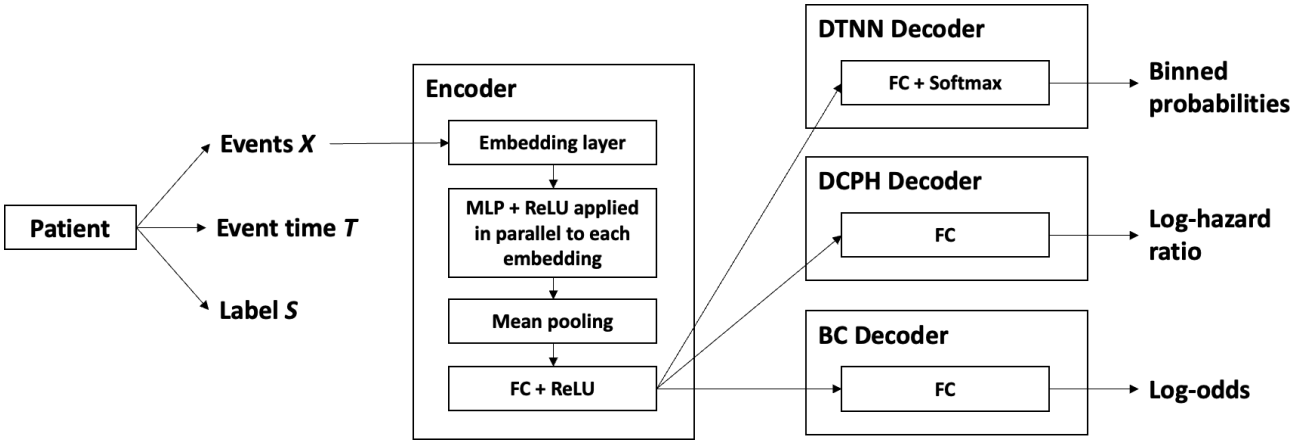
Figure 1. Distribution of observed diagnosis ages in years (upper panel) and months (lower panel). Children with diagnoses before respective diagnosis age cutoffs (marked by the red line) were excluded. Note that there were 2 ADHD diagnoses before the age cutoff of 3 years. ADHD: attention-deficit/hyperactivity disorder; FA: food allergy; ROM: recurrent otitis media.

Our features were based on encounters taking place before the following predefined, condition-specific prediction ages: 15 months, 3 years, 4 months, and 3 months for autism, ADHD, ROM, and FA, respectively (Figure 1). These ages were chosen to be clinically useful prediction times that were earlier than most observed diagnoses. Individuals diagnosed or censored before these cutoffs were excluded from the analysis. To prevent temporal data leakage, the events used for prediction were limited to those taking place before the first diagnosis code (*ICD-10* [*International Classification of Diseases, Tenth Revision*]) associated with the outcome of interest. The distribution of censoring ages can be found in Figure S2 in Multimedia Appendix 1.

The use of predefined diagnosis age cutoffs was a deliberate design decision. First, we aimed to demonstrate the predictive value of detection models based solely on EHR data collected from early ages [17]. Second, using fixed age-offs standardizes the data collection period for all individuals, which simplifies analysis and ensures consistency across the dataset. This approach allows us to focus on understanding model performance across various clinical conditions without the additional complexity of time-dependent updates.

For each diagnosis, the dataset was partitioned randomly, allocating 60% for training, 20% for validation, and 20% for testing.

Model Development



Overview

Each observation was represented by the triplet {X,T,S}, where $X\subseteq Rd$ is a *d*-dimensional feature vector, $T\in(0,Emax]$ is an observed event or censoring time over a finite time horizon, and $S\in\{0,1\}$ indicates whether *T* is a right-censoring time (*S=0*) or an event time (*S=1*). The observed time *T* is the minimum of the event time *E* and the right-censoring time *C*, that is, T=min(E,C).

The model selection process began with experimenting with different combinations of fully connected layers and transformer architectures. See Figure 2 for the final model architectures.

RenderX

Figure 2. Model architectures of DTNN, DCPH, and BC. BC: binary classification; DCPH: deep Cox proportional hazard; DTNN: discrete-time neural network; FC: fully connected; MLP: multilayer perceptron; ReLU: rectified linear unit.

Pretraining Medical Concept Embeddings

Patient histories were represented as timestamped sequences of DUHS EHR events, including *ICD-10* diagnosis codes, medications (RxNorm [18] codes), procedures (Current Procedural Terminology [19] codes), and laboratories (Logical Observation Identifiers Names and Codes [20] codes). Events were mapped to corresponding Word2Vec embeddings, which were learned by training the model on these event sequences to capture contextual relationships between codes. The model used a Continuous Bag of Words approach with negative sampling, producing embeddings of size 256. Padding and out-of-vocabulary indices were also included and mapped to a vector of zeroes. Table S3 in Multimedia Appendix 1 details the hyperparameters used during the training process.

Encoder Architecture

The BC and TTE models all shared a common underlying encoder architecture comprised of (1) an embedding layer, (2) a fully connected layer with rectified linear unit activation applied in parallel to each embedding, (3) a global mean pooling layer, and (4) a fully connected layer with rectified linear unit activation. The embedding layer was initialized with frozen pretrained weights from the Word2Vec model. The sequence length was fixed at 512. Shorter sequences were padded, while longer sequences were truncated by selecting the most recent events preceding the age cutoff for a given model. The mean pooling layer was applied across the sequence dimension, resulting in a single fixed-length vector with dimension equal to that of the embeddings.

Prediction Head

In DTNN, the prediction head was a single fully connected hidden layer with Softmax activation, producing a probability distribution across multiple bins. The bin boundaries can be found in Table S4 in Multimedia Appendix 1. Under the common assumption of noninformative right-censoring, we may ignore the censoring density and optimize the likelihood $P(t, s|x;\theta)$ over the observed data $D=\{xi,ti,si\}i=1N$ by minimizing the following loss:

$$LMLE(\theta)=-(silog\ p\theta(ti|xi)+(1-si)log\ P\theta(ti|xi))$$

where $P\theta$ is the survival function associated with $p\theta$ and T has been discretized such that each ti indicates which interval contains min(E,C).

In BC and DCPH, the prediction head was a fully connected hidden layer predicting the log-odds and log-hazard ratio, respectively, with corresponding binary cross entropy or cox negative partial log-likelihood [21] loss. Whereas BC directly predicts the probability that diagnosis will be observed (by applying the logistic function to the predicted log-odds), with DCPH this probability may be derived from the predicted log-hazard ratio and baseline hazard function. Note that for BC, we assumed a constant predicted probability irrespective of the time point.

Hyperparameter Tuning

The hyperparameters, consisting of learning rate and weight decay, were then chosen through a grid search to minimize loss on the validation set (Table S5 in Multimedia Appendix 1). These optimized models were subsequently used for evaluation on the test set.

Model Evaluation

Calibration Curves

The BC models were evaluated using the probability calibration module from the *scikit-learn* library [22], while the TTE models were evaluated by comparing the observed probabilities (ie, estimated survival probabilities of the Kaplan-Meier estimator) and the predicted probabilities at selected time intervals [23].

Performance Metrics

Our primary evaluation metrics were the time-varying area under the receiving operating characteristic curve (AUC_t) and time-varying average precision (AP_t) [24], which quantify the model's ability to discriminate between individuals diagnosed before the age t (positives; $S=1, t\leq t$) and individuals remaining event-free beyond age t (negatives; $t>t$). This time-dependent approach is necessary due to censoring, which prevents many diagnoses from being observed. In contrast, the standard area under the receiving operating characteristic curve (AUC) and average precision (AP) do not differentiate between nondiagnosed individuals with short versus long follow-up,

XSL•FO
RenderX

making them unsuitable for evaluating predicted diagnosis probabilities.

Harrell concordance index [25] was also used to quantify the agreement between likelihood predictions and event times. This metric quantifies the model's ability to discriminate between individuals diagnosed earlier and those diagnosed later or not at all.

For each metric, we computed the 95% CI of the distribution over performance obtained from 100 bootstrap samples in the test set.

As we were unable to directly assess the accuracy of the predicted probabilities because diagnoses were not fully observed in the dataset, we instead contextualized them and reasoned about their correctness by analyzing the corresponding published trends.

Subgroup Analysis

To explore possible differential effects of each model setup on specific demographics, we analyzed model predictions and performance in subgroups defined by YOB, follow-up length (ie, age at censoring), sex, race, and insurance. Biological sex was classified as male or female. Race was categorized into the following groups: Asian, Black or African American, White, unavailable, and other. Insurance status was separated into public, private, and other categories.

To assess the performance of our models on out-of-distribution (OOD) data, we extended the evaluation to include children born after 2018 and individuals with a follow-up duration of <5 years for the YOB and follow-up length plots, respectively. For the YOB plots, 2019 and 2020 were designated as OOD years for $BC_{YOB\leq 2018}$. Since $BC_{t\geq 5}$ also fulfilled the YOB≤2018 criteria, the same years were, by extension, considered OOD. Similarly, for the follow-up length plots, individuals with a follow-up duration of ≥5 years were categorized as in-distribution, while those with <5 years were classified as OOD.

Semisynthetic ROM Dataset

To further explore the effect of early censoring on each method's ability to predict diagnosis probability, we simulated early censoring for ROM cases. Unlike ADHD, most ROM diagnoses were observed rather than censored due to the earlier age of diagnosis. Leveraging prior knowledge of true ROM labels, we introduced artificial censoring by scaling the true censoring distribution such that the maximum age is at 1.2 years to mimic the ADHD scenario. Generating a semisynthetic ROM dataset served 2 purposes: reproducing earlier findings on BC limitations with censored data and demonstrating DTNN model performance under such conditions. Additional DTNN and BC models were trained on this semisynthetic train dataset and subsequently evaluated on the original test dataset.

This study follows the Consolidated Reporting of Machine Learning Studies guidelines (Checklist 1) [26].

Results

Patient Characteristics

Records for 57,701 unique patients meeting study criteria were initially extracted. After excluding children born after 2020, the evaluation dataset comprised 43,536 patients (Table 1). Based on the respective diagnosis age cutoffs (Figure 1), we further excluded 1 individual with autism as an outlier due to a diagnosis within the first month of birth, along with 2 individuals with ADHD, 25 individuals with ROM, and 70 with FA. Additionally, individuals with censoring ages preceding the age cutoffs were excluded: 9332 from the autism dataset, 17,691 from the ADHD dataset, 6171 from the ROM dataset, and 5847 from the FA dataset.

[a]ADHD: attention-deficit/hyperactivity disorder.

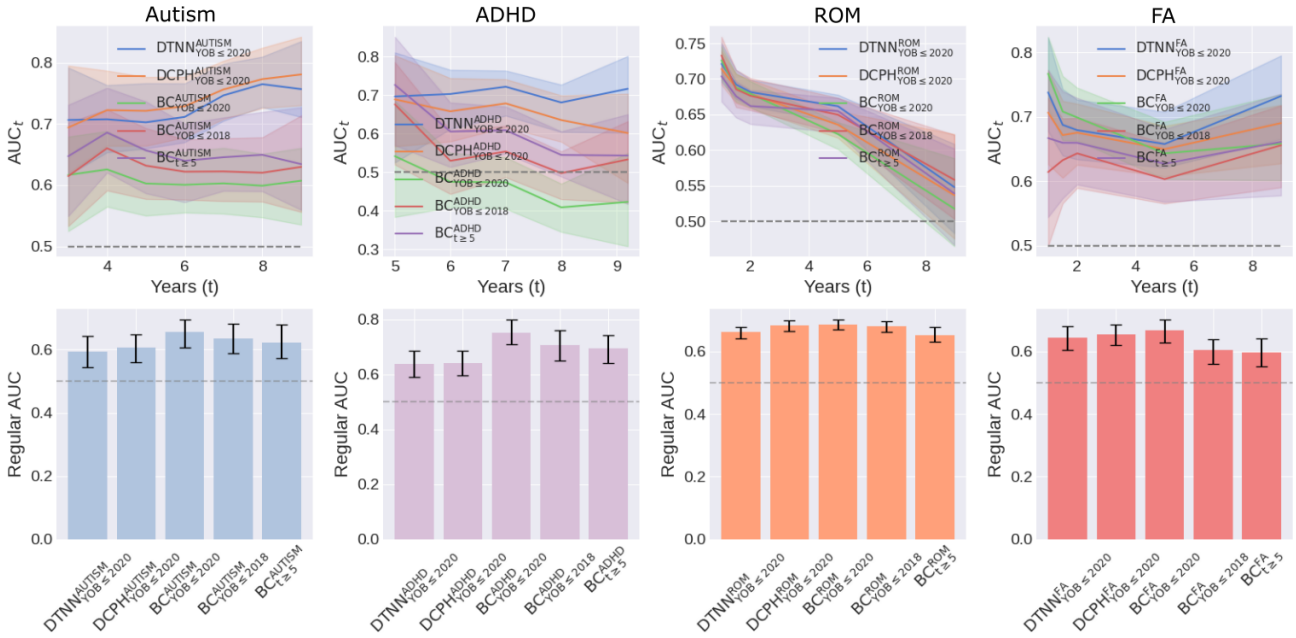
[b]ROM: recurrent otitis media.

[c]FA: food allergy.

[d]N/A: not applicable.

Male-to-female ratios were 3.7 for autism, 2.3 for ADHD, 1.3 for ROM, and 1.5 for FA. All diagnoses were associated with sex (P<.001) and racial status (P<.001). ROM and FA were associated with insurance status (P<.001), but autism and ADHD were not (P=.12 and P=.69, respectively). Private insurance rates were 3178/5201 (61.1%) and 596/916 (65.1%) in the ROM and FA groups, respectively, compared to 316/749 (42.2%) and 288/618 (46.6%) in the autism and ADHD groups, respectively.

The mean age at diagnosis for autism and ADHD was 3.75 years and 6.22 years, respectively, higher than that for ROM and FA, which were 1.57 years and 2.01 years, respectively (Figure 1).



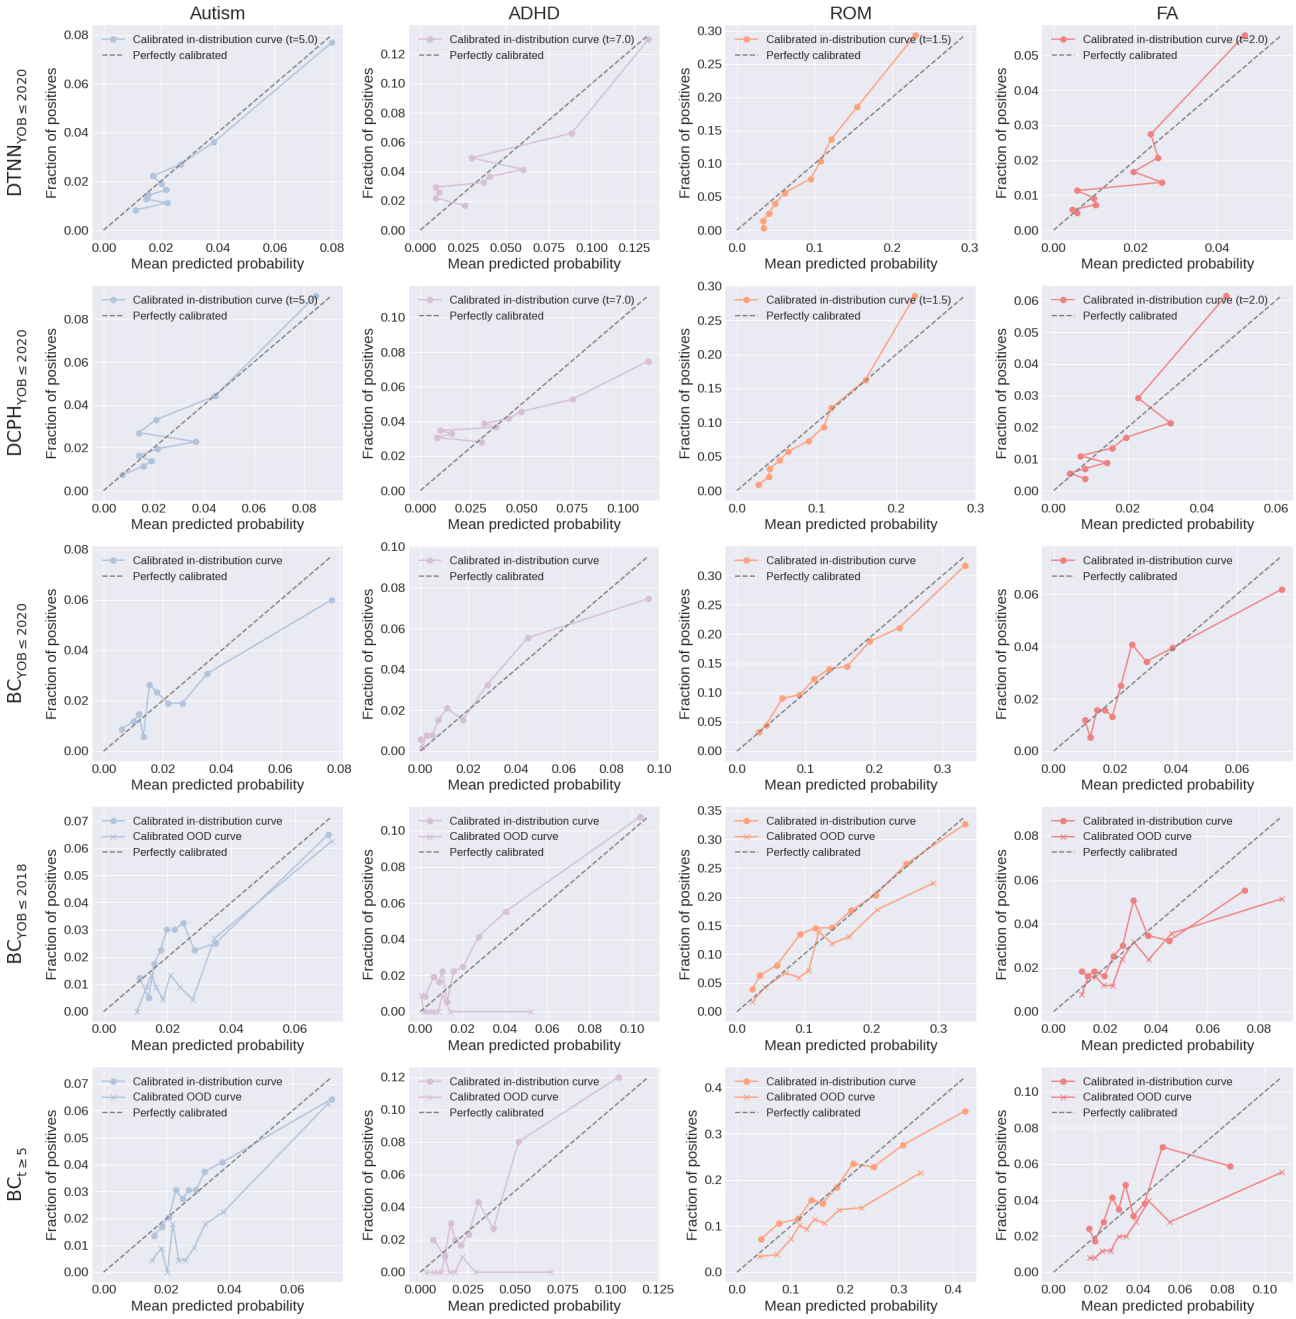
Analysis of Performance Metrics

In general, the TTE models consistently matched or outperformed BC models with higher AUC_t values across all conditions (Figure 3 and Table S6 in Multimedia Appendix 1). At clinically relevant operating time points, the AUC values for $DTNN_{YOB\leq2020}$ and $DCPH_{YOB\leq2020}$ were 0.70 (95% CI 0.66 - 0.77) and 0.72 (95% CI 0.66 - 0.78) at t=5 for autism, 0.72 (95% CI 0.65 - 0.76) and 0.68 (95% CI 0.62 - 0.74) at t=7 for ADHD, 0.72 (95% CI 0.70 - 0.75) and 0.71 (95% CI 0.69 - 0.74) at t=1 for ROM, and 0.74 (95% CI 0.68 - 0.82) and 0.71 (95% CI 0.63 - 0.77) at t=1 for FA, compared to 0.60 (95% CI 0.55 - 0.66), 0.47 (95% CI 0.40 - 0.54), 0.73 (95% CI 0.70 - 0.75), and 0.77 (95% CI 0.71 - 0.82) for $BC_{YOB\leq2020}$, respectively.

Conversely, the regular AUC values for $BC_{YOB\leq2020}$ were consistently higher than those for $DTNN_{YOB\leq2020}$ and $DCPH_{YOB\leq2020}$. Notably, a statistically significant difference (P<.05) was observed in the ADHD prediction task (BCYOB≤2020ADHD: AUC 0.75, 95% CI 0.71 - 0.80; DTNNYOB≤2020ADHD: AUC 0.64, 95% CI 0.59 - 0.69; DCPHYOB≤2020ADHD: AUC 0.64, 95% CI 0.60 - 0.69). With filtering, $BC_{YOB\leq2020}$ and $BC_{t\geq5}$ exhibited decreased regular AUC, with the latter experiencing a larger decline.

XSL•FO
RenderX

Figure 3. Comparison of AUC_t (solid lines) and regular AUC (bar graphs). ADHD: attention-deficit/hyperactivity disorder; AUC: area under the receiving operating characteristic curve; AUC_t: time-varying area under the receiving operating characteristic curve; BC: binary classification; DCPH: deep Cox proportional hazard; DTNN: discrete-time neural network; FA: food allergy; ROM: recurrent otitis media; t: t denotes follow-up length; YOB: year-of-birth.

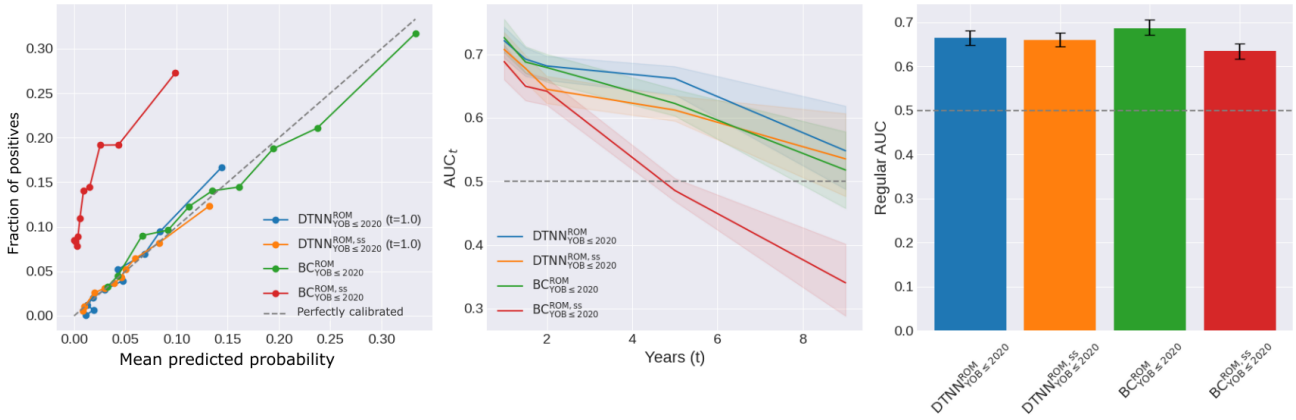


The regular AP and AP_t exhibited similar trends as described above, with higher AP_t but lower regular AP for TTE models (Figure S3 and Table S7 in Multimedia Appendix 1). However, direct comparison and interpretation are difficult due to the variation in test prevalence across different datasets. The concordance index, comparing ordered predicted event probabilities with observed event times, further demonstrates that the TTE models consistently performed as well as or better than the BC models (Table S8 in Multimedia Appendix 1). In particular, $DTNN_{YOB\leq2020}$ and $DCPH_{YOB\leq2020}$ achieved 0.656 and 0.667 for autism, 0.682 and 0.657 for ADHD, as compared to 0.629 and 0.558 for $BC_{YOB\leq2020}$, respectively.

The predicted probabilities for all models closely align with the observed estimates for in-distribution years, demonstrating overall good calibration, while OOD curves (ie, years 2019 and 2020) for $BC_{YOB\leq2018}$ and $BC_{t\geq5}$ show poor calibration (Figure 4).

XSL•FO
RenderX

Figure 4. Calibration analysis. The predicted probabilities were compared with observed event rates across different probability bins, using Kaplan-Meier estimates for the TTE models and true binary outcomes for the BC models. OOD curves (ie, years 2019 and 2020) were also added for $BC_{YOB\leq2018}$ and $BC_{t\geq5}$. ADHD: attention-deficit/hyperactivity disorder; BC: binary classification; DCPH: deep Cox proportional hazard; DTNN: discrete-time neural network; FA: food allergy; OOD: out-of-distribution; ROM: recurrent otitis media; t: t denotes follow-up length; TTE: time-to-event.



Semisynthetic Censoring Experiment Results

The DTNNYOB≤2020ROM, ss performance remained comparable to DTNNYOB≤2020ROM and BCYOB≤2020ROM, exhibited good calibration, AUC_t and regular AUC values. However, BCYOB≤2020ROM, ss displayed worse calibration due to underprediction, and had lower AUC_t and regular AUC values (Figure 5). Note that comparing performances beyond 1.2 years would be unfair, as those observed times were not available for model learning during training in the semisynthetic setup.

XSL•FO
RenderX

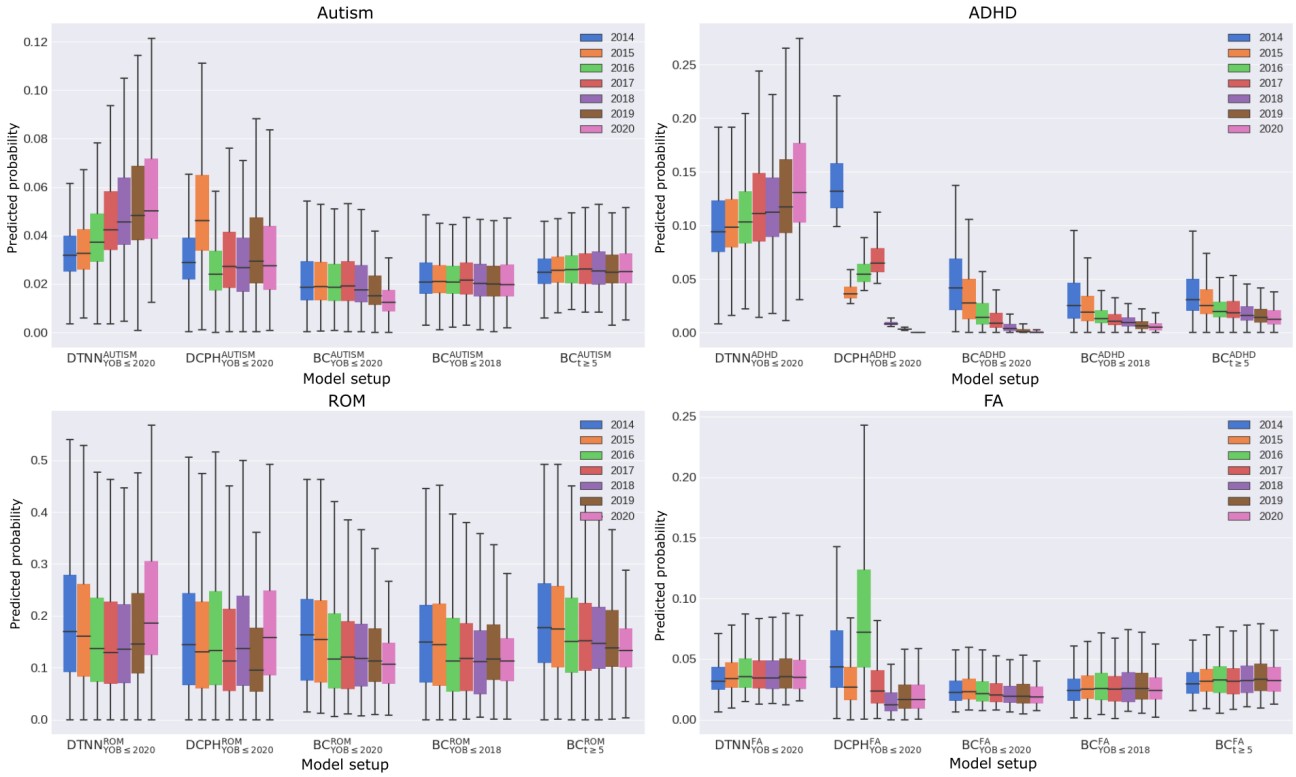


Figure 5. Comparison of performance metrics evaluated on the original test set between BC and DTNN models trained on original and semisynthetic ROM train datasets. AUC: area under the receiving operating characteristic curve; AUC_t: time-varying area under the receiving operating characteristic curve; BC: binary classification; DTNN: discrete-time neural network; ROM: recurrent otitis media; YOB: year-of-birth.

Subgroup Analyses

Probabilities predicted by $BC_{YOB\leq2020}$ decreased over time across all conditions. This trend was less pronounced for $BC_{YOB\leq2018}$ and $BC_{t\geq5}$ (Figure 6). In contrast, the probabilities predicted by $DTNN_{YOB\leq2020}$ for autism and ADHD showed a consistent yearly increase. For ROM, predicted probabilities declined from 2014 to 2017, then increased from 2018 onward. For FA, predicted probabilities modestly increased from 2014 to 2015, then stabilized at approximately 3.4% - 3.5% in subsequent years. The results for $DCPH_{YOB\leq2020}$ were heterogeneous.

Figure 6. Grouped analysis of predicted probability distributions by year-of-birth. ADHD: attention-deficit/hyperactivity disorder; BC: binary classification; DCPH: deep Cox proportional hazard; DTNN: discrete-time neural network; FA: food allergy; ROM: recurrent otitis media; t: t denotes follow-up length; YOB: year-of-birth.

We expanded our YOB subgroup analysis to include 2019 and 2020 to evaluate BC model behaviours during these OOD years (Figure 6). $BC_{t\geq5}$ exhibited a modest decrease in predicted probabilities across all the conditions, more pronounced in 2020 than in 2019, while $BC_{YOB\leq2018}$ remained relatively stable.

There was a positive correlation observed between the predicted probability and follow-up length in all BC models, albeit to a lesser extent in $BC_{YOB\leq2020}$ and $BC_{t\geq5}$ (Figure 7). A similar trend was apparent in the analysis of the concordance between predicted nonevent probabilities with the observed censoring times (Table 2), with BCYOB≤2020ADHD showing the highest concordance index of 0.734. BC predictions appeared to align with the test prevalence (Figures S7-S9 in Multimedia Appendix 1), whereas DTNN and DCPH predictions did not (Figures S5 nd S6 in Multimedia Appendix 1).

XSL•FO
RenderX

Figure 7. Grouped analysis of predicted probability distributions by follow-up length in years. ADHD: attention-deficit/hyperactivity disorder; BC: binary classification; DCPH: deep Cox proportional hazard; DTNN: discrete-time neural network; FA: food allergy; ROM: recurrent otitis media; t: t denotes follow-up length; YOB: year-of-birth.

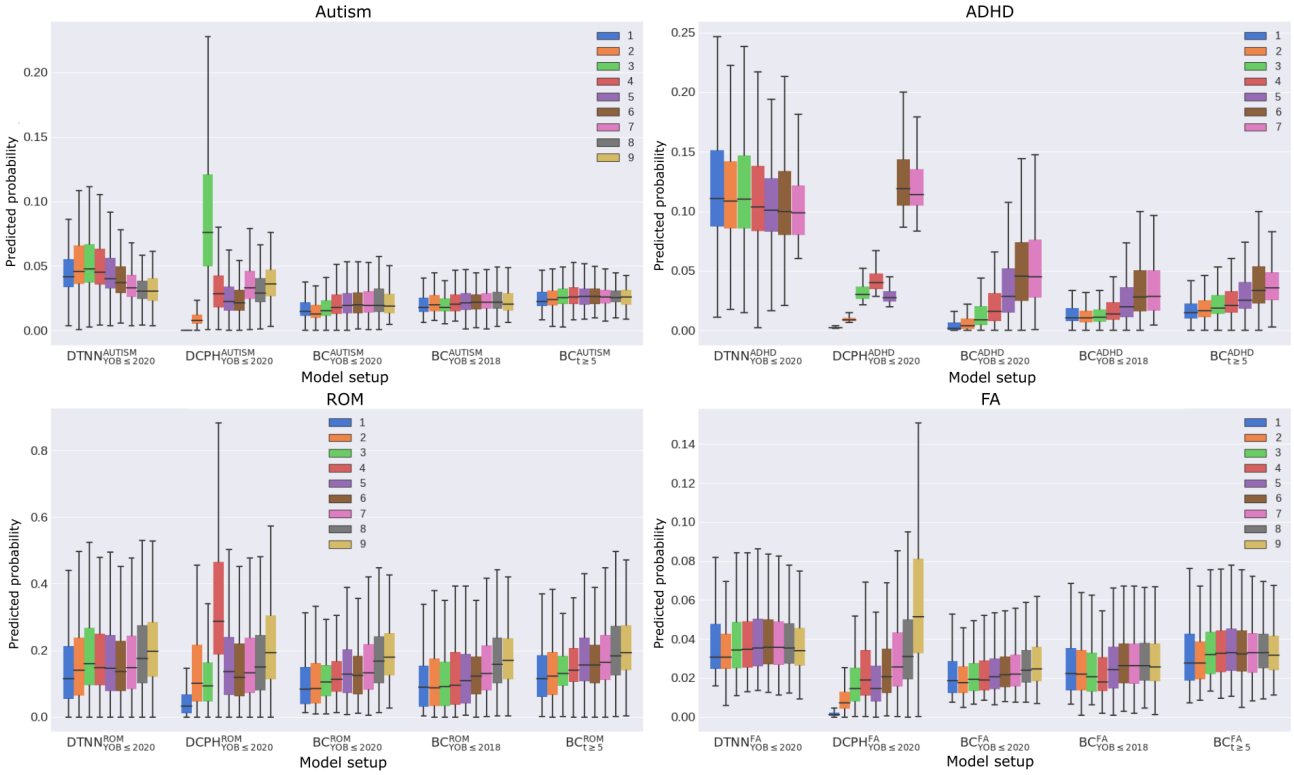

Table . Concordance index by comparing ordered predicted nonevent probabilities of BC[a] models with observed censoring times.

	Autism	ADHD[b]	ROM[c]	FA[d]
$BC_{YOB\leq2020}$[e]	0.581	0.734	0.605	0.558
$BC_{YOB\leq2018}$	0.533	0.625	0.605	0.535
$BC_{t\geq5}$[f]	0.5	0.605	0.576	0.491

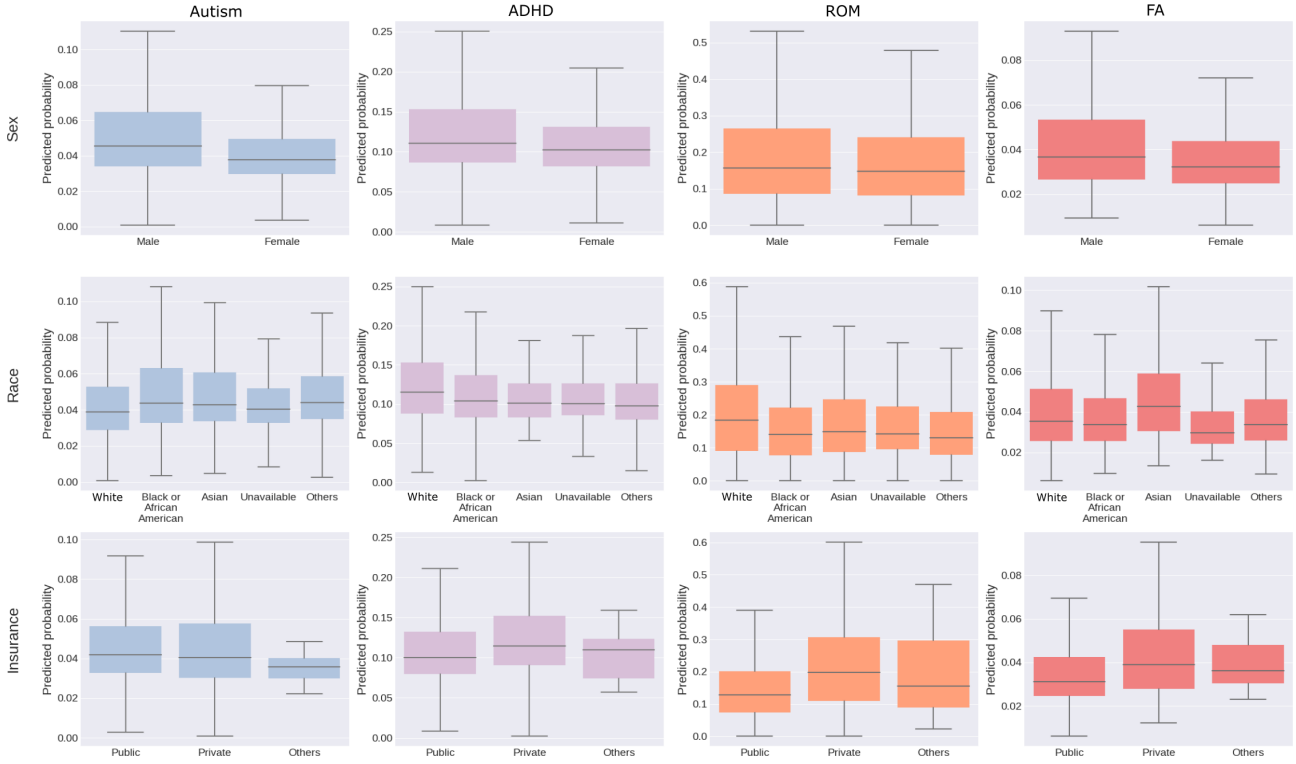
[a]BC: binary classification.

[b]ADHD: attention-deficit/hyperactivity disorder.

[c]ROM: recurrent otitis media.

[d]FA: food allergy.

[e]YOB: year-of-birth.



[f]t denotes follow-up length.

In all 4 conditions, DTNN predicted a greater likelihood of diagnosis for males. Among the racial groups, Asians had the highest predicted probability for autism and FA, while White individuals displayed the highest predicted probability for ADHD and ROM. Regarding insurance status, individuals with private insurance were more likely to be diagnosed with ROM and FA; however, findings for autism and ADHD were equivocal (Figure 8).

The individual results of the subgroup analysis by demographics for each model setup are available in Figures S10-S12 in Multimedia Appendix 1.

Discussion

Principal Findings

Our study contributes to the understanding of how right-censoring influences model performance and predicted probabilities over time using EHR data. We highlight inherent limitations of BC in such contexts, even with filtering strategies. Furthermore, our results reinforce the potential of TTE approaches, particularly DTNN, in mitigating bias from the censoring distribution, leading to superior discrimination, calibration, and clinical prevalence prediction.

Principal Results

First, we demonstrated that BC cannot disentangle the probability of diagnosis and early censoring, even with filtering. The BC models displayed poor AUC_t performance, despite achieving high regular AUC scores (Figure 3 and Table S6 in Multimedia Appendix 1). This discrepancy arises because AUC_t calculation excludes individuals censored before prediction time *t* whereas regular AUC calculation does not. Thus, the AUC is artificially inflated by "correctly" predicting diagnosed individuals in this subgroup of individuals who were censored early as negative cases. With filtering, $BC_{YOB\leq2018}$ and $BC_{t\geq5}$ benefitted less, resulting in lower regular AUC scores because more true cases with later diagnoses were excluded.

Spurious positive correlations between the predicted probability and follow-up length imply that BC models were unduly benefitting from early censoring (Figure 7), along with increased concordance between predicted nonevent probabilities and observed censoring times (Table 2). Similarly, these differences were less prominent in $BC_{YOB\leq2020}$ and even less in $BC_{t\geq5}$, but not completely absent.

This contrast was exacerbated in long-horizon prediction tasks such as ADHD, with the degree of variation corresponding with the tail end of the diagnosis age distributions (Figure 1). ADHD showed the highest proportion of later diagnoses, followed by autism and FA, and the lowest in ROM. These results corroborate observations associating censoring with biased improved outcomes, where hazard ratios fall below 1 compared to complete follow-up and correlate inversely with the proportion of censored cases [27].

Second, we found that TTE models outperformed BC models on all datasets. In diagnoses with longer time horizons, heavy right-censoring leads to many individuals having unknown status, while shorter prediction time horizons tend to have better follow-up. $DTNN_{YOB\leq2020}$ and $DCPH_{YOB\leq2020}$ achieved comparable or higher AUC_t scores in predicting ROM and FA (Figure 3 and Table S6 in Multimedia Appendix 1), suggesting that TTE models matched or surpassed BC models on datasets with less censoring. This superiority is particularly pronounced in autism and ADHD datasets, which experience heavier censoring. The main insight is that TTE models are well-suited to predict clinical outcomes, especially those with prolonged time horizons.

In our semisynthetic ROM censoring experiment, we reproduced the limitations of BC as evidenced by the deterioration in AUC_t and regular AUC performance of BCYOB≤2020ROM, ss when evaluated on the original dataset (Figure 5 and Table S6 in Multimedia Appendix 1). This result supports our earlier claim that the BC models were underpredicting diagnosed individuals with early censoring. We also demonstrated that

XSL•FO
RenderX

DTNNYOB≤2020ROM, ss remained well-calibrated and maintained comparable AUC_t performance as DTNNYOB≤2020ROM (Figure 5), demonstrating the applicability of our TTE approach in situations with partially observed information.

We also examined the impact of BC filtering strategies on OOD years. Specifically, we extended the evaluation to include 2019 and 2020 (Figure 6). Notably, a discernible decline in predicted probabilities was observed for $BC_{t\geq5}$ across all clinical conditions, with a slightly more pronounced drop in 2020 compared to 2019. In contrast, predicted probabilities by $BC_{YOB\leq2018}$ remained relatively stable during the same OOD years. This suggests that the inclusion of older individuals (ie, born before 2018) with shorter follow-up (ie, <5 years) makes predictions more stable on OOD years. However, including these individuals results in declining predicted probabilities due to early censoring on in-distribution years, as we have previously demonstrated. Moreover, $BC_{YOB\leq2018}$ and $BC_{t\geq5}$ showed poor calibration for all diagnoses on OOD years (Figure 4), rendering them unsuitable for clinical deployment.

Temporal and demographics trends were poorly represented in BC and DCPH. The probability of diagnosis should remain stable or increase over time due to improved awareness and tools unless specific interventions are implemented. However, $BC_{YOB\leq2020}$ exhibited declining predicted probability for all diagnoses because the models assigned lower probability scores to individuals born later, despite the absence of temporal information during learning. Inadvertently, BC predictions follow test prevalence, which also contributes to its poor performance in the demographics subgroup analysis.

The unclear patterns in DCPH models likely result from a violation of the proportional hazards assumption, which is common in practice. For example, varying severity levels in autism and ADHD diagnoses can lead to nonproportionality, where low-likelihood groups initially exhibit delays in hazard before catching up with the high-likelihood groups [28]. By assuming constant hazard rates over time, DCPH models may not fully leverage the complexity of likelihood representations and time-dependent covariate impacts. While excelling in providing generalized representations at a population level (Figure 3 and Figure S4 in Multimedia Appendix 1), our findings suggest inconsistent or inaccurate outcomes in subgroup analyses (Figures 6 and 7, and Figures S10-S12 in Multimedia Appendix 1). DTNN, however, does not assume proportional hazards, enabling better capture of time-dependent covariate influences on survival.

In contrast to the BC and DCPH models, the diagnosis probabilities predicted by the DTNN models (Figures 6 and 8) are in keeping with actual prevalence, reflecting both temporal and demographic trends. For example, autism prevalence increased from 2.24% in 2014 to 2.79% in 2019 [29], with higher rates among males and Black individuals [30]. Our demographics analysis for ADHD also concurs with trends toward increased prevalence in males and White individuals [31]. Note that the reported prevalence in DUHS may exceed nationwide estimates, given its status as a regional hub for neurodevelopmental diagnosis.

Interestingly, for ROM, our DTNN models appear consistent with distinctive temporal patterns including (1) declining prevalence from 2014 to 2017 associated with the availability of postpneumococcal conjugate vaccines [32] and (2) increasing prevalence from 2018 to 2020 amid the COVID-19 pandemic [33]. The DTNN models also accurately predict increased likelihood associated with male sex, White race, lower socioeconomic status [32,34], and private insurance, which reflect health care use disparities [35,36].

Our models suggest stable FA prevalence (~3.4% - 3.5%), adding to mixed data that challenge whether rates have increased (range: 4.8% - 8%) [37]. This discrepancy may arise due to difficulties in estimating true prevalence [38,39] or our stricter diagnostic criteria (*ICD-10* code+IgE-based laboratory test) compared to other studies using surrogate laboratory tests or self-report, which tend to overestimate rates of clinical disease [40-42]. Demographically, our findings corroborate higher FA prevalence among males [43] and Asian and non-Hispanic Black individuals compared to non-Hispanic White individuals [44]. Additionally, our models corroborated the lower FA prevalence reported among children with public insurance [45].

Our findings suggest that TTE models, particularly the DTNN, should be preferred in clinical settings dealing with right censored outcomes. First, the DTNN models outperformed BC models, yielding clinically meaningful discriminatory performance with $AUC_t\geq0.7$ at early ages across all 4 clinical conditions, supporting earlier diagnoses and timely interventions. Second, the DTNN approach addresses label bias that may lead to underprediction, as evidenced by its superior discrimination, calibration and ability to reflect clinical prevalence. While the modelling approach is arguably more challenging, it avoids the need for complex and often opaque filtering procedures.

Limitations

Our study has important limitations. First, it is confined to data from DUHS only, which primarily serves a population with a high representation of Black and White individuals. This demographic makeup may limit the generalizability of the results to other health systems with different patient demographics. Second, computable phenotypes are imperfect, as the identification and timing of diagnosis can vary in practice. Third, not all information, including vital signs and laboratory values, was used during the training process. Fourth, we do not include every possible filtering strategy and competing model, which may contribute to the breadth of our findings. Fifth, sex bias may also influence diagnosis trends, with males being more likely to be diagnosed with autism in practice. To the extent that sex affects the distribution of event times, the discrete-time approach can help mitigate this bias, because it does not conflate diagnosis probability with timing unlike BC and DCPH approaches. However, to the extent that sex also influences the probability of diagnosis at any given point, this is not a bias that we can overcome by choice of model alone and will require efforts to change assessment practices. Finally, the constrained size of our dataset prevents us from conducting finer subgroup

XSL•FO
RenderX

analyses. For example, we could not explore temporal trends among different demographics, such as instances where autism rates among Black children surpassed those among White children [46]. To address these limitations, we recommend incorporating data from diverse health systems, including a broader range of clinically relevant EHR data, exploring additional filtering strategies, and expanding dataset size to enable more detailed subgroup analyses.

Conclusion

Machine learning practitioners should acknowledge the inherent limitations of BC on right-censored outcomes and consider TTE approaches, particularly DTNN, in the clinical context. Our study paves the way for future research to identify and optimize models to improve patient outcomes.

Abstract

Background: Spirometry can be performed in an office setting or remotely using portable spirometers. Although basic spirometry is used for diagnosis of obstructive lung disease, clinically relevant information such as restriction, hyperinflation, and air trapping require additional testing, such as body plethysmography, which is not as readily available. We hypothesize that spirometry data contains information that can allow estimation of static lung volumes in certain circumstances by leveraging machine learning techniques.

Objective: The aim of the study was to develop artificial intelligence-based algorithms for estimating lung volumes and capacities using spirometry measures.

Methods: This study obtained spirometry and lung volume measurements from the Mayo Clinic pulmonary function test database for patient visits between February 19, 2001, and December 16, 2022. Preprocessing was performed, and various machine learning algorithms were applied, including a generalized linear model with regularization, random forests, extremely randomized trees, gradient-boosted trees, and XGBoost for both classification and regression cohorts.

Results: A total of 121,498 pulmonary function tests were used in this study, with 85,017 allotted for exploratory data analysis and model development (ie, training dataset) and 36,481 tests reserved for model evaluation (ie, testing dataset). The median age of the cohort was 64.7 years (IQR 18 - 119.6), with a balanced distribution between genders, consisting 48.2% (n=58,607) female and 51.8% (n=62,889) male patients. The classification models showed a robust performance overall, with relatively low root mean square error and mean absolute error values observed across all predicted lung volumes. Across all lung volume categories, the models demonstrated strong discriminatory capacity, as indicated by the high area under the receiver operating characteristic curve values ranging from 0.85 to 0.99 in the training set and 0.81 to 0.98 in the testing set.

Conclusions: Overall, the models demonstrate robust performance across lung volume measurements, underscoring their potential utility in clinical practice for accurate diagnosis and prognosis of respiratory conditions, particularly in settings where access to body plethysmography or other lung volume measurement modalities is limited.

Introduction

Pulmonary function testing (PFT) provides physiological measurements of the respiratory system across multiple dimensions, typically classified into (1) spirometry, which measures air flow, lung volumes, and capacities during a expiratory forced vital capacity (FVC) maneuver; (2) static lung volumes; and (3) gas exchange parameters such as the diffusing capacity for carbon monoxide and oxygen saturations [1]. PFTs are critical for the diagnosis and prognostication of respiratory disorders, and provide a noninvasive method for measuring and monitoring the degree of respiratory impairment [2]. They are recommended for the initial evaluation of patients with chronic dyspnea and other respiratory symptoms, as well as for individuals at risk of respiratory complications due to transplant or surgery [3,4].

XSL•FO
RenderX

Basic spirometry remains the most widely used component of PFT, largely due to its size and portability, allowing it to be performed in clinic office settings or remotely at home with adequate training. However, spirometry, by definition is an expiratory FVC maneuver that focuses on assessing airflow limitations and does not directly measure static lung volumes, which can be integral to understanding many respiratory conditions [4]. Accurate determination of static lung volumes traditionally necessitates more complex and resource-intensive techniques such as body plethysmography or gas dilution methods, with body plethysmography serving as the current gold standard [3,5,6]. However, these methods, while precise, may not always be readily accessible, cost-effective, or suitable for routine clinical practice outside a specialized pulmonary function laboratory.

Advancements in artificial intelligence (AI) techniques have introduced new avenues in health care, offering the potential to derive comprehensive insights from existing data, including patterns not easily recognizable through human interpretation or standard statistical modeling. A prior study by Beverin et al [7] examined the prediction of total lung capacity from spirometry using three tree-based machine learning (ML) models, achieving a mean squared error of 560.1 mL. They further developed models to classify restrictive ventilatory impairment, achieving a sensitivity and specificity of 83% and 92%, respectively. However, they did not explore prediction of the complete lung volume assessments. Predicting functional residual capacity status, for example, could facilitate the prevention of atelectasis during anesthesia [8]. Another study by Evankovich et al [9] developed a regression model in patients with chronic obstructive pulmonary disease (COPD) to predict residual volume and its elevation status, achieving an area under the receiver operating characteristic curve (ROC) of 0.95 for predicting residual volume above 175%. However, these models lack applicability beyond the COPD cohort [9]. Given this context, we hypothesized that ML models could predict static lung volumes using spirometry alone across a diverse cohort of lung conditions. Such an approach could reduce the need for identifying those who would benefit most from formal lung volume assessments. In this study, we applied ML approaches to develop and validate an algorithm for estimating lung volumes and capacities from standard spirometry. We further examined the model performance among subsets of physiologic derangements such as obstructive and restrictive ventilatory disorders.

Methods

Cohort Selection

This study was approved by the Institutional Review Board (20‐009821) with a waiver of consent. The dataset curated for this study was obtained from the Mayo Clinic PFT database, which houses PFT data from two distinct US regions (Midwest and Southeast), with records from February 19, 2001, to December 16, 2022. The PFTs performed on the same day—with paired spirometry and lung volume data, without the use of methacholine or a bronchodilator—were identified. Individuals under 18 years of age and patients who opted out of authorizing their data for research use were excluded from the analysis. All lung volume measurements were performed using body plethysmography. For models trained to classify normal versus abnormal lung volume measures, an additional requirement was applied to ensure nonmissing demographics within the boundaries of the Global Lung Initiative GLI2021 lung volume estimation equations [10]. If an individual underwent multiple PFTs, only their most recent PFT measurement comprising both lung volumes and spirometry was used. The following lung volume measures were selected for prediction: expiratory reserve volume (ERV), functional residual capacity (FRC), residual volume (RV), total lung capacity (TLC), the ratio of RV to TLC as a percentage (RV/TLC), and vital capacity (VC).

Preprocessing

Following the initial database query, the dataset was augmented with reference lung function measures for both spirometry and lung volume measures, including the lower limit of normal function (LLN), the upper limit of normal function (ULN), and the expected volume. These values were generated using a custom package built according to the Global Lung Initiative pulmonary function testing reference equation publications [1,11,12]. The LLN and ULN values were used to assign “normal” (within the LLN/ULN range) or “abnormal” (below LLN or above ULN) status to reformulate the lung volume regression problem into a classification task.

Both the regression and classification data sets were split into independent training and testing subsets using a randomized 70/30 split before any downstream exploratory analysis or model development. Features provided to the models included forced expiratory volume in the first second of exhalation (FEV1), forced vital capacity (FVC), the ratio of FEV1 and FVC (FEV1/FVC), peak expiratory flow, estimated maximum vital capacity, age, gender, height, weight, and race (White, African American, Northeast Asian, Southeast Asian, and Other).

Model Selection and Evaluation

A randomized grid search was performed using various ML algorithms, including a generalized linear model with regularization, distributed random forests, extremely randomized trees, gradient-boosted trees, and XGBoost. Models were tuned using appropriate parameter grids via five-fold cross-validation on the training dataset to provide estimates of performance summarized using applicable metrics, including root mean squared error (RMSE) for regression and area under the receiver operating characteristic curve (ROC-AUC) for classification [13]. Final tuning parameters were selected from the candidate model with the highest cross-validation performance (lowest RMSE for regression, highest ROC-AUC for classification), which was ranked highest among all explored configurations. The model was then refitted to the full training data set using the chosen hyperparameters before evaluation on the testing dataset (Multimedia Appendix 1). For the classification models, the probability threshold was selected to maximize the Youden index on the training data set.

The regression model performance was evaluated visually using prediction scatter plots and summary metrics, including RMSE,

XSL•FO
RenderX

mean absolute error (MAE), mean signed difference, mean percentage error (MPE), mean absolute percentage error (MAPE), and the correlation-based coefficient of determination [14]. The classification model was evaluated with the area under the receiver-operating-characteristic curve (AUC), accuracy , sensitivity (SENS), specificity, positive predictive value, negative predictive value (NPV), precision, recall, positive likelihood ratio (LRT+), negative likelihood ratio (LRT-), odds ratio, and F1-score. All modeling was performed using the H2O AutoML cluster (version 3.44.0.3) [15]. Further details regarding the grid search process, parameter tuning, and model implementation are available in the H2O official documentation [15] (Multimedia Appendix 2).

In the cohort summary tables, categorical data were displayed as counts and percentages, while continuous data were displayed as medians and ranges. Standardized mean differences were computed to identify significant differences in variables between the training and testing datasets, with insignificant differences defined as a value <0.1. The regression and classification models were applied to the specific PFT patterns (normal, obstructed, restricted, and mixed pattern) defined by the American Thoracic Society (ATS) [10]. All analyses were performed using R software (version 4.2.2; R Foundation for Statistical Computing) on a Google Cloud Platform virtual machine.

Ethical Considerations

This study was approved by the Mayo Clinic Institutional Review board (22-009471) and was determined to be exempt (45 CFR 46.104d, Category 4). All data was deidentified for this study, and no compensation was provided to the participants

Results

A total of 121,498 PFTs were used in this study, with 85,017 allocated for exploratory data analysis and model development and 36,481 tests reserved for model evaluation. The median age across the cohort was 64.7 years (IQR 18 - 119.6), with a nearly balanced gender distribution between genders, with 48.2% (n=58,607) female patients and 51.8% (n=62,889) male patients. The cohort was predominantly White (n= 114,388, 94.1%), followed by African American patients (n=4,656, 3.8%). Of particular importance, the distribution of baseline PFT measures—both spirometry and lung volumes—showed no differences between the training and testing datasets. Standardized mean differences, indicating the degree of difference between the training and testing sets, were minimal across all variables, suggesting a well-balanced model development and testing cohorts. A complete breakdown is provided in Table 1.

Multimedia Appendix 3 stratifies the same cohort according to the ATS classification criteria for pulmonary function patterns (ie, normal, obstructive, restrictive, and mixed pattern). This stratification highlights differences in demographics and pulmonary function measures between individuals with normal, obstructive, restrictive, or mixed patterns assigned using spirometry. Predictably, spirometry measures—including FEV1, FVC, and the FEV1/FVC ratio—significantly differed between groups (*P* values<.001), as did all phenotype-related parameters presented in the table.

Lung Volume Regression

The final models chosen for evaluation were selected based on the lowest RMSE values and varied minimally in type across the lung volumes of interest. XGBoost models were identified as the best approach for predicting all lung volumes except TLC, for which traditional gradient-boosted trees showed superior performance.

Model metrics were similar between the training and testing cohorts, suggesting a reasonable trade-off between overfitting and underfitting during model training (Table 2). Findings showed a strong performance overall, with relatively low RMSE and MAE values observed across all predicted lung volumes. MPE showed a negative skew across all lung volumes. However, quantile-quantile plot analyses showed that predicted values closely followed a theoretical normal distribution, with slight underprediction and overprediction of high and low values at the extremes, respectively. Paired with mean signed differences of zero—also known as the mean bias error—these evaluations suggest no global bias in the direction of model predictions. Instead, these skewed MPE values were the result of extreme values at the tails of the distribution. A complete breakdown of model performance metrics is presented in Table 2, with complementary prediction scatter plots in Figure 1. Further subgroup analysis with different ATS patterns showed relatively similar results overall and across all categories in Multimedia Appendix 2).

Lung Volume Classification

Due to limitations in demographic information (ie, age and race) required for the calculation of LLN and ULN boundaries, a total of 114,377 PFTs from the regression cohort were successfully recharacterized for the development of classification models, with 34,314 PFTs reserved for model evaluation. A comparison of demographics, spirometry, and lung volumes between the training and testing data sets can be seen in Multimedia Appendices 5 and 6. These tables mirror the factors presented in Table 1, except for the lung volume classes (normal vs abnormal), which are unique to this subset.

Similar to the regression tasks, the final classification models selected for downstream evaluation varied minimally in type across lung volumes and were selected based on the largest ROC-AUC values. Traditional gradient-boosted trees ranked best for classifying lung volume status for FRC and vital capacity. XGBoost models ranked at the top for all other lung volume classifications. Across all lung volume categories, the models demonstrated strong discriminatory capacity, as indicated by high AUC values ranging from 0.85 to 0.99 in the training dataset and 0.81 to 0.98 in the testing dataset. High accuracy scores, ranging from 0.74 to 0.93, illustrate the ability of each model to correctly classify instances overall, with sensitivity scores ranging from 0.73 to 0.93 in the testing data set, indicating the effectiveness in identifying positive cases (ie, lung volume measurements outside the expected normal range). The high NPVs (ranging from 0.84 to 0.94) highlight each model's ability to correctly identify normal lung volumes. The greater variation in positive predictive value across the lung volume classes (ranging from 0.35 - 0.94) suggests that some models may struggle to identify positive cases correctly, relative to the larger population of normal test findings. Classification performance metrics can be found in Table 3, with complementary ROC curves in Figure 2.

Figure 2. Classification receiver operating characteristic (ROC) curves.

When stratified by PFT patterns, unique strengths, and weaknesses were observed across subgroups (Multimedia Appendix 7). These variations can be attributed to the limitations of the training data, feature space, and models, while others were driven by the rarity of certain lung volume abnormalities in specific spirometry-defined patterns. For instance, in classifying ERV status—arguably the most challenging lung volume explored in this study—the model showed consistently high NPVs across all spirometry pattern types, highlighting general confidence in predicting normal lung volume status. However, it achieved notably better sensitivity in the "restriction" and "mixed pattern" subsets (0.91 and 0.75). Comparing these sensitivities and other metrics to those in the "normal" and "obstruction" subgroups, the model seems to struggle to detect positive cases in patients with normal or obstructive spirometry findings.

Discussion

The development of ML models to predict lung volume status (normal vs abnormal findings) from spirometry in over 110,000 patients has yielded highly encouraging results, displaying remarkable discriminatory power with high AUC values (0.81 - 0.95) across measured lung volumes. Estimates of FRC, TLC, RV, and the RV/TLC ratio status show strong sensitivity and specificity. These metrics remain largely consistent across spirometry-defined pattern subgroups, with a few exceptions that can generally be attributed to the rarity of abnormal lung volume measures in certain spirometry patterns. The ability to predict lung volume measures without having to perform extensive testing represents a promising innovation for improving the diagnosis and management of dyspnea and chronic respiratory diseases, particularly in the primary care setting [16]. The strong predictive performance of lung volume measurement underscores the potential of these models as a transformative tool in respiratory medicine, offering substantial clinical implications and opportunities for enhancing patient care.

The performance of the regression models showed a high correlation between the training and testing datasets, suggesting that the models were able to effectively capture the relationship between spirometry-derived features and measured lung volumes and capacities derived from body plethysmography. The effectiveness of the models was evident in their ability to closely approximate lung volumes with minimal deviation from true values on average. The RMSE and MAE values are low relative to their respective lung volume ranges. For instance, the median TLC measure in the cohort was 5.5 L, with the model attaining an MAE of 0.43 L and an MAPE of 7.92%. The ability to accurately estimate the RV/TLC ratio further highlights the potential of these models in capturing the dynamic interplay between these volumes, which is particularly relevant in differentiating between common lung conditions such as COPD, asthma, and restrictive lung diseases [17-20]. The high R-squared values observed for TLC (0.87 in the training set and 0.85 in the testing set) underscore the model's capacity to capture a significant portion of the variance in TLC measurement. Similarly, the robust estimation of RV (R-squared of 0.73 in the training set and 0.71 in the testing set) and FRC (R-squared of 0.78 in the training set and 0.75 in the testing set) further validates model reliability in estimating lung volumes crucial for the evaluation of respiratory function. The model demonstrated a high correlation for vital capacity (R^2=0.98). However, this finding is misleading, as spirometry already provides an accurate estimate of vital capacity, making it trivial

XSL•FO
RenderX

to map to a similar value obtained via body plethysmography, assuming minimal measurement error and consistent effort on the part of the patient when executing breathing maneuvers. A significant change in TLC has been reported to be 10% over one year, whereas this model was able to predict TLC within 7.5% and 550 mL [10]. No significant changes were reported in FRC or RV over time. Considering the performance metrics as a whole, the potential of these models to augment clinical practice is encouraging, with R-squared values exceeding 0.7 for all volumes except ERV, which seems to be the most challenging volume to predict accurately. Estimation of TLC, RV, and their ratio (RV/TLC) is particularly promising, as the accurate estimation of the RV/TLC ratio facilitates the identification of air trapping and hyperinflation, which are key factors in many patients' symptomatology [3,17-20]. Moreover, the reasonable estimation of FRC suggests its potential utility as an indicator for restrictive lung disease diagnosis and treatment. This is particularly important as body plethysmography directly measures only FRC, which is then used to calculate the other variables.

Focusing on the estimation of ERV, the notably high MAPE indicates a relatively subpar overall performance. Given that ERV has the narrowest range of measured values (ie, median 0.8 L, (IQR 0-44) L and a large RMSE of 0.31 relative to the ERV range, this elevated MAPE may be partially influenced by the smaller margin for error [21]. ERV measures the volume of air that an individual can exhale after completing a normal tidal breath. Pairing this with spirometry, individuals with a higher ERV may experience more difficulty with exhalation or exhibit an obstructive pattern on spirometry with a lower FEV1 measure [22,23]. A higher ERV could be a sign of lung hyperinflation, while other factors like obesity, pregnancy, and significant ascites can decrease ERV [22,24]. Lung hyperinflation in obstructed patients, which is defined as elevated FRC, RV, RV/TLC, or occasionally ERV, is highly variable in patients and occurs inconsistently over time [23,25]. This inconsistency, combined with ERV's narrow range, makes it challenging to predict.

Highlighting a more robust model, predictions for the RV/TLC ratio are strong overall, with AUC values ranging from 0.8 to 0.86 across all patterns and 0.91 in the full cohort. Except for normal pattern PFTs, the model consistently achieved sensitivities >0.84, but it struggled to identify positive cases in normal spirometry tests. While spirometry alone does not directly measure RV or TLC, FEV1 and FVC can indirectly reflect changes in lung volumes. In obstructive lung diseases, a reduction in FEV1/FVC ratio combined with an increase in the RV/TLC ratio often indicates air trapping [22-25]. In restrictive diseases, such as pulmonary fibrosis, spirometry may show decreased FVC with a preserved or decreased RV/TLC ratio, suggesting reduced air trapping [22-25]. Given the absence of abnormal FEV1 and FVC values, normal spirometry patterns would not usually suggest the existence of an abnormal RV/TLC ratio, potentially explaining the reduced sensitivity to predicting abnormal RV/TLC in normal spirometry.

A previous study used a CatBoost model to predict the TLC from spirometry, yielding good results [7]. The study reports an MSE of 560.1 mL for TLC and a positive predictive value for reduced TLC of 8% or 67%, depending on the model parameters. However, this study only focused on TLC and did not assess other pulmonary physiologic parameters obtained through lung volume measurements, such as FRC and RV. These parameters are necessary as they are crucial for assessing prognosis in various respiratory diseases [26-30].

Several studies have highlighted the importance of lung volume assessments for the diagnosis and prognosis of respiratory diseases [31]. In routine practice, it can aid in the early detection, diagnosis, and monitoring of respiratory conditions such as COPD, restrictive lung diseases, and neuromuscular disorders affecting respiratory function [10,32,33]. For instance, lung volume measurements (specifically, FRC and TLC) strongly correlate with mortality risk among patients with idiopathic pulmonary fibrosis [27,28,30]. This illustrates that the prediction of lung volumes from traditional spirometry holds substantial promise in clinical scenarios where lung volume measurements cannot be directly performed, such as primary care offices, or health care facilities in rural areas where the equipment for measuring lung volumes is not readily accessible. Another scenario is when a patient is not capable of physically performing lung volume measurements, which could involve physical conditions that prevent them or any number of other limitations that could potentially limit them. Additionally, it may facilitate personalized treatment plans by providing a more nuanced understanding of a patient's lung capacities, as lung volume measurements are typically performed only after a patient is determined to have an abnormal spirometry, unless in specialized centers.

Accurate assessment of lung volumes is pivotal in diagnosing and monitoring various respiratory conditions, including COPD, interstitial lung diseases, neuromuscular disorders, and restrictive lung diseases [4,32]. If lung volume measurements are not performed, vital capacity is often used as a surrogate [34,35]. However, there is a significant error in the application of this method, as a reduced vital capacity can be seen in restrictive lung disease and obstructive lung disease with increased residual volume [36]. A restrictive defect on lung volume measurements has rarely been seen occurring with normal vital capacity, and approximately 58% of the time with low vital capacity measurements [36]. Another study showed that when forced vital capacity >100% predicted in males or >85% predicted in females ruled out a restrictive pattern on lung volumes [37]. The use of direct lung volume prediction models, such as those developed in this study, have a significantly better performance than those used in these prior studies and could reduce the frequency of clinical scenarios where lung volumes are unknown.

The AI model's ability to estimate lung volumes from readily available spirometry data streamlines these diagnostic procedures. A typical spirometry test may take approximately 30 - 45 minutes, while lung volume measurements add another 15 - 30 minutes [38,39]. Replacing or complementing traditional, more resource-intensive lung volume measurement techniques with the AI model's predictions from spirometry data offers cost-effective alternatives. The physician fee for spirometry ranges from $29.62 to $150.68, depending upon the medications used, while measuring lung volumes adds another

XSL•FO
RenderX

$59.98 to the cost [40]. This approach optimizes healthcare resources, reduces patient burden associated with additional tests, and potentially increases the efficiency of healthcare delivery.

The accessibility of spirometry in various healthcare settings, coupled with the estimation of both lung volumes via the developed models, opens avenues for telemedicine applications. Remote monitoring and assessment of spirometry are already being performed and could be facilitated and enhanced with automated decision support systems utilizing models such as those developed in this study [41-43]. Such strategies could enable the continuous monitoring of patients with chronic respiratory conditions that affect lung volumes [41-43]. This aligns with the evolving landscape of telemedicine, emphasizing its potential in respiratory care.

Despite the remarkable performance of the predictive models, certain limitations warrant consideration. Model training and testing relied on datasets with potential biases in demographic variables, including a majority-White population (91%) of older adults (median age 64.7) years. These factors potentially limit the generalizability to diverse populations, although this model was developed with patients of all ages from two distinct regions of the United States (Midwest and Southeast). Further validation across broader demographic groups from various clinical settings is essential to establish widespread applicability and reliability. Moreover, continuous refinement and validation of the models using larger datasets encompassing a broader spectrum of respiratory conditions and disease severities is imperative. This iterative process would enhance model performance while preventing model drift, ensuring its efficacy in diverse clinical scenarios even as standard clinical practices are updated or changed.

In conclusion, the development of AI models for predicting lung volumes from spirometry represents an advancement in pulmonary function assessment. The remarkable sensitivity and specificity offered by the classification models affect a transformative approach to complement traditional lung volume measurement techniques. While the regression models may not attain the same level of performance, the continuous nature of their estimates provides a unique addition to supplement and contextualize binary classifications, potentially elucidating new insights into the remote monitoring of pulmonary function. If integrated into clinical practice, these models hold the promise of revolutionizing respiratory care, enabling more comprehensive and accessible assessments of lung function, and ultimately improving patient outcomes. Overall, the models demonstrate robust performance across lung volume measurements, underscoring their potential utility in clinical practice for accurate diagnosis and prognosis of respiratory conditions in locations where access to body plethysmography or other lung volume measurement modalities is challenging..

Abstract

Background: Language barriers contribute significantly to health care disparities in the United States, where a sizable proportion of patients are exclusively Spanish speakers. In orthopedic surgery, such barriers impact both patients' comprehension of and patients' engagement with available resources. Studies have explored the utility of large language models (LLMs) for medical translation but have yet to robustly evaluate artificial intelligence (AI)–driven translation and simplification of orthopedic materials for Spanish speakers.

Objective: This study used the bilingual evaluation understudy (BLEU) method to assess translation quality and investigated the ability of AI to simplify patient education materials (PEMs) in Spanish.

Methods: PEMs (n=78) from the American Academy of Orthopaedic Surgery were translated from English to Spanish, using 2 LLMs (GPT-4 and Google Translate). The BLEU methodology was applied to compare AI translations with professionally human-translated PEMs. The Friedman test and Dunn multiple comparisons test were used to statistically quantify differences in translation quality. A readability analysis and feature analysis were subsequently performed to evaluate text simplification success and the impact of English text features on BLEU scores. The capability of an LLM to simplify medical language written in Spanish was also assessed.

Results: As measured by BLEU scores, GPT-4 showed moderate success in translating PEMs into Spanish but was less successful than Google Translate. Simplified PEMs demonstrated improved readability when compared to original versions (P<.001) but were unable to reach the targeted grade level for simplification. The feature analysis revealed that the total number of syllables and average number of syllables per sentence had the highest impact on BLEU scores. GPT-4 was able to significantly reduce the complexity of medical text written in Spanish (P<.001).

Conclusions: Although Google Translate outperformed GPT-4 in translation accuracy, LLMs, such as GPT-4, may provide significant utility in translating medical texts into Spanish and simplifying such texts. We recommend considering a dual approach—using Google Translate for translation and GPT-4 for simplification—to improve medical information accessibility and orthopedic surgery education among Spanish-speaking patients.

large language models; LLM; patient education; translation; bilingual evaluation understudy; GPT-4; Google Translate

Introduction

It has been well documented that racial and ethnic minority patient groups in the United States endure substantial limitations in patient care [1]. Specifically, significant disparities in health care outcomes between White populations and Hispanic populations persist in several overarching domains of medicine, including but not limited to rates of diabetes, hypertension, and insurance status [2]. Moreover, previous research suggests that language barriers may be associated with larger lapses in perioperative process-of-care outcomes [3], and patient populations who experience language barriers also face increased predisposition to hospital readmission and emergency department visits, further highlighting their susceptibility to undesired health care outcomes [4].

In the field of orthopedic surgery, these disparities are broadly evident [5-7]. From initial access to orthopedic care to postoperative outcomes, Spanish-speaking patients contend

XSL•FO
RenderX

with significant barriers in accessing high-quality care [6,7]. Hispanic populations often have limitations in their ability to schedule appointments for orthopedic concerns and often do not pursue revision surgery in cases of nonoptimal outcomes after surgical intervention [7,8]. During orthopedic clinic visits, more than half of Spanish-speaking patients have been asked to rely on nonqualified or ad hoc interpreters rather than professional services, indicating that this patient group faces limitations in access to clear and accurate information about orthopedic procedures and services [9]. These disparities may interact and thereby have implications on patient-reported outcome measures (PROMs) for Spanish-speaking populations. Additionally, recent work has evaluated the suitableness of PROMs for Spanish-speaking populations [10]. Commonly used PROMs for Spanish-speaking patient groups were shown to be written at a reading level above the recommended complexity for patient populations in the United States. Technological advancements can provide avenues to address these concerns if they are implemented in a manner that is tailored to their intended patient populations [11,12]. Thus, given the widespread documentation of disparities in orthopedic care that Spanish-speaking patients endure, further evaluation of how emerging technologies can address these lapses is extremely important.

Artificial intelligence (AI) has provided unique solutions to problems in health care, including those related to graduate medical education and patients' comprehension of medical text [13-17]. Recent work has turned to using publicly available large language models (LLMs) to translate patient discharge summaries and frequently asked questions. The utility of these tools in translating medical text has been illustrated in qualitative textual evaluations conducted via human grading [18,19]. However, studies have yet to evaluate AI-enabled textual translation through robust quantitative analysis involving bilingual evaluation understudy (BLEU) analysis [20]. This methodology quantitatively rates machine-translated text against human translation and has been used in clinical studies [21-23]. Additionally, no study has evaluated AI-driven simplification of Spanish medical text, although AI-driven simplification is a functionality that our group previously quantitatively evaluated for English medical text [16,24,25].

The goals of this study were twofold. First, we aimed to conduct a robust quantitative evaluation of machine translations of medical text by using BLEU analysis, and second, we aimed to assess whether AI platforms can be used to simplify orthopedic medical text written in Spanish.

Methods

Study Design

A total of 78 patient education materials (PEMs) from the American Academy of Orthopaedic Surgery (AAOS) were translated from English into Spanish, using 4 different GPT-4 input prompts via the application programming interface (prompts 1 - 4; Multimedia Appendix 1) [26] and Google Translate via the googletrans package (SuHun Han). Each machine-generated translation was compared to the professionally human-translated reference from the AAOS, using BLEU analysis via the Natural Language Toolkit (NLTK) [27]; BLEU scores range from 0 to 1, with scores of ≥0.5 indicating high similarity to a designated reference text. A Friedman test, followed by a Dunn multiple comparisons test, was performed for each BLEU score to quantify differences in translation quality. Unigram, bigram, trigram, and fourgram precision analyses were conducted to further assess the translation quality. A Friedman test was followed by Dunn multiple comparisons for each precision metric.

To assess the simplification of the PEMs, we compared the readability of translations generated by GPT-4's prompt 1 and that of the original AAOS Spanish versions before and after simplification. Spanish text was simplified by using a standardized prompt that was validated for medical use cases [16]. Text complexity was analyzed by counting sentences, words, and syllables with custom functions and the NLTK library [27]. Readability was evaluated by using the Fernández-Huerta readability formula (FH = 206.84 – [0.60 × P] − [1.02 × F]; FH: reading ease score; P: average number of syllables per 100 words; F: average number of sentences per 100 words) [28] and the INFLESZ readability formula (INFLESZ = 206.835 – [62.3 × S/P] – [P/F]; S: total number of syllables; P: total number of words; F: total number of sentences) [29]. The Wilcoxon matched-pairs signed rank test was applied to compare the original and simplified versions, and the Spearman correlation coefficient was used to measure the strength of the association between the simplification process and improved readability.

To assess the impact of original English text features on translation quality, a feature analysis was performed. Random forest regression was completed, using 4 input features (number of words, average number of words per sentence, total number of syllables, and average number of syllables per sentence) of the original English PEM, to predict 20 distinct BLEU scores. These scores encompassed 4 BLEU scoring methods for Google Translate and 4 different GPT-4 input prompts. A 5-fold cross-validation was used to minimize overfitting of the data and to ensure robust feature importance calculations. Average importance scores across all folds were calculated to assess the contribution of each feature for translation performance.

Ethical Considerations

No application was submitted for review board assessment because no human or animal participants participated directly or indirectly in this study. The University of California, Irvine Institutional Review Board does not require assessment of studies that do not directly or indirectly involve human or animal participants. This study consisted solely of a quantitative evaluation of machine translations and was hence exempt from any institutional review.

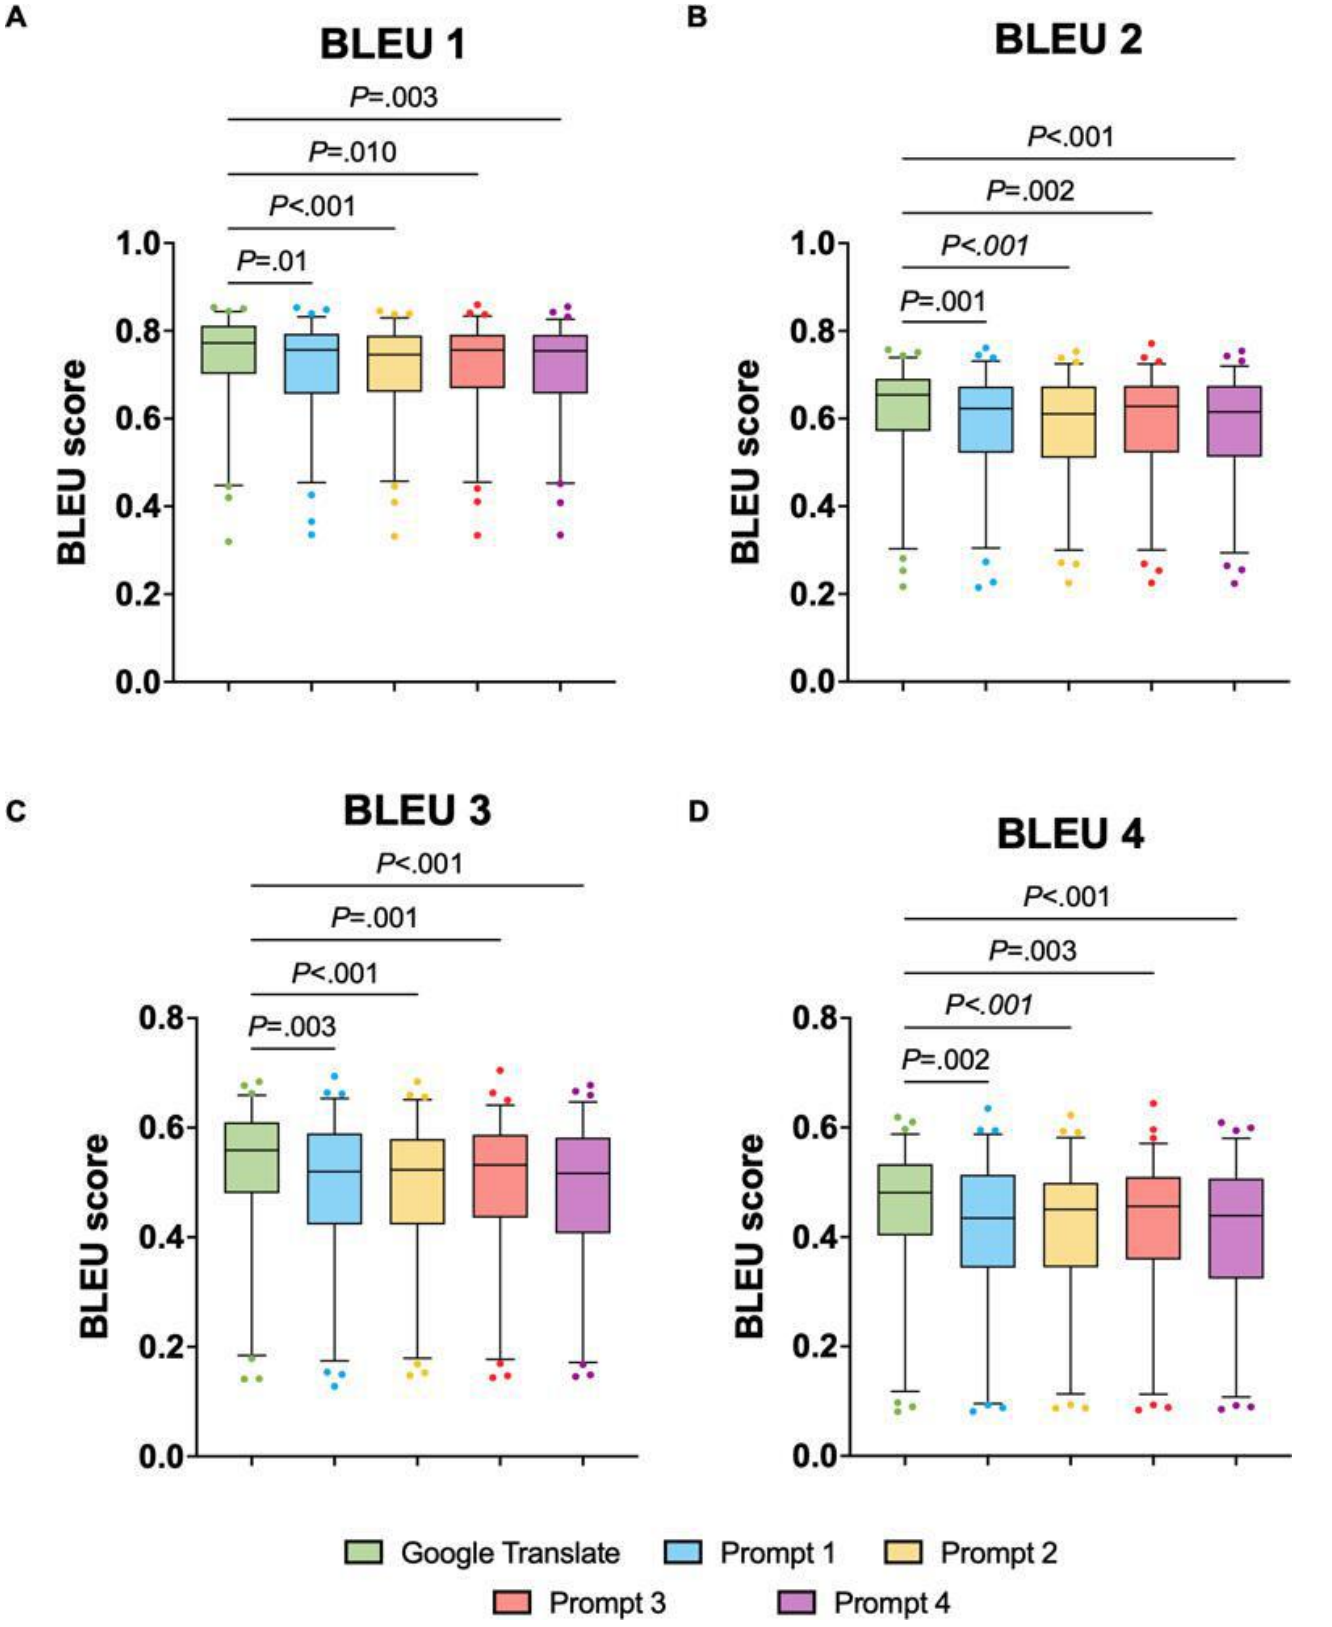
Results

BLEU Analysis

BLEU 1 scores (Figure 1A) revealed a statistically significant difference between Google Translate and each prompt (prompt 1: rank sum difference=63.00; P=.01; prompt 2: rank sum difference=81.00; P<.001; prompt 3: rank sum difference=65.00;

XSL•FO
RenderX

P=.01; prompt 4: rank sum difference=71.00; *P*=.003). No significant differences were observed among the 4 GPT prompts (all *P* values were >.05). For BLEU 1, Google Translate had the highest rank sum (290.0), while prompt 2 had the lowest (209.0). Prompt 1 had a rank sum of 227.0, while prompts 3 and 4 had rank sums of 225.0 and 219.0, respectively.



For BLEU 2 scores (Figure 1B), a similar trend was observed, with significant differences between Google Translate and prompts 1, 2, 3, and 4. The rank sum difference was 76.00 between Google Translate and prompt 1 (*P*<.001), 79.00 between prompt 2 and Google Translate (*P*<.001), 73.00 between prompt 3 and Google Translate (*P*=.002), and 77.00 between prompt 4 and Google Translate (*P*<.001). Again, no statistically significant differences were found between the 4 GPT prompts (all *P* values were >.05). The rank sum for Google Translate was the highest (295.0), followed by those for prompt 3 (222.0), prompt 1 (219.0), and prompt 4 (218.0). Prompt 2 had the lowest rank sum (216.0).

For the BLEU 3 scores (Figure 1C), the Dunn test also showed significant differences between Google Translate and each prompt (prompt 1: rank sum difference=72.00; *P*=.003; prompt 2: rank sum difference=85.00; *P*<.001; prompt 3: rank sum difference=76.00; *P*=.001; prompt 4: rank sum difference=82.00; *P*<.001). No significant differences were found between the 4 GPT prompts (all *P* values were >.05). The rank sums were as follows: 297.0 for Google Translate, 225.0 for prompt 1, 212.0 for prompt 2, 221.0 for prompt 3, and 215.0 for prompt 4.

Finally, BLEU 4 scores (Figure 1D) followed the same pattern as the BLEU scores in all 3 prior BLEU analyses, as the Dunn test revealed significant differences between Google Translate and each prompt (prompt 1: rank sum difference=74.00; *P*=.002; prompt 2: rank sum difference=77.00; *P*<.001; prompt 3: rank sum difference=72.00; *P*=.003; prompt 4: rank sum difference=82.00; *P*<.001). Google Translate had the highest rank sum (295.0), followed by prompt 3 (223.0), prompt 1 (221.0), and prompt 2 (218.0). Prompt 4 had the lowest rank sum (213.0).

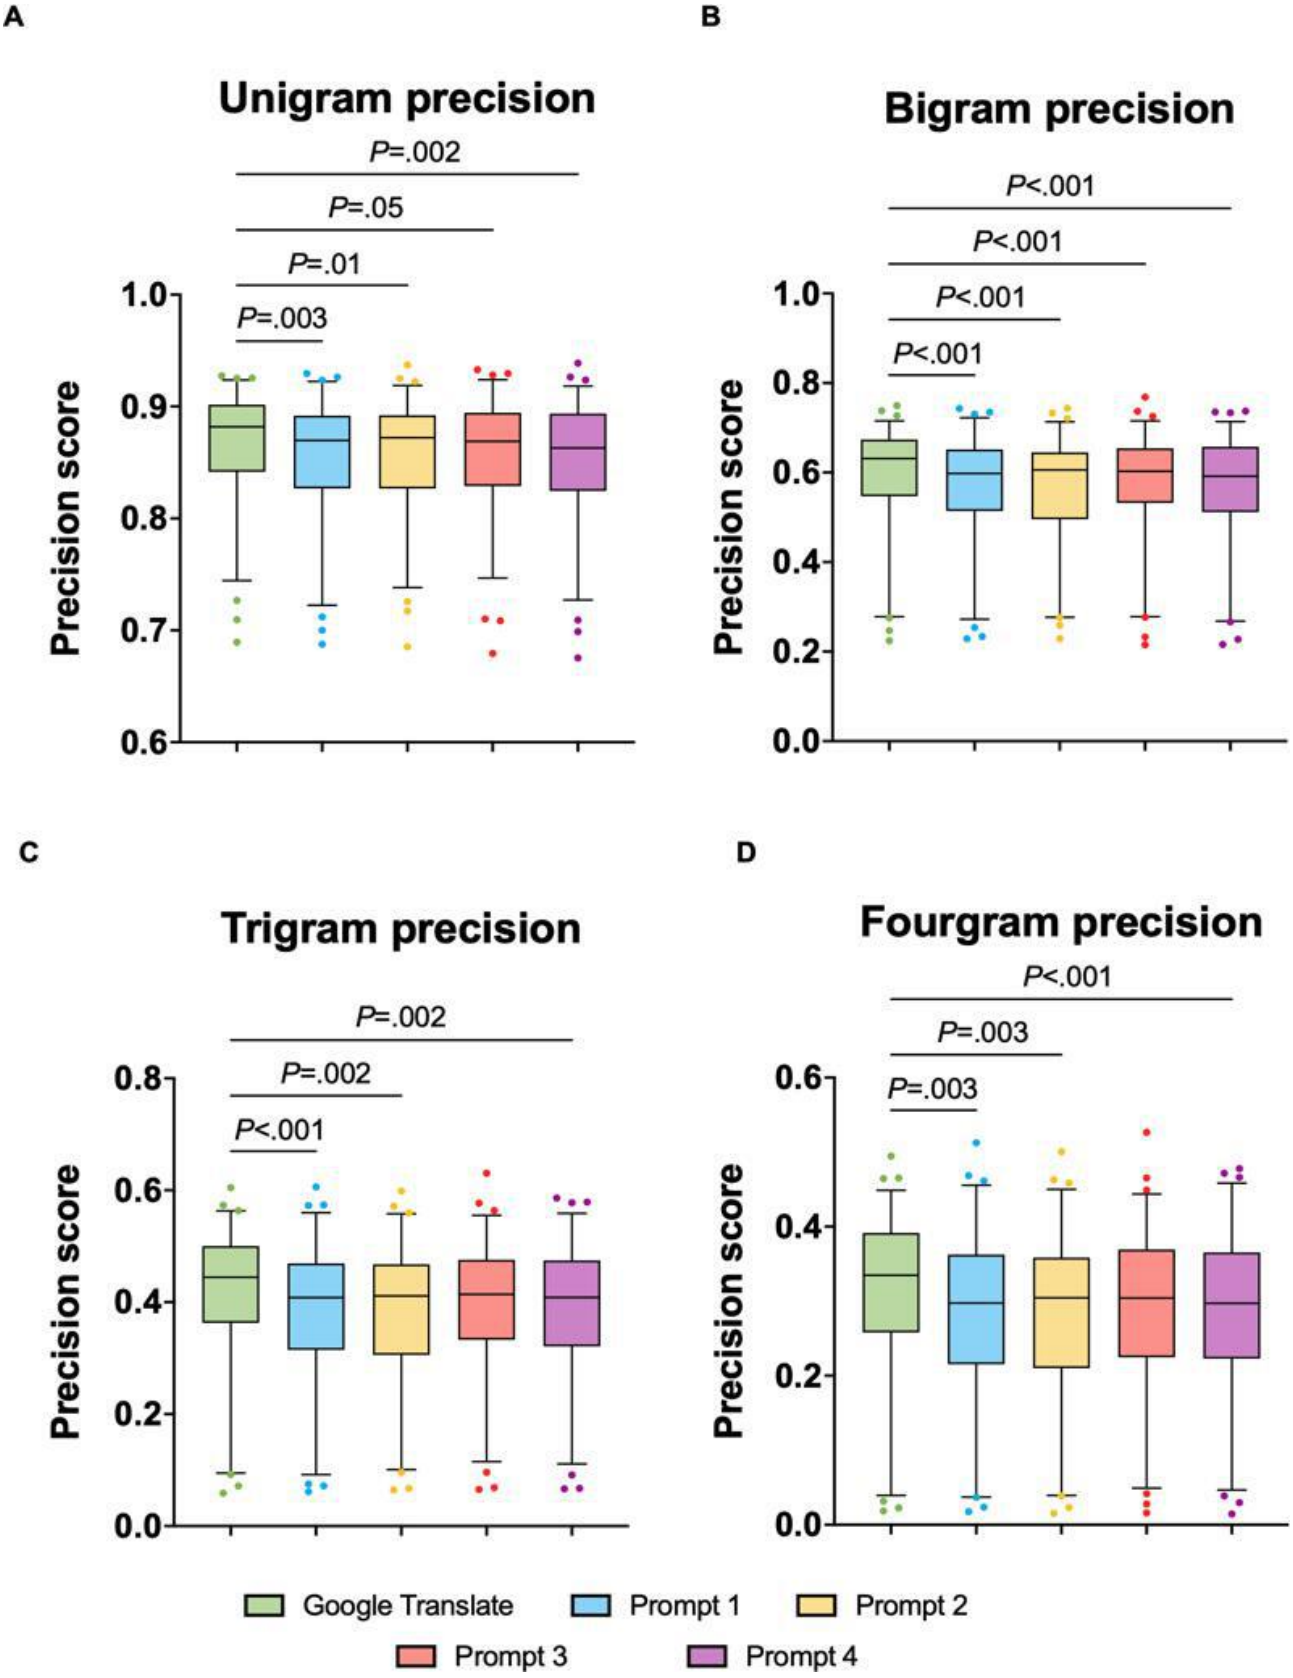
Figure 1. BLEU scores for Google Translate and 4 GPT-4 input prompts (prompts 1-4). Box plots display the BLEU 1 (**A**), BLEU 2 (**B**), BLEU 3 (**C**), and BLEU 4 (**D**) scores for translations generated by Google Translate and the 4 different GPT-4 input prompts. BLEU: bilingual evaluation understudy.

N-Gram Precision Analysis

The unigram precision analysis (Figure 2A) revealed significant differences between Google Translate and prompts 1, 2, 3, and 4. The rank sum difference was 71.50 between Google Translate and prompt 1 (*P*=.003), 64.00 between prompt 2 and Google Translate (*P*=.01), 55.50 between prompt 3 and Google Translate (*P*=.05), and 74.00 between prompt 4 and Google Translate (*P*=.002). Google Translate had the highest rank sum (287.0), followed by prompt 3 (231.5), prompt 2 (223.0), and prompt 1 (215.5). Prompt 4 had the lowest rank sum (213.0).

XSL•FO
RenderX



The bigram precision analysis (Figure 2B) also revealed significant rank sum differences between Google Translate and each prompt (prompt 1: rank sum difference=93.00; *P*<.001; prompt 2: rank sum difference=88.50; *P*<.001; prompt 3: rank sum difference=79.50; *P*<.001; prompt 4: rank sum difference=99.00; *P*<.001). Google Translate had the highest rank sum (306.0), followed by prompt 3 (226.5). Prompt 2 followed with a rank sum of 217.5, and prompts 1 and 4 had a rank sum of 213.0 and 207.0, respectively.

For the trigram precision analysis (Figure 2C), the Dunn test revealed a pattern that was slightly different from the previously established pattern, with significant differences between Google Translate and prompt 1 (rank sum difference=80.00; *P*<.001), between Google Translate and prompt 2 (rank sum difference=73.00; *P*=.002), and between Google Translate and prompt 4 (rank sum difference=74.00; *P*=.002). There was no significant difference in trigram precision between Google Translate and prompt 3 (*P*=.07). Google Translate had the highest rank sum (290.0), followed by prompt 3 (237.0). Prompt 2 had a rank sum of 217.0, while prompt 4 had a rank sum of 216.0. The lowest rank sum for trigram precision was recorded for prompt 1 (210.0).

The fourgram precision analysis (Figure 2D) showed the same pattern of significance as that in the trigram analysis, with significant differences between Google Translate and GPT prompts 1, 2, and 4. The rank sum difference between Google Translate and prompt 1 was 71.00 (*P*=.003). The rank sum differences between Google Translate and prompt 2 and between Google Translate and prompt 4 were 72.00 (*P*=.003) and 78.00 (*P*<.001), respectively. Fourgram precision showed no statistically significant difference between Google Translate and prompt 3 (*P*=.06). Google Translate had the highest rank sum (289.0), while prompt 3 ranked second with a rank sum of 235.0. Prompt 1 had a rank sum of 218.0, and prompt 2 closely followed with a rank sum of 217.0. Prompt 4 had the lowest rank sum (211.0).

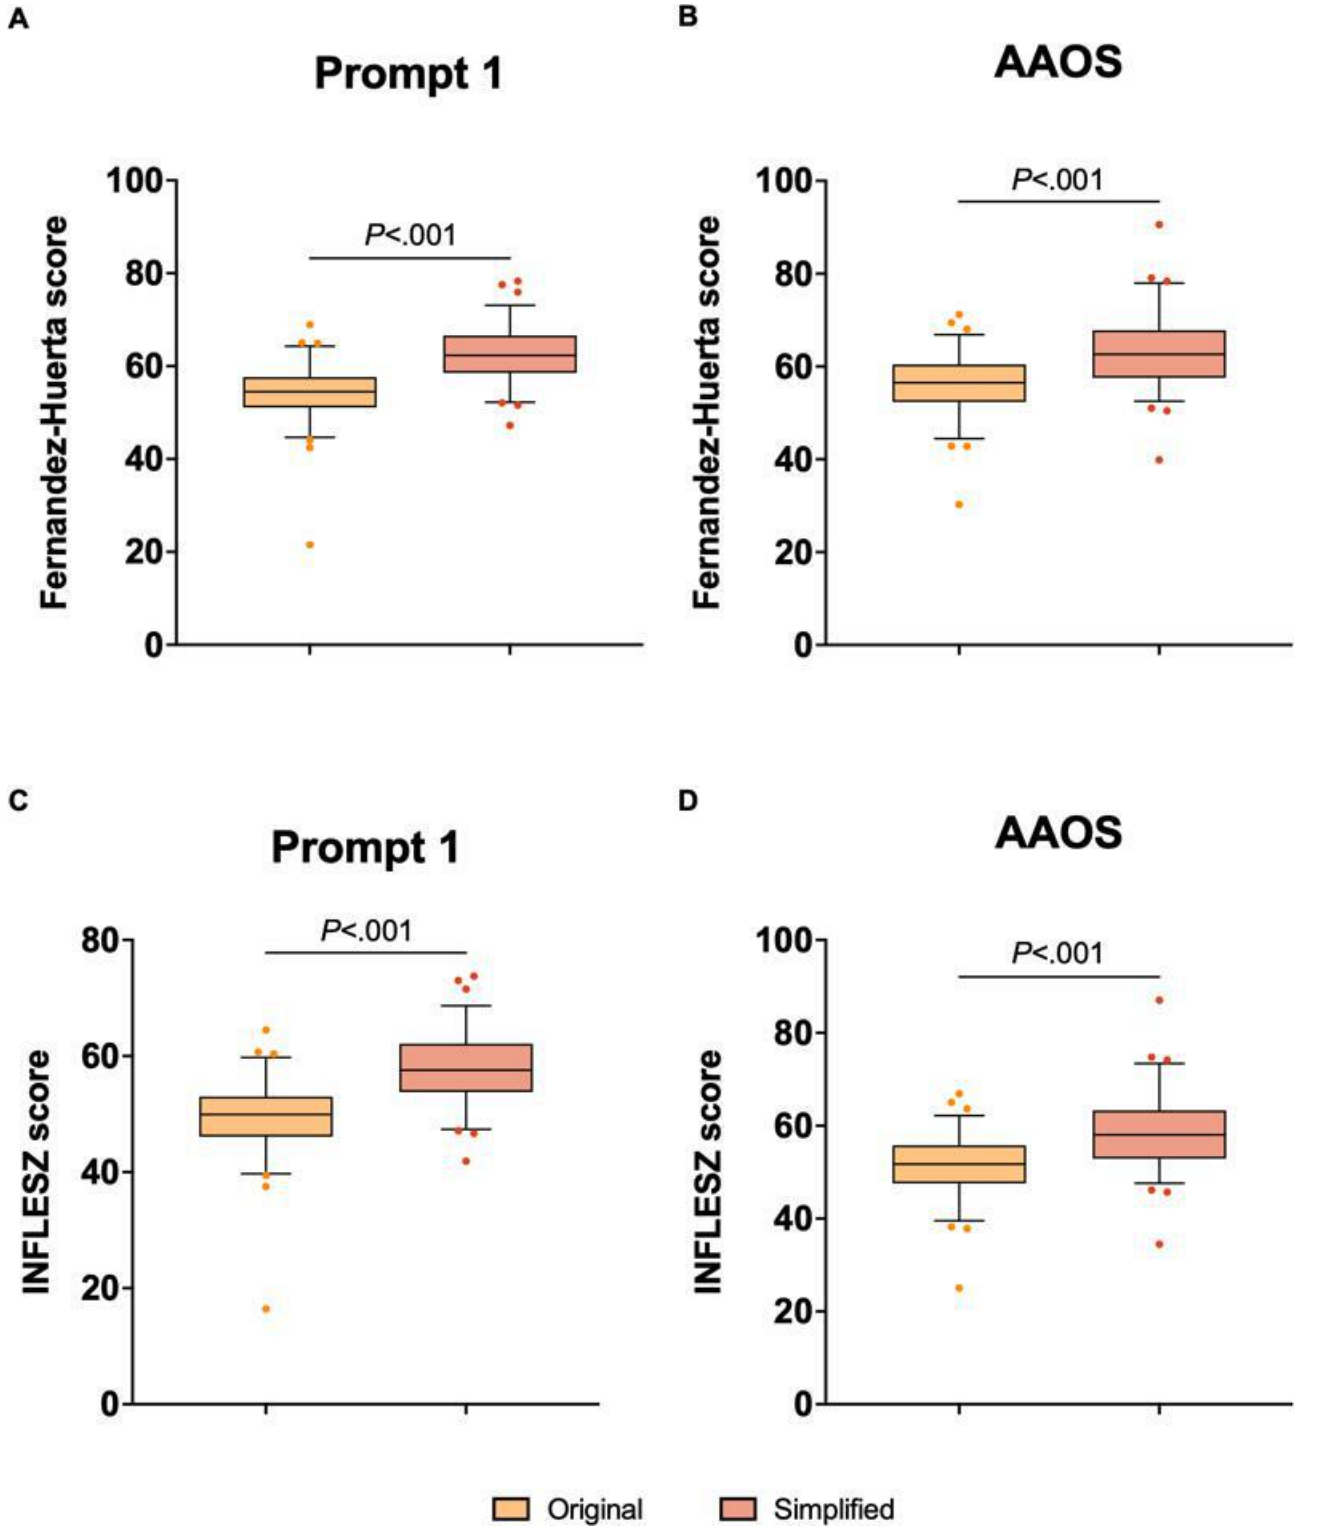
Figure 2. N-gram precision for Google Translate and 4 GPT-4 input prompts (prompts 1-4). Box plots display unigram (**A**), bigram (**B**), trigram (**C**), and fourgram (**D**) precision scores for translations generated by Google Translate and the 4 different GPT-4 input prompts.

Simplification Analysis

As measured by the Fernández-Huerta scores, the simplified prompt 1 PEM translations and simplified AAOS Spanish PEMs demonstrated significant improvements in readability when compared to the original translations (Figure 3). The Wilcoxon (W) test for prompt 1 showed a significant difference between the original and simplified translations, with a W value of 3059 (P<.001); the median difference was 7.846, and the Spearman



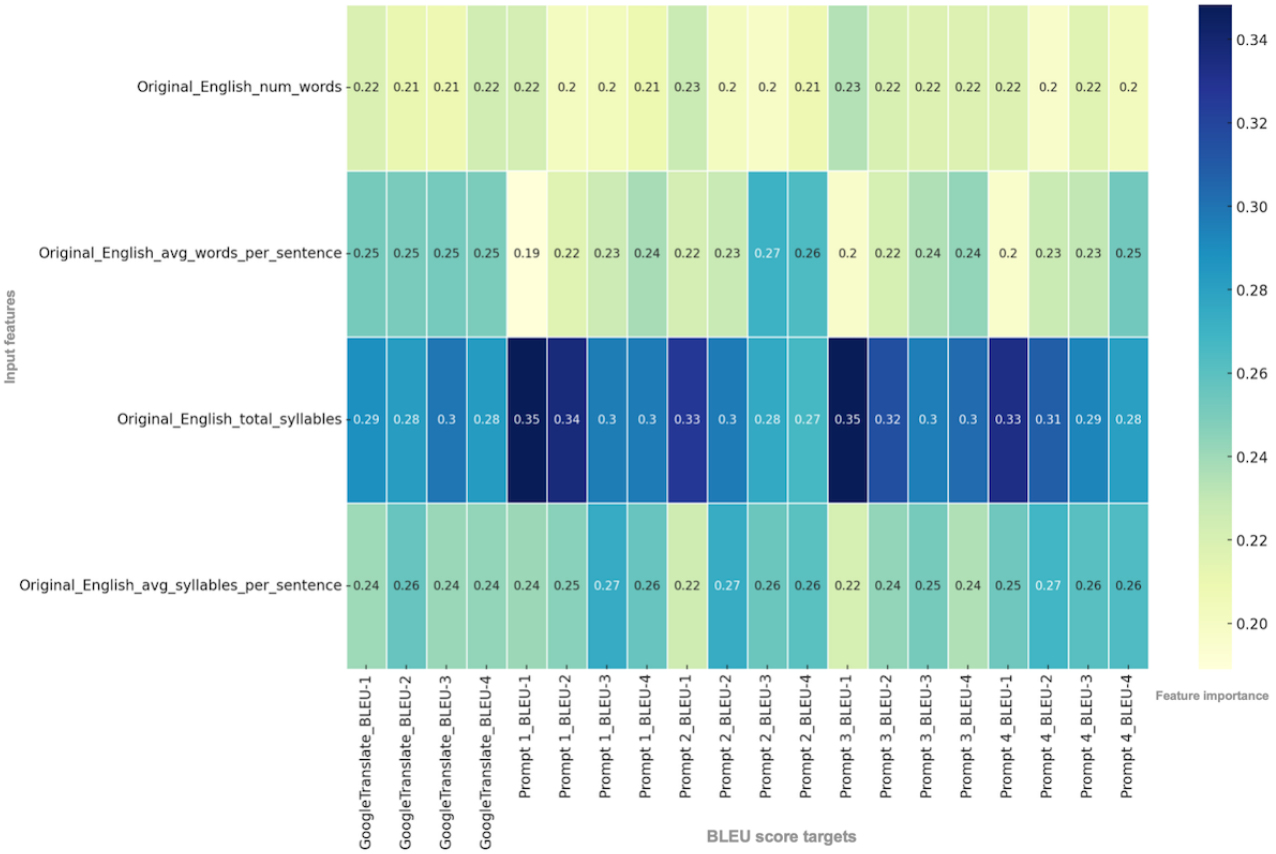
XSL•FO
RenderX

correlation coefficient was 0.6459 (P<.001). For the AAOS Spanish version, the Wilcoxon test revealed a significant improvement after simplification, with a W value of 3055 (P<.001) and a median difference of 5.807; the Spearman correlation coefficient was 0.6731 (P<.001).

For the INFLESZ scores, similar results were observed. For prompt 1, the Wilcoxon matched-pairs signed rank test indicated a significant difference between the original and simplified translations, with a W value of 3058 (P<.001); the median difference was 7.830, and the Spearman correlation coefficient was 0.6591 (P<.001). For the AAOS Spanish PEMs, the Wilcoxon test showed a significant improvement after simplification, with a W value of 3045 (P<.001) and a median difference of 5.887; the Spearman correlation coefficient was 0.6926 (P<.001).

XSL•FO
RenderX

Figure 3. Fernández-Huerta and INFLESZ scores for the original translations by prompt 1 and the AAOS and for their simplified versions. Box plots display the Fernández-Huerta readability scores (**A and B**) and INFLESZ readability scores (**C and D**) for the original and simplified versions of the PEMs generated by GPT-4's prompt 1 (**A and C**) and for the original and simplified AAOS translations (**B and D**). AAOS: American Academy of Orthopaedic Surgery; PEM: patient education material.



Feature Analysis

The feature importance analysis of the original English text features revealed that the total number of syllables was the most influential predictor of BLEU scores across Google Translate and GPT-4 prompts, serving as the most important feature (ie, input variable) in every iteration, with scores ranging from 0.27 to 0.35 (Figure 4). The feature importance range for the number of words was 0.2 to 0.23, that for the average number of words per sentence was 0.19 to 0.27, and that for the average number of syllables per sentence was 0.22 to 0.27. Overall, syllable-based features, particularly the total number of syllables, served as the highest-importance features in determining BLEU scores across all translation methods.

XSL•FO
RenderX

Figure 4. Feature importance scores of English text characteristics for predicting BLEU scores. The heat map shows the relative importance of 4 input features—number of words, average number of words per sentence, total number of syllables, and average number of syllables per sentence—in predicting BLEU scores across the 4 BLEU analyses for each of the 5 translation methods. Darker colors represent higher feature importance. avg: average; BLEU: bilingual evaluation understudy; num: number.

Discussion

Context

Disparities in communication with Spanish-speaking populations can negatively affect patient education and subsequent outcomes in the field of orthopedic surgery [5-7]. Accurate translation of medical text is one component of properly educating Spanish-speaking patient populations about orthopedic conditions. For orthopedic surgeons, it is vital to ensure that Spanish-speaking patients are properly informed about their conditions and opportunities for surgery, given their increased propensity for hospital readmission, complications, and negative outlooks on surgical intervention [6-8]. Previous work provided a foundation for quantitatively evaluating AI-based medical text translation; however, no study has used BLEU methodology to provide a robust, machine learning–based evaluation of translation success. Additionally, no study has evaluated the AI-enabled simplification of Spanish text. Given the recently outlined need for simplified Spanish text among Spanish-speaking patient populations, this is a pressing need in the field [10]. Our study used a robust corpus of patient-facing orthopedic medical text that included language from across various subspecialties and topics of orthopedic surgery, including the spine, hip, knee, and upper extremities, among others. Through analyzing the success of openly accessible LLMs in translating such text, we aimed to comprehensively assess the translation options available for orthopedic practice.

Translation Success

This study demonstrated that LLMs, such as ChatGPT, can translate orthopedic PEMs with moderate success, as quantified through BLEU analysis. By experimenting with 4 different model prompts, we explored whether prompt optimization could enhance translation effectiveness. Our findings suggest that while prompt optimization can improve translation outcomes, Google Translate generally provides superior translation quality when compared to human-translated benchmarks. This superior performance highlights the potential of Google Translate for rapid translation tasks, such as translating patient directives in discharge summaries and other patient-facing documents. However, despite its prevalent use, Google Translate's limitations underscore the need for alternative translation solutions [19,30,31]. The feature analysis conducted within our study also revealed that the syllable complexity of the original English text is a critical predictor of successful translation for both Google Translate and ChatGPT, indicating areas for further refinement in translation approaches. An example AI translation, along with the original English and Spanish versions of the same PEM, can be found in Multimedia Appendix 1.

Simplification Success

We also assessed the capability of ChatGPT in simplifying medical texts written in Spanish, using a standardized simplification prompting structure that was previously evaluated by our group. Although the platform was able to simplify the

XSL•FO
RenderX

text, it did not achieve the targeted grade level specified in our prompts. This limitation aligns with prior studies that highlighted challenges in simplifying English medical texts [16]. However, despite existing challenges with the precision of AI-simplified text in meeting prespecified grade levels, the ability of ChatGPT to simplify texts could greatly benefit Spanish-speaking patients, given that no alternative exists to aid patient comprehension in this way. This is of great importance, considering the complexity of the PROMs and other tools used to assess the operative success of orthopedic procedures in this patient group [10]. Further studies should elucidate ways to best optimize the simplification of Spanish texts via AI platforms.

Recommendations

Based on our results, we offer several recommendations for orthopedic surgeons. Although Google Translate remains a superior tool for translating English to Spanish due to its adherence to human translation quality, LLMs, such as ChatGPT, also show moderate success and can be considered for specific use cases. Importantly, ChatGPT's ability to simplify Spanish texts makes it a valuable tool for enhancing patient comprehension and engagement, particularly when translation by a native Spanish speaker is not feasible. We recommend using ChatGPT as an adjunct tool for both translating and simplifying medical texts. Surgeons should continue to use Google Translate for straightforward translations, but they should also consider leveraging ChatGPT's simplification capabilities to improve the accessibility of medical information. Further research into simplification methodologies is essential for optimizing PROMs and ultimately enhancing patient satisfaction following surgical care. We believe that this technology, once it is fully optimized and vetted, will have the potential to be incorporated into the electronic health record to aid in medical record management through textual translation of records for patients.

Limitations

This study, while providing insights into the potential of LLMs for translating and simplifying medical texts, has several limitations. First, this study assessed existing models, only tested English-to-Spanish translations, and used a relatively small amount of content, thereby limiting the generalizability of our findings. Second, the BLEU metric, which we used to evaluate translation accuracy, primarily measures literal translation and may not fully capture semantic equivalence, which is critical in medical contexts. Future research could benefit from incorporating additional evaluations that involve human assessment to provide a more nuanced analysis. Third, this study's focus was on technical performance; we did not directly measure the impact on patient outcomes, such as comprehension, adherence, and satisfaction. Future studies should aim to link the quality of translations and simplifications to specific patient-centered outcomes. Clinical studies would provide valuable insights into the way that Spanish-speaking patient populations interact with and subsequently benefit from AI-enhanced PEMs, such as those analyzed in this study. Lastly, although the corpus of 78 PEMs covered a broad scope of orthopedic literature from all subspecialties, this means that the results of this study only reflect the language used in standard orthopedic practice. Future studies should aim to replicate our results in other medical specialties to provide a broad understanding of the capabilities of AI in translation and simplification.

Conclusions

This study highlights the utility and limitations of AI-driven tools in translating and simplifying medical texts for Spanish-speaking orthopedic patients. Our findings indicate that while Google Translate provides superior accuracy in translating medical texts, LLMs, such as ChatGPT, demonstrate moderate success and offer significant benefits in simplifying complex medical information into more comprehensible formats. Our recommended dual approach—leveraging Google Translate for accuracy and ChatGPT for simplification—presents a practical solution for enhancing patient education and engagement. Such advancements underscore the potential of AI to bridge the language gap in health care and thereby improve treatment outcomes. Future research should continue to refine these AI tools and enhance their precision and accessibility to meet the diverse needs of patient populations, thereby ensuring that all patients receive care that is both understandable and culturally competent.

Conflicts of Interest

None declared.

Abstract

Background: Despite significant time spent on billing, family physicians routinely make errors and miss billing opportunities. In other disciplines, machine learning models have predicted Current Procedural Terminology codes with high accuracy.

Objective: Our objective was to derive machine learning models capable of predicting diagnostic and billing codes from notes recorded in the electronic medical record.

Methods: We conducted a retrospective algorithm development and validation study involving an academic family medicine practice. Visits between July 1, 2015, and June 30, 2020, containing a physician-authored note and an invoice in the electronic medical record were eligible for inclusion. We trained 2 deep learning models and compared their predictions to codes submitted for reimbursement. We calculated accuracy, recall, precision, F_1-score, and area under the receiver operating characteristic curve.

Results: Of the 245,045 visits eligible for inclusion, 198,802 (81%) were included in model development. Accuracy was 99.8% and 99.5% for the diagnostic and billing code models, respectively. Recall was 49.4% and 70.3% for the diagnostic and billing code models, respectively. Precision was 55.3% and 76.7% for the diagnostic and billing code models, respectively. The area under the receiver operating characteristic curve was 0.983 for the diagnostic code model and 0.993 for the billing code model.

Conclusions: We developed models capable of predicting diagnostic and billing codes from electronic notes following visits to a family medicine practice. The billing code model outperformed the diagnostic code model in terms of recall and precision, likely due to fewer codes being predicted. Work is underway to further enhance model performance and assess the generalizability of these models to other family medicine practices.

KEYWORDS

machine learning; ML; artificial intelligence; algorithm; predictive model; predictive analytics; predictive system; family medicine; primary care; family doctor; family physician; income; billing code; electronic notes; electronic health record; electronic medical record; EMR; patient record; health record; personal health record

Introduction

Previous research has revealed that family physicians spend nearly 50% of their day on electronic medical records (EMRs) and that most of this time is spent on administrative tasks, including documentation of notes and billing [1]. Physicians in the United States and Canada spend an average of 3.4 hours and 2.2 hours per week, respectively, writing, reviewing, submitting, and disputing claims with significant financial losses [2,3]. Tseng et al [4] estimated total professional billing costs for a typical primary care physician at nearly US $100,000 using time-driven activity-based costing. In addition to billing costs, attending and resident family physicians routinely make significant errors and miss opportunities in the context of billing [5,6].

While reasons for these errors and missed opportunities are multifactorial, experts have focused on a lack of education as a primary driver [7,8]. However, the literature demonstrates that even when robust practice management curricula are introduced, billing performance does not improve significantly [9]. Moreover, experienced attending family physicians report challenges with complex billing tasks, suggesting that accumulated experience does not enhance comfort [10].

Given limitations in education and training as quality improvement interventions, other system-focused strategies are warranted [11]. One potential solution is the use of artificial intelligence to predict diagnostic and billing codes from notes.

XSL•FO
RenderX

Kim et al [12] demonstrated 87% accuracy of their machine learning model to predict Current Procedural Terminology (CPT) codes for spine surgery from operative dictations. Another study demonstrated 98% accuracy of a neural network in assigning CPT codes to pathology reports [13].

Little is known about whether similar approaches would work in family medicine, where presenting problems and assessments are highly diverse. Our primary objective was to assess the accuracy of machine learning models in predicting diagnostic and billing codes from the notes recorded in EMRs for visits to family physicians. Based on similar studies, we hypothesized that both the diagnostic and billing code models would generate predictions with at least 90% accuracy [12-14].

Methods

Design and Setting

We conducted a retrospective model development and validation study at a large academic Family Health Team (FHT) in Ontario, Canada, with approximately 50,000 visits per year. The FHT is in a more urban setting with a patient census of approximately 21,000 rostered to 26 attending physicians. Approximately 55-60 first-year resident physicians rotate through annually.

Faculty physicians at this site are primarily compensated through capitation payments but also submit invoices for individual visits as part of the province's Family Health Organization funding model. A single-payer system predominates, with most invoices submitted to the provincial health insurance plan for reimbursement. A minority of invoices are submitted to other insurance plans, including the Workplace Safety and Insurance Board or a third party (eg, Blue Cross) or directly to patients. In addition to faculty and residents, locum physicians provide clinical coverage and submit invoices for individual visits.

Following a patient visit, physicians document their note in an EMR often in the SOAP (subjective, objective, assessment, plan) format. To submit an invoice, physicians must select 1 or more diagnostic codes and 1 or more billing codes. Invoices are compiled electronically in the EMR, reviewed by FHT billing personnel, and subsequently submitted to the provincial health insurance plan for payment every month.

Oscar is the EMR used in this study, and it contains a combination of structured and unstructured data organized into modules. Structured fields include demographics, billing (invoice number, diagnostic codes, billing codes, and billing history), preventative interventions, disease registry, laboratory results, measurements, consultations, allergies, medications, risk factors, and family history. Unstructured fields include social history, medical history, and free text chart notes.

Ethical Considerations

This study received local research ethics board approval (FMED-6780 - 20) from Queen's University Health Sciences Research Ethics Board. The approval covered secondary analyses of these data without additional consent. Physicians were given an opportunity to censor specific patients or opt out of participation. Following the opt-out process, data of the included patients were exported as a flat file and stored on a secure server meeting local privacy requirements. Data were subsequently anonymized and deidentified during the preprocessing stage.

Participants and Sampling

Between July 1, 2015, and June 30, 2020, 245,045 visits containing a documented note and an invoice submitted to the provincial health insurance plan for payment were eligible for inclusion. The included data comprised invoices containing diagnostic and billing codes and information about the status of reimbursement, corresponding visit information including the length of appointment, the date of birth of the patient, the patient's gender, and the physician's free text note for the visit. We excluded visits that had invoices that were not paid or were deleted.

Data Preprocessing

We first transformed data into a Pandas Dataframe for additional preprocessing, including deidentification, linkage of appointments with relevant features, feature scaling, and clinical text processing.

Deidentification

Data were initially in an identifiable form but were anonymized using an automated PERL-based deidentification software package designed for free-text medical records [15]. The software uses a combination of lexical look-up tables, regular expressions, and simple heuristics to locate traditional personal health information, including common names and date variations [15]. This information was then tokenized and removed.

Linking of Appointments With Relevant Features

In Oscar, appointments are associated with both billing and diagnostic codes and contain the length of time for the visit. We linked appointments as an entity with the following data:

1. Demographic data for the patient, including age at the time of the appointment and gender.
2. Free text chart notes from the relevant table: Oscar does not relate a single note entity to an appointment. Notes were linked with their corresponding appointment by an exact match of dates. The signed and verified note by the attending physician was matched in cases of multiple notes from 1 session.
3. Historical diagnostic codes listed 6 months preceding the appointment date: these codes were recorded, and the frequency of the codes was summed.

Feature Scaling for Structured Data

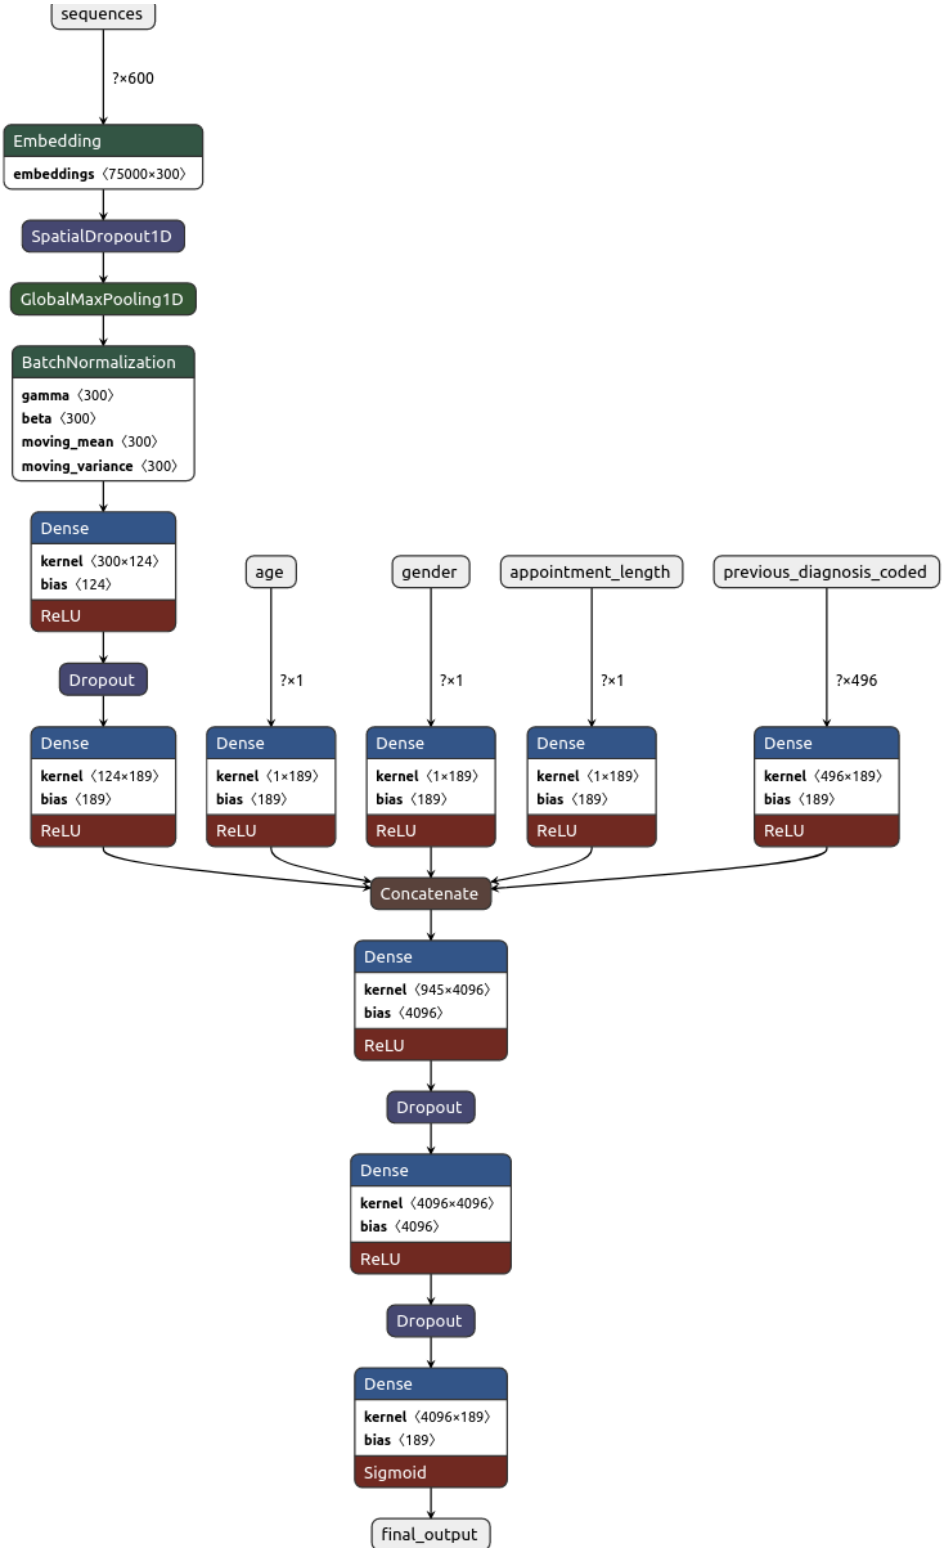
To facilitate the use of neural networks with a gradient descent approach, we scaled our data to achieve values between 0 and 1. We used different feature scaling for different fields: (1) *MinMax scaler* from Scikit-learn for age and appointment duration [16]; (2) binary encoding for male and female; and (3) *MultiLabelBinarizer* for one-hot encoding of historical diagnostic codes [16].

Clinical Text Processing

We applied the following preprocessing steps to overcome common challenges encountered with clinical text, including

XSL•FO
RenderX

domain-specific language, spelling mistakes, and redundant phrases [17]:



1. Stop words: we removed stop words (eg, “a,” “the,” “is”) from the text using the list contained in the NLTK package in Python [18].
2. Oscar-specific domain language: clinical notes signed by physicians include a phrase “SIGNED AND VERIFIED BY,” so *regex* was applied to remove this phrase from the text.
3. Deidentification tokens: the deidentification tool replaces all personally identifiable information with specific tokens. We removed these tokens from the text.
4. Spelling mistakes: we corrected potential spelling errors by applying the Symmetric Delete spelling correction algorithm (SymSpell) with the MEDLINE unigram dictionary, which includes over 28 million unique terms.
5. Punctuation: we removed punctuation from the text.
6. Vectorization: we vectorized the text into a sequence of numbers in the *term frequency–inverse document frequency* format [19].

Model Training and Testing

We used Tensorflow and Keras to construct one model each for the prediction of diagnostic codes and billing codes. Each model uses the same model architecture with the following layers. A graphical representation of the model architecture is presented in Figure 1.

XSL•FO
RenderX

Figure 1. Graphical representation of model architecture. ReLU: rectified linear unit.

One input layer for the vectorized note and 1 input layer are assigned for each structured data feature including age, gender, previous diagnostic codes, and appointment duration. For text classification, we used a submodel architecture called *fasttext* [20]. For structured data classification, we used a simple, fully connected, single-level Dense layer followed by a Dropout layer [21]. Weights were randomly set in the inputs. We then concatenated the text classification output layer and each structured data output layer and applied multiple layers of a Dense network followed by a Dropout layer with a rectified linear unit (ReLU) activation function. The final output layer contains a sigmoid activation function and returns multilabel outputs.

Analysis

We divided data for model development into training, testing, and validation sets, using 70% (139,161/198,802) of notes for training and 30% (59,641/198,802) for testing and validation.

XSL•FO
RenderX

In the testing set, the diagnostic code model assigned 1 of 459 unique diagnostic codes while the billing code model assigned 1 of 157 unique billing codes. These codes are based on the Ontario Health Insurance Plan Schedule of Benefits for family medicine [22]. Each model initially returned a prediction score for each code ranging from 0 to 1. The prediction threshold to transform scores into labels (ie, the most likely diagnostic and billing code for the note) was selected by optimizing for the F_1-score. The diagnostic and billing codes predicted by the deep learning models were compared to the codes selected by the clinician or updated by the FHT's billing personnel that were ultimately billed to the health insurance plan.

Given the size of both datasets, we were unable to manually review and validate the diagnostic and billing codes of notes. However, the family medicine practice in our study benefits from having dedicated administrative staff who review invoices monthly and correct errors prior to submission for reimbursement.

Several metrics of model performance, including accuracy (correct predictions divided by total predictions), recall or sensitivity (true positives/[true positives+true negatives]), precision or positive predictive value (true positives/[true positives+false positives]), F_1-score (2*true positives/[2*true positives+false positives+false negatives]), and area under the receiver operating characteristic curve, were calculated after testing using bootstrapping. We report 95% confidence intervals. Given the multiclass nature of diagnostic and billing code prediction and anticipated class imbalances, we report microaverages as a default unless otherwise specified. We generated performance metrics using *sklearn* in Python.

Results

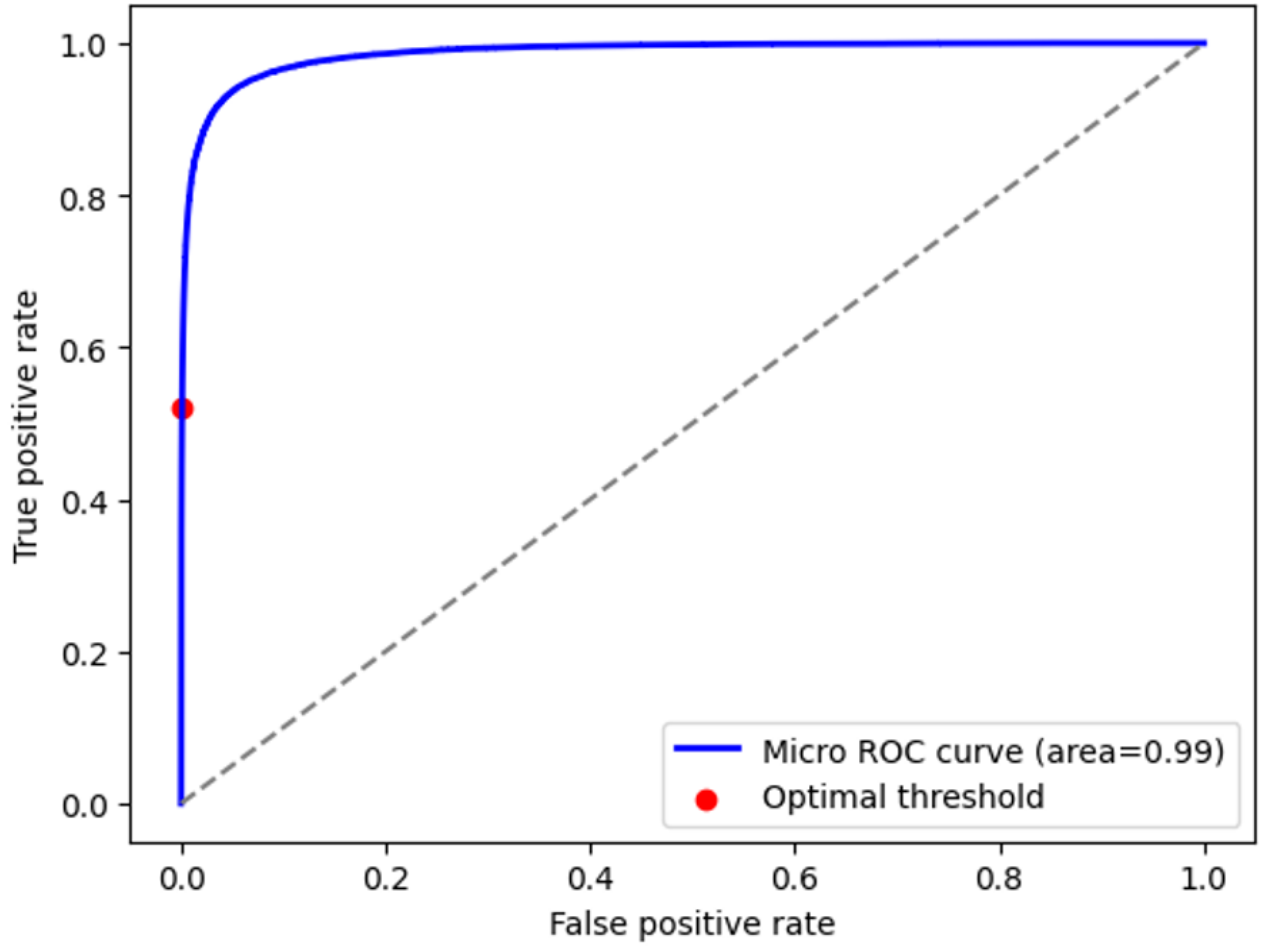
Of the 245,045 visits eligible for inclusion, 198,802 (81%) were included in model derivation, representing 32,425 unique patients. Three physicians opted out of participation in the study. Collectively, there were 448 unique note authors (faculty, physicians, resident physicians, or nurses). For training, 139,161 notes were used, while 29,820 and 29,821 notes were used for testing and validation, respectively. The mean length of notes was 195 (SD 102) words in the training, testing, and validation sets. The training, testing, and validation sets are compared in Table 1.

Table . Comparison of the training, testing, and validation datasets in model development.

	Training (n=139,161)	Testing (n=29,820)	Validation (n=29,821)
Ages, n (%)			
Patients aged 0-17 years	76,539 (55)	16,341 (54.8)	16,431 (55.1)
Patients aged 18-65 years	40,078 (28.8)	8707 (29.2)	8678 (29.1)
Patients aged >65 years	22,405 (16.1)	4771 (16)	4771 (16)
Sex, n (%)			
Male patients	85,027 (61.1)	18,160 (60.9)	18,370 (61.6)
Female patients	54,134 (38.9)	11,660 (39.1)	11,451 (38.4)
Notes, mean (SD)			
Note length (number of words)	194.7 (102.2)	195.0 (102.0)	194.7 (101.4)
Number of diagnostic codes per appointment	1.3 (0.6)	1.3 (0.6)	1.3 (0.6)
Number of billing codes per appointment	1.0 (0.1)	1.0 (0.1)	1.0 (0.1)
Codes, n (%)			
799	16,268 (11.7)	3426 (11.5)	3477 (11.7)
300	7779 (5.6)	1706 (5.7)	1706 (5.7)
916	6708 (4.8)	1440 (4.8)	1428 (4.8)
250	6666 (4.8)	1381 (4.6)	1425 (4.8)
401	5747 (4.1)	1223 (4.1)	1217 (4.1)
A007A	90,803 (65.2)	19,601 (65.7)	19,470 (65.3)
A001A	7139 (5.1)	1521 (5.1)	1563 (5.2)
G590A	6596 (4.7)	1378 (4.6)	1396 (4.7)
K005A	5887 (4.2)	1279 (4.3)	1235 (4.1)
G010A	4745 (3.4)	972 (3.3)	1041 (3.5)

The overall accuracy of the diagnostic and billing code models were 99.8% (95% CI 99.79% - 99.80%) and 99.5% (95% CI 99.57% - 99.60%), respectively. The recall (sensitivity) was 49.4% (95% CI 49.07% - 51.77%) for the diagnostic code model and 70.3% (95% CI 68.68% - 72.17%) for the billing code model. The precision (positive predictive value) was 55.3%

XSL•FO
RenderX



(95% CI 54.31% - 55.79%) for the diagnostic code model and 76.7% (95% CI 72.29% - 74.58%) for the billing code model. The F_1-scores were 52.2% (95% CI 51.56% - 52.16%) and 73.4% (95% CI 72.29% - 74.58%) for the diagnostic and billing code models, respectively. Measures of model performance are reported in Table 2. The area under the receiver operating characteristic curves for the diagnostic and billing code models are shown in Figures 2 and 3, respectively. The precision-recall curves are shown in Figures 4 and 5, respectively.

Table . Measures of performance for the diagnostic and billing code models.

	Diagnostic code model (95% CI)	Billing code model (95% CI)
Accuracy, %	99.8 (99.79 - 99.80)	99.5 (99.5 - 99.60)
Recall, %	49.4 (49.07 - 51.77)	70.3 (68.68 - 72.17)
Precision, %	55.3 (54.31 - 55.79)	76.7 (72.29 - 74.58)
F_1-score, %	52.2 (51.56 - 52.16)	73.4 (72.29 - 74.58)
AUC[a]	0.983 (0.9833 - 0.9863)	0.993 (0.9921 - 0.9943)

Figure 5. Precision-recall (PR) curve for the billing code model.

In the testing set, code 799 (“symptoms, signs and ill-defined conditions”) was the most commonly appearing diagnostic code (n=3425) followed by code 300 (“mental disorders – neuroses and personality disorders”; n=1707) and then code 916 (“well baby care”; n=1439). Code A007 (“intermediate assessment or well baby care”) was the most billed code (n=19,601). Code A001 (“minor assessment”) was the second most billed code (n=1520), followed by code G590A (“immunization – influenza agent”; n=1783). The top 10 most common diagnostic and billing codes and corresponding model performances are listed in Table 3.

XSL•FO

Discussion

Principal Results

To our knowledge, this study is the first to report the development and internal validation of machine learning models for the prediction of diagnostic and billing codes in family medicine. While the models were highly accurate in terms of predictions, their recall and precision were much lower. These differences in performance are characteristic of multiclassification problems where high rates of overall accuracy are driven by higher classification of true negatives than identification of true positives. In the context of diagnostic and billing codes, however, correctly generating the relevant codes is much more useful than excluding irrelevant or inappropriate codes.

Unsurprisingly, the billing code model outperformed the diagnostic code model likely due to fewer codes being predicted. The lower precision and F_1-score of the diagnostic code model suggest that the model struggles to correctly identify and classify true positive cases. There are a few possible explanations for this finding. First, the dataset was imbalanced with most diagnostic labels relating to ill-defined conditions (code 799), mental disorders (code 300), well baby care (code 916), and diabetes mellitus (code 250). Performance for these codes was noticeably better than for the overall dataset with recall ranging from 63% - 92% and precision ranging from 59% - 84%. Second, misclassification was also possible. Patients of the academic FHT where the study was conducted are known to be medically comorbid and socially complex. Consequently, encounter notes may yield several diagnostic labels; however, only 1 code may be selected for the visit.

Part of the challenge in selecting a diagnostic label for these encounters is observed among the top performing diagnostic codes. Although code 799 ("symptoms, signs and ill-defined conditions") was the most frequent code in the dataset, recall was higher for several other codes, including codes 650 ("delivery – normal; pregnancy – uncomplicated; complications of pregnancy, childbirth and the puerperium – normal pregnancy"), 916 ("well baby care") and 250 ("diabetes mellitus including complications"). These differences in performance are likely due to challenges in making sense of nonspecific symptoms in the case of code 799 as opposed to pregnancy (code 650) for a patient seeking antenatal care or a patient following up for diabetes (code 250).

We anticipated that the billing code model would perform better at predicting codes that were more frequently selected. The highest recall was for P004A, the billing code for minor prenatal assessment. Patients are seen several times during their pregnancy leading to the accumulation of these codes in historical invoices. Along with straightforward visit documentation, we suspect the model was able to predict the P004A code more fluently.

Limitations

While our study is the first to derive and validate models to predict diagnostic and billing codes in family medicine, our results should be interpreted with caution. Our data were drawn from 1 academic FHT located in a single province and our models have not yet been externally validated. As a result, our findings may not be generalizable to other family medicine settings (eg, community or nonacademic) or other jurisdictions.

We observed heterogeneity in the performance of the model in classifying diagnostic and billing codes. Due to the size of the dataset, limited resources, and administrative constraints, we were unable to perform more detailed analyses relating to the interpretability and explainability for the diagnostic and billing code predictions. Such analyses may have uncovered factors influencing the model's performance for each code and remain an important target for future work.

One factor that likely influenced performance is clinical note quality [23]. Generally, longer notes provide more information with the corollary being that more information tends to yield better predictions. However, longer notes may also contain more copied information, which may negatively impact natural language processing performance [23]. Similarly, previous work has shown differences in the documentation practices of trainee and attending physicians [24]. The notes of trainee physicians tend to be longer and more complete while attending physicians are most interested in the assessment and plan section of notes [24-26]. Critically, quality of documentation is challenging to assess, especially in family medicine settings where no validated tools exist.

Comparison With Prior Work

Our findings are generally consistent with the results of previous studies. Using the open-source Medical Information Mart for Intensive Care III (MIMIC-III) database, various groups have developed machine learning models for the prediction of diagnostic (*International Classification of Diseases, Ninth Revision* [*ICD-9*]) codes from discharge summaries achieving micro F_1-scores between 57.5 - 58.9 [27]. Performance discrepancies between our diagnostic code model and the models in these studies may be attributed to differences between encounter notes and discharge summaries. The latter tend to be more comprehensive in capturing details regarding a patient's initial presentation, their course and management in the hospital, and follow-up plans after discharge. These sections provide ample substrate on which to base predictions.

In the context of billing, Ye [13] developed a 3-layer neural network to predict CPT codes based on the diagnosis header and diagnosis recorded in pathology reports and achieved accuracy of 97.5%. However, their model only predicted 5 codes using text with a median length of 12 words. In contrast, Burns et al [14] developed a neural network to predict 232 CPT codes from procedural text with a mean word count of 10 words per text and achieved 82.1% accuracy. On average, notes in our study were approximately 10 times larger than those in the study by Burns et al, with a comparable number of billing codes and much higher accuracy [14].

Implications

Despite the challenges associated with billing, including missed revenue opportunities and errors, the performance of our models suggest that more work is needed before machine-learned solutions for diagnostic and billing code prediction can be

XSL•FO
RenderX

deployed in practice. Such work includes external validation with other academic and community family medicine clinics, prospective validation to compare performance with physicians, and the testing of generative pretrained transformer architectures.

Once completed, there are different ways these models could be embedded within existing billing workflows. Models could be integrated with existing EMRs providing diagnostic and billing code predictions to end-users in real-time. Physicians could review predictions before finalizing codes for submission. Alternatively, physicians could bill visits as they currently do with the model surfacing its predictions for encounters for which a code was missed or an error was made. Additionally, the model could be combined with rule-based approaches to reduce common errors.

Conclusions

Our study is the first to describe the development and validation of machine learning models for the prediction of diagnostic and billing codes in family medicine. Model performance was heterogeneous and requires further analysis to uncover the factors associated with the prediction of specific diagnostic and billing codes. In addition to addressing model explainability, future work will incorporate additional structured data, consider the impacts of note characteristics and authorship on model performance, and explore validation in other family medicine settings.

Acknowledgments

We would like to thank Dr Angela Coderre-Ball for her time in reviewing and providing feedback on the manuscript.

Conflicts of Interest

AR and MJ cofounded 12676362 Canada Inc doing business as Caddie Health. Both AR and MJ hold an equity stake in the company. DB previously served as an advisor to Caddie Health and held an equity stake in the company. Caddie Health had previously licensed the models described in this work for commercialization. At the time of writing, the company is not active commercially and has no sources of revenue.

Abstract

Background: Deep learning techniques have shown promising results in the automatic classification of respiratory sounds. However, accurately distinguishing these sounds in real-world noisy conditions poses challenges for clinical deployment. In addition, predicting signals with only background noise could undermine user trust in the system.

Objective: This study aimed to investigate the feasibility and effectiveness of incorporating a deep learning–based audio enhancement preprocessing step into automatic respiratory sound classification systems to improve robustness and clinical applicability.

Methods: We conducted extensive experiments using various audio enhancement model architectures, including time-domain and time-frequency–domain approaches, in combination with multiple classification models to evaluate the effectiveness of the audio enhancement module in an automatic respiratory sound classification system. The classification performance was compared against the baseline noise injection data augmentation method. These experiments were carried out on 2 datasets: the International Conference in Biomedical and Health Informatics (ICBHI) respiratory sound dataset, which contains 5.5 hours of recordings, and the Formosa Archive of Breath Sound dataset, which comprises 14.6 hours of recordings. Furthermore, a physician validation study involving 7 senior physicians was conducted to assess the clinical utility of the system.

Results: The integration of the audio enhancement module resulted in a 21.88% increase with $P<.001$ in the ICBHI classification score on the ICBHI dataset and a 4.1% improvement with $P<.001$ on the Formosa Archive of Breath Sound dataset in multi-class noisy scenarios. Quantitative analysis from the physician validation study revealed improvements in efficiency, diagnostic confidence, and trust during model-assisted diagnosis, with workflows that integrated enhanced audio leading to an 11.61% increase in diagnostic sensitivity and facilitating high-confidence diagnoses.

Conclusions: Incorporating an audio enhancement algorithm significantly enhances the robustness and clinical utility of automatic respiratory sound classification systems, improving performance in noisy environments and fostering greater trust among medical professionals.

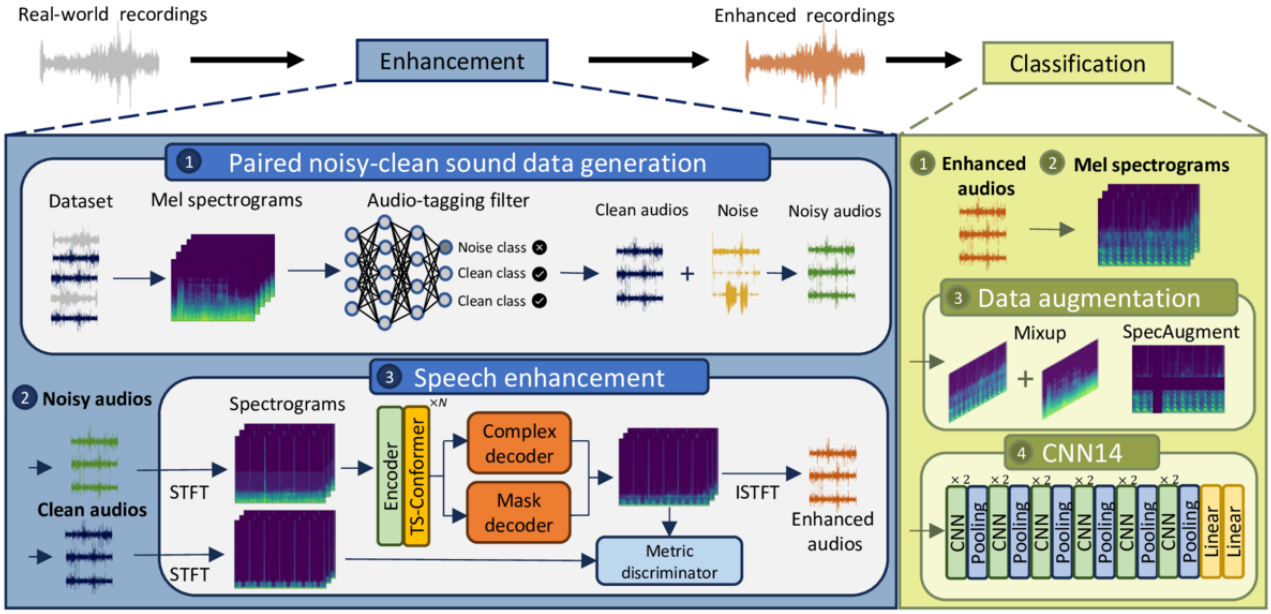
Introduction

Background

Respiratory sounds play a crucial role in pulmonary pathology. They provide insights into the condition of the lungs noninvasively and assist disease diagnosis through specific sound patterns and characteristics [1,2]. For instance, wheezing is a continuous high-frequency sound that often indicates typical symptoms of chronic obstructive pulmonary disease and asthma [3]; crackling, on the other hand, is an intermittent low-frequency sound with a shorter duration that is a common respiratory sound feature among patients with lung infections [4]. The advancement of machine learning algorithms and medical devices enables researchers to investigate approaches for developing automated respiratory sound classification systems, reducing the reliance on manual inputs from physicians and medical professionals.

In earlier studies, researchers have engineered handcrafted audio features for respiratory sound classification [5]. Recently, neural network–based methods have become the de facto methods for lung sound classification. For example, Kim et al [6] fine-tuned the pretrained VGG16 algorithm, outperforming the conventional support vector machine (SVM) classifier. Wanasinghe et al [7] incorporated mel spectrograms, mel-frequency cepstral coefficients, and chroma features to expand the feature set input to a convolutional neural network (CNN), demonstrating promising results in the identification of pulmonary diseases. Pessoa et al [8] proposed a hybrid CNN model architecture that integrates time-domain information with spectrogram-based features, delivering a satisfactory performance. Moreover, various advanced architectures have been proposed to extract both long-term and short-term information from respiratory sounds based on the characteristics of crackle and wheeze sounds and have shown enhanced performance [9-13]. Recent works have used advanced contrastive learning strategies to enhance intraclass compactness and interclass separability for further improvements [14-17]. These advancements in neural network structures have shown increasing promise in achieving reliable respiratory sound classification.



Despite these advancements, significant challenges remain for the clinical deployment of automatic respiratory sound classification systems due to complex real-world noisy conditions [6,18]. Augmentation techniques, such as time shifting, speed tuning, and noise injection, have been key strategies to effectively improve the noise robustness and generalizability of a machine learning model [9,14,16,19-23]. While these approaches have shown promising results in respiratory sound classification tasks, their practical utility as modules for building clinical decision support systems remains in doubt. This is primarily attributed to their inability to provide clinicians with intelligible raw audio to listen to facilitate decision-making, thus making the current augmentation-based approach seem black box and hindering acceptance and adoption by medical professionals.

In fact, given the blooming use of artificial intelligence (AI) in health care, the issue of liability has been the focus. The prevailing public opinion suggests that physicians are the ones to bear responsibility for errors attributed to AI [24]. Hence, when these systems are opaque and inaccessible to physicians, it becomes challenging to have them assume responsibility without a clear understanding of the decision-making process. This difficulty is particularly pronounced for seasoned and senior physicians, who hesitate to endorse AI recommendations without transparent rationale. The resulting lack of trust contributes to conflicts in clinical applications. Therefore, elucidating the decision-making process is crucial to establishing the trust of physicians [25]. Moreover, exceptions are frequent in the field of medicine. For instance, in cases in which bronchioles undergo significant constriction, the wheezing sound may diminish to near silence, a phenomenon referred to as silent wheezing. This intricacy could confound AI systems, necessitating human intervention (ie, listening directly to the recorded audio) [26].

To address these challenges, we propose an approach that involves integrating an audio enhancement module into the respiratory sound classification system, as shown in Figure 1. This module aims to achieve noise-robust respiratory sound classification performance while providing clean audio recordings on file to support physicians' decision-making. By enhancing the audio quality and preserving critical information, our system aimed to facilitate more accurate assessments and foster trust among medical professionals. Specifically, we devised 2 major experiments to evaluate this approach in this study. First, we compared the performance of our noise-robust system through audio enhancement to the conventional method of noise augmentation (noise injection) under various clinical noise conditions and signal-to-noise ratios (SNRs). Second, we conducted a physician validation study to assess confidence and reliability when listening to our cleaned audio for respiratory sound class identification. To the best of our knowledge, this is the first study showing that deep learning enhancement architecture can effectively remove noise while preserving discriminative information for respiratory sound classification algorithms and physicians. Importantly, this study validates the clinical potential and practicality of our proposed audio enhancement front-end module, contributing to more robust respiratory sound classification systems and aiding physicians in making accurate and reliable assessments.

Related Work

Audio Enhancement

Audio enhancement is a technique that has been widely used in the speech domain, where it is referred to as speech enhancement. These techniques are primarily used in the front-end stage of automatic speech recognition systems to improve intelligibility [27-29]. Within speech enhancement, deep neural network approaches can be categorized into 2 main domains: time-frequency–domain approaches and time-domain approaches.

Time-frequency–domain approaches are used to estimate clean audio from the short-time Fourier transform (STFT) spectrogram, which provides both time and frequency information. Kumar and Florencio [30] leveraged noise-aware training [31] with psychoacoustic models, which decided the importance of frequency for speech enhancement. The result demonstrated the potential of deep neural network–based speech enhancement in complex multiple-noise conditions, such as real-world environments. In the research by Yin et al [32], they designed a 2-stream architecture that predicts amplitude and phase separately and further improves the performance. However, various research studies [33-35] have indicated that the conventional loss functions used in regression models (eg, L_1 and L_2) do not strongly correlate with speech quality, intelligibility, and word error rate. To address the issue of discriminator evaluation mismatch, Fu et al [36] introduced MetricGAN. This approach tackles the problem of metrics that are not entirely aligned with the discriminator's way of distinguishing between real and fake samples. They used perceptual evaluation of speech quality (PESQ) [37] and short-time objective intelligibility (STOI) [38] as evaluation functions, which are commonly used for assessing speech quality and intelligibility, as labels for the discriminator. Furthermore, the performance of MetricGAN can be enhanced by adding a learnable sigmoid function for mask estimation, including noisy recording for discriminator training, and using a replay buffer to increase sample size [39]. Recently, convolution-augmented transformers (conformers) have been widely used in automatic speech recognition and speech separation tasks due to their capacity in long-range and local contexts [40-42]. Cao et al [43] introduced a conformer-based metric generative adversarial network (CMGAN), which leverages the conformer structure along with MetricGAN for speech enhancement. In the CMGAN model, multiple 2-stage conformers are used to aggregate magnitude and complex spectrogram information in the encoder. In the decoder, the prediction of the magnitude and complex spectrogram are decoupled and then jointly incorporated to reconstruct the enhanced recordings. Furthermore, CMGAN achieved state-of-the-art results on the VoiceBank+DEMAND dataset [44,45].

On the other hand, time-domain approaches directly estimate the clean audio from the raw signal, encompassing both the magnitude and phase information, enabling them to enhance noisy speech in both domains jointly. Macartney and Weyde [46] leveraged Wave-U-Net, proposed in the study by Thiemann et al [44], to use the U-Net structure in a 1D time domain and demonstrated promising results in audio source separation for speech enhancement. Wave-U-Net uses a series of downsampling and upsampling blocks with skip connections to make predictions. However, its effectiveness in representing long signal sequences is limited due to its restricted receptive field. To overcome this limitation, the approaches presented in the studies by Pandey and Wang [47] and Wang et al [48] divided the signals into small chunks and repeatedly processed local and global information to expand the receptive field. This dual-path structure successfully improved the efficiency in capturing long sequential features. However, dual-path structures are not memory efficient as they require retaining the entire long signal during training. To address the memory efficiency issue, Park et al [49] proposed a multi-view attention network.

XSL•FO
RenderX

They used residual conformer blocks to enrich channel representation and introduced multi-view attention blocks consisting of channel, global, and local attention mechanisms, enabling the extraction of features that reflect both local and global information. This approach also demonstrated state-of-the-art performance on the VoiceBank+DEMAND dataset [44,45].

Both approaches have made significant progress in performance improvements in recent years. However, their suitability for enhancing respiratory sounds collected through stethoscopes remains unclear. Therefore, for this study, we applied these 2 branches of enhancement models and compared their effectiveness in enhancing respiratory sounds in real-world noisy hospital settings [32,43,46,49].

Respiratory Sound Classification

In recent years, automatic respiratory sound classification systems have become an active research area. Several studies have explored the use of pretrained weights from deep learning models, showing promising results. Kim et al [6] demonstrated improved performance over SVMs by fine-tuning the pretrained VGG16 algorithm. Gairola et al [22] used effective preprocessing methods, data augmentation techniques, and transfer learning from ImageNet [50] pretrained weights to address data scarcity and further enhance performance.

As large-scale audio datasets [51,52] become more accessible, pretrained audio models are gaining traction, exhibiting promising performance in various audio tasks [53-55]. Studies have explored leveraging these pretrained audio models for respiratory sound classification. Moummad and Farrugia [17] incorporated supervised contrastive loss on metadata with the pretrained 6-layer CNN architecture [53] to improve the quality of learned features from the encoder. Chang et al [56] introduced a novel gamma patch-wise correction augmentation technique, which they applied to the fine-tuned 14-layer CNN (CNN14) architecture [53], achieving state-of-the-art performance. Bae et al [16] used the pretrained Audio Spectrogram Transformer (AST) [54] with a Patch-Mix strategy to prevent overfitting and improve performance. Kim et al [57] proposed a representation-level augmentation technique to effectively leverage different pretrained models with various input types, demonstrating promising results on the pretrained ResNet, EfficientNet, 6-layer CNN, and AST.

However, few of these studies have explicitly addressed the challenge of noise robustness in clinical settings. To improve noise robustness, data augmentation techniques such as adding white noise, time shifting, stretching, and pitch shifting have been commonly used [9,14]. These augmentations enable networks to learn efficient features under diverse recording conditions. Nonetheless, the augmented recordings may not accurately represent the conditions in clinical settings, potentially introducing artifacts and limiting performance improvement. In contrast to the aforementioned works, Kochetov et al [18] proposed a noise-masking recurrent neural network to filter out noisy frames during classification. They concatenated a binary noise classifier and an anomaly classifier with a mask layer to suppress the noisy parts, allowing only the filtered frames to pass through, thereby preventing noises from affecting the classification. However, the International Conference in Biomedical and Health Informatics (ICBHI) database lacks noise labels in the metadata, and the paper did not specify how these labels were obtained, rendering the results nonreproducible. Emmanouilidou et al [58] used multiple noise suppression techniques to address various noise sources, including ambient noise, signal artifacts, heart sounds, and crying, using a soft-margin nonlinear SVM classifier with handcrafted features. Similarly, our work uses a pipeline for noise enhancement and respiratory sound classification. However, we advanced this approach by using deep learning models for both tasks, enabling our system to handle diverse noise types and levels without the need for bespoke strategies for each noise source. Furthermore, we validated our system's practical utility through experiments across 2 respiratory sound databases and a physician validation study, demonstrating its improved performance and clinical relevance.

Methods

Datasets

This section presents 2 respiratory sound datasets and 1 clinical noise dataset used in this study.

ICBHI 2017 Dataset

The ICBHI 2017 database is one of the largest publicly accessible datasets for respiratory sounds, comprising a total of 5.5 hours of recorded audio [59]. These recordings were independently collected by 2 research teams in Portugal and Greece from 126 participants of all ages (79 adults, 46 children, and 1 unknown). The data acquisition process involved heterogeneous equipment and included recordings from both clinical and nonclinical environments. The duration of the recorded audio varies from 10 to 90 seconds. Within this database, 6898 respiratory cycles result in 920 annotated audio samples. Among these samples, 1864 contain crackles, 886 contain wheezes, and 506 include both crackles and wheezes, whereas the remaining cycles are categorized as normal.

Formosa Archive of Breath Sound

The Formosa Archive of Breath Sound (FABS) database comprises 14.6 hours of respiratory sound recordings collected from 1985 participants. Our team collected these recordings at the emergency department of the Hsin-Chu Branch at the National Taiwan University Hospital (NTUH). We used the CaRDIaRT DS101 electronic stethoscope, where each recording is 10 seconds long.

To ensure the accuracy of the annotations, a team of 7 senior physicians meticulously annotated the audio samples. The annotations focused on identifying coarse crackles, wheezes, or normal respiratory sounds. Unlike the ICBHI 2017 database, our annotation process treated each audio sample in its entirety rather than splitting it into respiratory cycles. This approach reduces the need for extensive segmentation procedures and aligns with regular clinical practice. To enhance the quality of the annotations, we implemented an annotation validation flow called "cross-annotator model validation." This involved training multiple models based on each annotator's data and validating the models on data from other annotators. Any data with

XSL•FO
RenderX

incongruent predictions were initially identified. These data then underwent additional annotation by 3 senior physicians randomly selected from the original annotation team for each sample to achieve the final consensus label. The FABS database encompasses 5238 annotated recordings, with 715 containing coarse crackles, 234 containing wheezes, and 4289 labeled as normal respiratory sound recordings. The detailed comparison between the ICBHI 2017 dataset and the FABS database is shown in Table 1.

Table 1. Comparison between the International Conference in Biomedical and Health Informatics (ICBHI) and Formosa Archive of Breath Sound (FABS) datasets.

	ICBHI (n=126 patients)	FABS (n=1985 patients)
Age (y), mean (SD)	42.99 (32.08)	66.04 (17.64)
BMI (kg/m^2), mean (SD)	27.19 (5.34)	23.95 (4.72)
Sex, n (%)		
Male	79 (62.7)	974 (49.1)
Female	46 (36.5)	841 (42.4)
Unknown	1 (0.8)	170 (8.6)
Sampling rate (kHz)	4-44.1	16
Duration (hours)	5.5	14.6
Label	Crackle and wheeze, crackle, wheeze, and normal	Coarse crackle, wheeze, and normal
Equipment	AKG C417L microphone, Littmann Classic II SE stethoscope, Littmann 3200 electronic stethoscope, and Welch Allyn Meditron electronic stethoscope	CaRDIaRT DS101 electronic stethoscope

NTUH Clinical Noise Dataset

The noise dataset used in this study was sourced from the NTUH Hsin-Chu Branch. To replicate the noise sounds that physicians typically encounter in real-world clinical settings, we used the CaRDIaRT DS101 electronic stethoscope for collecting the noise samples. The NTUH clinical noise dataset consists of 3 different types of clinical noises: 8 friction noises produced by the stethoscope moving on different fabric materials; 18 environment noises recorded at various locations within the hospital; and 12 patient noises generated by patients during auscultation through conversations, coughing, and snoring.

Proposed Methods

As shown in Figure 1, our proposed noise-robust respiratory sound classification system includes two main components: (1) audio enhancement and (2) respiratory sound classifier.

Audio Enhancement Module

Audio enhancement is usually approached as a supervised learning problem [30,31,33-36,39,43], where the goal is to map noisy respiratory sound inputs to their clean counterparts. Mathematically, this task can be represented as learning a function f, mapping X_{noisy} to X_{clean}, where X_{noisy} represents the input noisy sound and X_{clean} denotes the corresponding clean sound. The enhanced output, X'_{clean}, is obtained as $X'_{clean}=f(X_{noisy})$ (1), where f is the audio enhancement model optimized during training.

To achieve high-quality enhancement, it is crucial to carefully select reference clean recordings from the respiratory sound database to generate high-quality paired noisy-clean sound data. To address this, we used an "audio-tagging filter" approach. This approach leverages a large pretrained audio-tagging model to identify clean samples and exclude recordings with irrelevant tags from the database. Specifically, we used the CNN14 pretrained audio neural network [53] that was trained on AudioSet [51], a comprehensive audio dataset containing 2,063,839 training audio clips sourced from YouTube covering 527 sound classes. Audio samples with the following audio event labels were filtered out: "music," "speech," "fire," "animal," "cat," and "domestic animals, pets." These labels were chosen as they were among the top commonest predictions of the audio-tagging model, indicating a higher likelihood of significant irrelevant noise in the recordings. By excluding these labels, we could ensure that the selected recordings could be used as reference clean audio. To validate the effectiveness of the filtering process, we manually checked the filtered recordings. The results showed that the tagging precision was 92.5%, indicating that this method is efficient and trustworthy. Moreover, as it is fully automatic, it is easy to reproduce the results.

In the ICBHI 2017 database, 889 clean audio samples were retained after filtering, consisting of 1812 cycles with crackling sounds, 822 cycles with wheezing sounds, 447 cycles with both crackling and wheezing sounds, and 3538 cycles with normal respiratory sounds. Alternatively, the filtered FABS clean samples comprised 699 recordings of coarse crackle respiratory sounds, 225 recordings of wheeze respiratory sounds, and 4238 recordings of normal respiratory sounds.

In this study, we used Wave-U-Net [46], Phase-and-Harmonics–Aware Speech Enhancement Network (PHASEN) [32], Multi-View Attention Network for Noise Erasure [49], and CMGAN [43] to compare the effectiveness of different model structures in enhancing respiratory sounds.

XSL•FO
RenderX

Respiratory Sound Classification

Training a classification model from scratch using a limited dataset may lead to suboptimal performance or overfitting. Therefore, we selected the CNN14 model proposed in the study by Kong et al [53], which had been pretrained on AudioSet [51], as our main classification backbone, and we further fine-tuned it on our respiratory datasets. We used log-mel spectrograms as the input feature, similar to previous works in respiratory sound classifications [6,9-11,14]. As the dataset is highly imbalanced, we used the balanced batch-learning strategy. To further improve model generalizability and performance, we incorporated data augmentation techniques, including Mixup [60] and SpecAugment [61], along with triplet loss [15,62] to enhance feature separability.

Mathematically, the classification task is formulated as a multi-class classification problem. The goal is to learn a mapping function, g: $Z \rightarrow Y$ (2), where Z represents the extracted features and Y denotes the target class labels. To obtain Z, input-enhanced audio signals X'_{clean} are transformed using the STFT to generate a spectrogram, followed by mel-filter banks to convert the frequency scale to the mel scale: Z=log-mel(STFT[X'_{clean}]) (3).

During training, the total loss function L_c combines cross-entropy loss and triplet loss: $L_c=L_{CE}+\lambda L_{triplet}$ (4).

Through grid search, λ=0.01 leads to the best performance.

Physician Validation Study

To further evaluate the effectiveness of audio enhancement for respiratory sound, we conducted a physician validation study using the clean, noisy, and enhanced recordings from a randomly selected 25% of the testing set on the ICBHI 2017 database. In this study, we invited 7 senior physicians to independently annotate these recordings without access to any noise level or respiratory sound class label. We instructed the physicians to label the respiratory class with a confidence score ranging from 1 to 5. The objective was to demonstrate that our proposed method not only enhances the performance of the classification model but also improves the accuracy of the respiratory sound classification and increases the confidence in manual judgment done by physicians. The physician validation study was a critical step in validating the clinical practicality and effectiveness of our proposed audio enhancement preprocessing technique in clinical settings.

Ethical Considerations

This study was approved by the institutional review board of the NTUH Hsin-Chu Branch (109-129-E) and complies with ethical guidelines for human research. It involved both prospective and retrospective data collection, with retrospective data fully deidentified to protect participant privacy. All prospective participants provided informed consent before data collection. No financial compensation was provided to participants, ensuring voluntary and unbiased participation.

Results

Overview

To assess the noise robustness of our proposed method, we conducted a comparative analysis using methods across various levels of noise intensity, as outlined in Textbox 1.

Textbox 1. Methods for various levels of noise intensity.

Clean

The respiratory sound classification models were only trained on clean data and tested on clean data. This approach served to establish the upper-bound performance for the overall comparison.

Noisy

The respiratory sound classification models were trained on clean data but tested on noisy data. As the models were not optimized for noise robustness, a significant drop in performance was expected.

Noise injection

The respiratory sound classification models were trained on synthesized noisy data and tested on noisy data. This approach represents the conventional method to enhance the noise robustness of the model.

Audio enhancement

The audio enhancement model functions as a front-end preprocessing step for the classification model. To achieve this, we first optimized the audio enhancement model to achieve a satisfactory enhancement performance. Subsequently, the respiratory sound classification model was trained on the enhanced data and tested on the enhanced data.

Experiment Setup

To evaluate the efficiency of our proposed method, we followed a similar setup as that in prior work [6,11,14] to have an 80%-20% train-test split on the database. Furthermore, the training set was mixed with the noise recordings from the NTUH clinical noise dataset with 4 SNRs (15, 10, 5, and 0 dB) with random time shifting. The test set was mixed with unseen noise data with 4 SNRs (17.5, 12.5, 7.5, and 2.5 dB), also subjected to random time shifting. For evaluation, we used the metrics of accuracy, sensitivity, specificity, and ICBHI score. Sensitivity is defined as the recall of abnormal respiratory sounds. Specificity refers to the recall of normal respiratory sounds. The ICBHI score, calculated as the average of sensitivity and specificity, provides a balanced measure of the model's classification performance.

XSL•FO
RenderX

Implementation Details

Technical Setup

The models were implemented using PyTorch (version 1.12; Meta AI) with the CUDA Toolkit (version 11.3; NVIDIA Corporation) for graphics processing unit acceleration. Training was conducted on an NVIDIA A100 graphics processing unit with 80 GB of memory. For clarity and reproducibility, the detailed implementation and computational setup is provided in Multimedia Appendix 1.

Preprocessing

We first resampled all recordings to 16 kHz. Next, each respiratory cycle was partitioned into 10-second audio segments before proceeding with feature extraction. In cases in which cycles were shorter in duration, we replicated and concatenated them to form 10-second clips in the ICBHI dataset. As the recordings in the FABS dataset are initially labeled per recording, there was no requirement for a segmentation process. Subsequently, these audio clips were mixed with the NTUH clinical noise dataset, generating pairs of noisy and clean data for further processing.

Enhancement Model Training

For enhancement model training, the 10-second audio clips were divided into 4-second segments. When implementing Wave-U-Net [43], the channel size was set to 24, the batch size was set to 4, and the number of layers of convolution upsampling and downsampling was set to 8. The model was trained using the Adam optimizer with a learning rate of 10^{-5} for 40 epochs when training using pretrained weights and 10^{-4} for 30 epochs when training from scratch. For the Multi-View Attention Network for Noise Erasure model [49], the channel size was set to 60, the batch size was set to 4, and the number of layers of up and down convolution was set to 4. The model was trained using the Adam optimizer with a learning rate of 10^{-6} for 10 epochs when training using pretrained weights and a learning rate of 10^{-5} for 10 epochs when training from scratch. When implementing PHASEN [32], which is trained in the time-frequency domain, we followed the original setup using a Hamming window of 25 ms in length and a hop size of 10 ms to generate STFT spectrograms. The number of 2-stream blocks was set to 3, the batch size was set to 4, the channel number for the amplitude stream was set to 24, and the channel number for the phase stream was set to 12. The model was trained using the Adam optimizer with a learning rate of 5×10^{-5} for 20 epochs when training using pretrained weights and a learning rate of 5×10^{-4} for 30 epochs when training from scratch. For CMGAN [43], we followed the original setting using a Hamming window of 25 ms in length and a hop size of 6.25 ms to generate STFT spectrograms. The number of 2-stage conformer blocks was set to 4, the batch size was set to 4, and the channel number in the generator was set to 64. The channel numbers in the discriminator were set to 16, 32, 64, and 128. The model was trained using the Adam optimizer with a learning rate of 5×10^{-5} for 20 epochs when training using pretrained weights and a learning rate of 5×10^{-4} for 30 epochs when training from scratch. These hyperparameters are also listed in Multimedia Appendix 2.

The pretrained weights for these models were trained on the VoiceBank+DEMAND dataset [44,45], which is commonly used in speech enhancement research.

Classification Model Training

For the classification model, the 4-second enhanced segments were concatenated back into 10-second audio clips. To generate the log-mel spectrogram, the waveform was transformed using STFT with a Hamming window size of 512 and a hop size of 160 samples. The STFT spectrogram was then processed through 64 mel filter banks to generate the log-mel spectrogram. In the training stage, we set the batch size to 32 and used the Adam optimizer with a learning rate of 10^{-4} for 14,000 iterations using pretrained weights from the model trained on the 16-kHz AudioSet dataset [51]. These hyperparameters are also listed in Multimedia Appendix 2.

Evaluation Outcomes

In this study, we compared the classification performance of conventional noisy data augmentation with our proposed audio-enhanced preprocessing. The test set was split into 2 groups, and each classification model was trained 10 times, yielding 20 values for statistical analysis. We conducted a 1-tailed *t* test to assess whether models trained on CMGAN-enhanced audio using pretrained weights showed significant improvements over other models. In addition, we reported speech quality metrics for various audio enhancement models and analyzed their correlation with classification performance.

The experiment results, as shown in Table 2, highlight the effectiveness of our proposed audio enhancement preprocessing strategy for noise-robust performances. In the case of the ICBHI 2017 database, the model trained solely on clean data experienced a 33.95% drop in the ICBHI score when evaluated on the synthesized noisy dataset. Noise injection improved the score by 19.73%, but fine-tuning PHASEN achieved the highest score, outperforming noise injection by 2.28%. Regarding the FABS database, using the classification model trained on clean recordings on the noisy recordings led to a 12.48% drop in the ICBHI score. Noise injection improved performance by 1.31%, but fine-tuning CMGAN outperformed noise injection by 2.79%. Across both datasets, the audio enhancement preprocessing method consistently improved performance compared to the noise injection augmentation technique. Furthermore, it showed improved sensitivity for all enhancement model structures, with the most significant improvement being 6.31% for the ICBHI database and 13.54% for the FABS database. This indicates that the audio enhancement preprocessing method enhanced the classification model's ability to distinguish abnormal respiratory sounds, which is crucial for the early detection of potential illnesses in clinical use.

[f]Second-best performance across all methods for this metric.

[g]MANNER: Multi-View Attention Network for Noise Erasure.

[h]CMGAN: convolution-augmented transformer–based metric generative adversarial network.

Comparing the 2 types of enhancement approaches, the time-frequency domain models (PHASEN and CMGAN) exhibited better performance in terms of ICBHI scores. In addition, CMGAN consistently showed high sensitivity across both datasets, indicating its potential for preserving respiratory sound features during audio enhancement. The spectrogram of the audio enhanced using CMGAN also revealed that it preserves more high-frequency information across all respiratory sound classes, as illustrated in Figure 2. In contrast, audio enhanced using other models either lost high-frequency information or retained too much noise, leading to misclassification as normal, resulting in higher specificity for those models. Moreover, we observed that, while our focus was on training a respiratory sound enhancement model, using pretrained weights from models trained on the VoiceBank+DEMAND dataset, which were originally designed for speech, still significantly improved classification performance in most cases. This highlights the cross-domain effectiveness of pretrained weights from the speech domain in respiratory sound tasks.

RenderX

To evaluate whether speech quality metrics, originally designed for speech, are effective for respiratory sounds, we analyzed their correlation with the ICBHI score and sensitivity. As shown in Table 3, the mean opinion score (MOS) of background noise intrusiveness (CBAK) and segmental SNR (SSNR) exhibited relatively higher correlations than other metrics, such as PESQ, STOI, the MOS of signal distortion, and the MOS of overall quality. Unlike these other metrics, which are primarily designed to assess speech intelligibility and quality, CBAK and SSNR focus on background noise intrusiveness and the SNR between recordings. This distinction explains why CBAK and SSNR show stronger correlations with classification performance, highlighting their potential applicability for respiratory sound analysis.

We evaluated the inference times of 4 audio enhancement models. Wave-U-Net generates 1 second of enhanced audio in just 1.5 ms, PHASEN does so in 3.9 ms, and MANNER does so in 11.7 ms. In contrast, CMGAN processes 1 second of audio in 26 ms—a longer time that is offset by its superior classification performance.

To further analyze the effectiveness of our proposed audio enhancement preprocessing method in handling different types of noise, we compared its performance using the noise injection method across various SNR levels. On the basis of the consistently outstanding performance of CMGAN across both datasets, we selected it for further analysis.

On the ICBHI database, as illustrated in Figure 3, the noise injection method performed better with environmental noises at SNR values of 2.5 and 12.5 dB. However, the front-end audio enhancement consistently performed better for patient and friction noises across almost all noise levels.

Regarding the FABS dataset, as shown in Figure 4, the noise injection method performed better with environmental and friction noises at an SNR value of 17.5 dB and patient noises at an SNR value of 2.5 and 7.5 dB. In all other situations, the audio enhancement preprocessing method demonstrated superior ICBHI scores.

These results suggest that our proposed strategy effectively mitigates the effects of various noise types while maintaining strong classification performance. This highlights the robustness and reliability of our approach in handling diverse noise scenarios and intensities, showcasing its potential for practical applications in clinical settings.

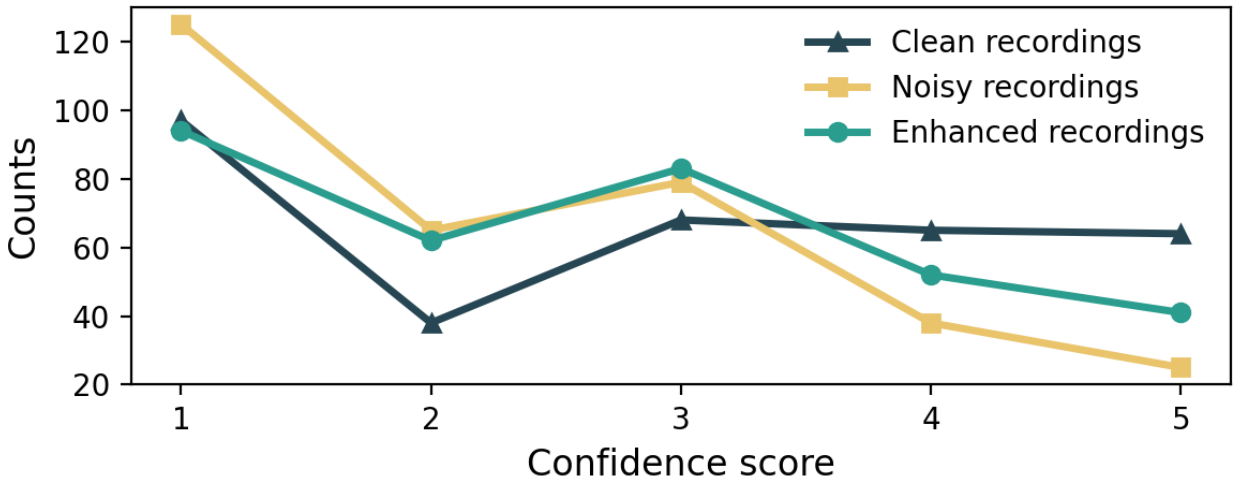
Physician Validation Study

To assess the practical utility of our proposed approach in clinical settings, we conducted a physician validation study using the ICBHI dataset. This study involved comparing the annotation results provided by 7 senior physicians under 3 different conditions: clean, noisy, and enhanced recordings. By evaluating physician assessments across these conditions, we aimed to determine the effectiveness of our enhancement approach in improving diagnostic accuracy and confidence.

As shown in Table 4, the presence of noise in the recordings had a noticeable impact on the physicians' ability to conduct a reliable judgment, reducing accuracy by 1.81% and sensitivity by 6.46% compared to the clean recordings. However, the recordings with audio enhancement exhibited notable improvement, with a 3.92% increase in accuracy and an 11.61% increase in sensitivity compared to the noisy recordings. The enhanced audio successfully preserved sound characteristics crucial for physicians in classifying respiratory sounds, leading to higher true positive rates in distinguishing adventitious sounds.



The enhanced audio recordings also received higher annotation confidence scores than the noisy recordings, as indicated in Figure 5 and Table 4. Moreover, the speech quality metrics PESQ, MOS of signal distortion, CBAK, MOS of overall quality, SSNR, and STOI positively correlated with the physicians' annotation confidence, as shown in Figure 6. These results underscore the potential of audio enhancement preprocessing techniques for practical application in real-world clinical settings.

Table 4. Annotation results from physicians on different types of recordings.

Type of recording	Accuracy (%)	Sensitivity (%)	Specificity (%)	ICBHI[a] score (%)	Confidence mean (SD)
Clean	49.4	23.23	72.32	47.77	2.88 (1.50)
Noisy	47.59	16.77	74.58	45.68	2.32 (1.29)
Enhanced	51.51	28.38	71.75	50.07	2.65 (1.36)

Ablation Study

Other Classification Model

To assess the effectiveness of our proposed speech enhancement preprocessing technique with different classification models, we conducted an ablation study. The hyperparameters used in this study are detailed in Multimedia Appendix 2. We used the fine-tuned CMGAN as the speech enhancement module as it showed consistently outstanding performance in previous experiments, as shown in Table 2.

For the ICBHI dataset, the speech enhancement preprocessing technique increased the sensitivity by 11.71% and the ICBHI score by 1.4% when using the AST model [54]. Similarly, when using the AST model with the Patch-Mix strategy [16], the speech enhancement preprocessing technique increased the sensitivity by 17.08% and the ICBHI score by 1.6%, as shown in Tables 5 and 6.

Regarding the FABS dataset, the speech enhancement preprocessing technique increased the sensitivity by 18.48% and the ICBHI score by 5.46% when fine-tuning the AST model [54]. When fine-tuning the AST model using the Patch-Mix strategy [16], the speech enhancement preprocessing technique increased the sensitivity by 13.04% and the ICBHI score by 0.68%, as shown in Tables 7 and 8.

These results demonstrate that the speech enhancement preprocessing technique effectively improves the performance of various respiratory sound classification models, including fine-tuning the AST and AST using the Patch-Mix strategy, on both the ICBHI and FABS datasets.

Metric Discriminator

Given that the metric discriminator optimizes PESQ, a metric primarily used in the speech domain for speech quality, a potential mismatch problem may arise when applied to respiratory sound tasks. To explore this issue, we conducted ablation studies on CMGAN's discriminator, examining the conformer generator-only model, the conformer generative adversarial network without PESQ estimation discriminator (with normal discriminator), and the complete setup (with metric discriminator). As shown in Table 9, the addition of a metric discriminator improved overall accuracy, sensitivity, and ICBHI score. This outcome indicates a positive contribution of the metric discriminator on PESQ to respiratory sound classification.

Table 9. Classification results of the convolution-augmented transformer–based metric generative adversarial network with different discriminator setups on the International Conference in Biomedical and Health Informatics (ICBHI) 2017 database.

Setup	Accuracy (%)	Sensitivity (%)	Specificity (%)	ICBHI score (%)
Generator only	65.81	58.21	72.42	65.32
With normal discriminator	66.19	55.61	75.39	65.5
With metric discriminator	66.72	62.28	70.58	66.43

Discussion

Principal Findings

This paper proposes a deep learning audio enhancement preprocessing pipeline for respiratory sound classification tasks. We also introduced a collection of clinical noise and a real-world respiratory sound database from the emergency department of the Hsin-Chu Branch at the NTUH. Our noise-robust method enhances model performance in noisy environments and provides physicians with improved audio recordings for manual assessment even under heavy noise conditions.

The experimental results indicated that audio enhancement significantly improved performance across all 3 types of noise commonly encountered during auscultation. Specifically, our approach achieved a 2.15% improvement (P<.001) over the conventional noise injection method on the ICBHI dataset and outperformed it by 2.79% (P<.001) on the FABS dataset. Moreover, time-frequency–domain enhancement techniques demonstrated superior performance for this task. Analyzing the

XSL•FO
RenderX

correlation between classification performance and speech quality metrics, we observed that CBAK and SSNR exhibited higher correlations with ICBHI scores. These metrics are strongly influenced by background noise but are unrelated to speech intelligibility, aligning with the experimental settings. In the physician validation study, enhanced recordings showed an 11.61% increase in sensitivity and a 14.22% improvement in classification confidence. A positive correlation was also observed between speech quality metrics and diagnostic confidence, highlighting the effectiveness of enhanced recordings in aiding physicians in detecting abnormal respiratory sounds. Our ablation study on various classification model structures revealed that audio enhancement preprocessing consistently improved performance. The findings showed enhanced sensitivity and higher ICBHI scores across both databases when tested with 2 state-of-the-art respiratory sound classification models. Furthermore, incorporating the metric discriminator PESQ was found to enhance downstream classification performance.

These findings validate the feasibility and effectiveness of integrating deep learning–based audio enhancement techniques into respiratory sound classification systems, addressing the critical challenge of noise robustness and paving the way for the development of reliable clinical decision support tools.

Limitations and Future Work

Despite the encouraging findings in this study, there is a need to explore the co-optimization of front-end audio enhancement and classification models. As most audio enhancement tasks primarily focus on speech, the evaluation metrics are not highly correlated with respiratory sounds, potentially leading to inefficient optimization. Addressing this issue is crucial for achieving better performance in respiratory sound classification in future work. Furthermore, future studies should incorporate other types of noise and more complex noise mixture strategies to enable the development of a more noise-robust respiratory sound classification model for real-world clinical use. By considering a diverse range of noise scenarios, the model can be better prepared to handle the variability and challenges encountered in actual clinical settings. In addition, we have to speed up the model inference by simplifying the model to make it suitable for real-time applications. At the same time, we must ensure that enhancement quality is maintained and critical respiratory sound characteristics are preserved. In our long-term future work, we aim to deploy this model in real clinical environments by integrating it into electronic stethoscopes. To ensure the method's generalizability, we plan to collect cross-site respiratory sound recordings from 100 patients across various clinical environments. Of these recordings, data from 80 patients will be used for training, whereas data from the remaining 20 patients will be reserved for testing as part of a validation process aligned with Food and Drug Administration requirements. This approach will help validate the model's performance and facilitate its adoption for practical use in clinical settings.

Conclusions

In this study, we investigated the impact of incorporating a deep learning–based audio enhancement module into automatic respiratory sound classification systems. Our results demonstrated that this approach significantly improved the system's robustness and clinical applicability, particularly in noisy environments. The enhanced audio not only improved classification performance on the ICBHI and FABS datasets but also increased diagnostic sensitivity and confidence among physicians. This study highlights the potential of audio enhancement as a critical component in developing reliable and trustworthy clinical decision support systems for respiratory sound analysis.

Abstract

Background: Although large language models (LLMs) show great promise in processing medical text, they are prone to generating incorrect information, commonly referred to as hallucinations. These inaccuracies present a significant risk for clinical applications where precision is critical. Additionally, relying on human experts to review LLM-generated content to ensure accuracy is costly and time-consuming, which sets a barrier against large-scale deployment of LLMs in health care settings.

Objective: The primary objective of this study was to develop an automatic artificial intelligence (AI) system capable of extracting structured information from unstructured medical data and using advanced reasoning techniques to support reliable clinical decision making. A key aspect of this objective is ensuring that the system incorporates self-verification mechanisms, enabling it to assess the accuracy and reliability of its own outputs. By integrating such mechanisms, we aim to enhance the system's robustness, reduce reliance on human intervention, and improve the overall trustworthiness of AI-driven medical summarization and evaluation.

Methods: The proposed framework comprises 2 layers: a summarization layer and an evaluation layer. The summarization layer uses Llama2-70B (Meta AI) and Mistral-7B (Mistral AI) models to generate concise summaries from unstructured medical data, focusing on tasks such as consumer health question summarization, biomedical answer summarization, and dialog summarization. The evaluation layer uses GPT-4-turbo (OpenAI) as a judge, leveraging pairwise comparison strategies and different prompt strategies to evaluate summaries across 4 dimensions: coherence, consistency, fluency, and relevance. To validate the framework, we compare the judgments generated by the LLM assistants in the evaluation layer with those provided by medical experts, offering valuable insights into the alignment and reliability of AI-driven evaluations within the medical domain. We also explore a way to handle disagreement among human experts and discuss our methodology in addressing diversity in human perspectives.

Results: The study found variability in expert consensus, with average agreement rates of 19.2% among all experts and 54% among groups of 3 experts. GPT-4 (OpenAI) demonstrated alignment with expert judgments, achieving an average agreement rate of 83.06% with at least 1 expert and comparable performance in cross-validation tests. The enhanced guidance in prompt design (prompt-enhanced guidance) improved GPT-4's alignment with expert evaluations compared with a baseline prompt, highlighting the importance of effective prompt engineering in auto-evaluation of summarization tasks. We also evaluated open-source LLMs, including Llama-3.3 (Meta AI) and Mixtral-Large (Mistral AI), and a domain-specific LLM, OpenBioLLM (Aaditya Ura), for comparison as LLM judges.

Conclusions: This study highlights the potential of LLMs as reliable tools for unstructured medical data summarization and evaluation to reduce the dependency on human experts and also states the limitations. The proposed framework, multiagent summarization and auto-evaluation, demonstrates scalability and adaptability for clinical applications while addressing key challenges like hallucination and position bias.

Introduction

In the era of big data, health care presents unique challenges for researchers, particularly due to the vast amount of unstructured data that can significantly impact patient outcomes [1]. A key challenge is extracting structured information from unstructured medical texts to facilitate search, analysis, and summarization for clinical decision-making [2]. Automatic systems often struggle with information extraction and summarization from medical data due to the length and noise in clinical texts [3], making accurate interpretation challenging.

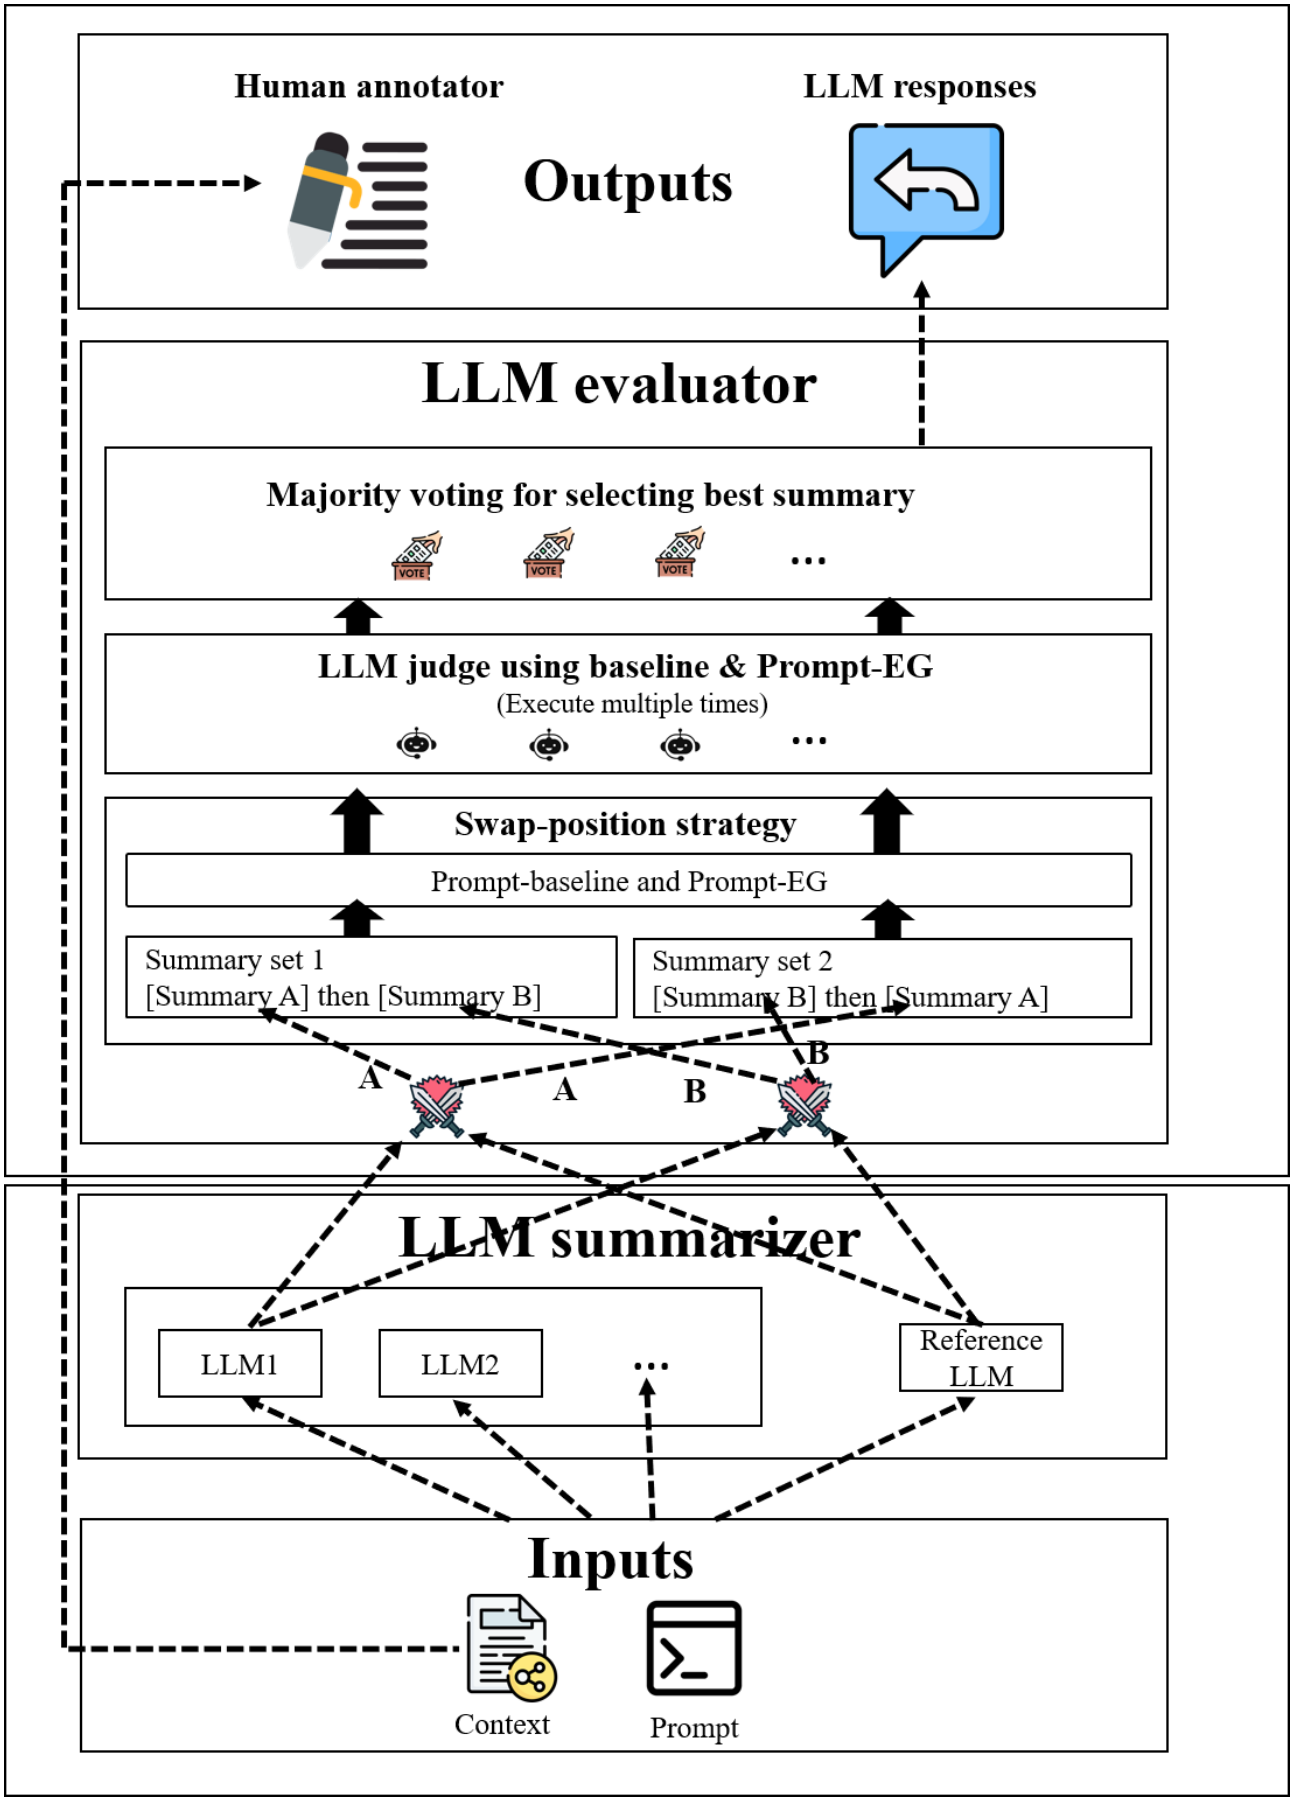
The rapid advancement of artificial intelligence (AI) is transforming the health care sector with large language models (LLMs) like GPT-4 (OpenAI) [4], which demonstrate impressive capabilities across a range of medical tasks [5-9]. For instance, older models like Med-PaLM (Google AI) and, subsequently, Med-PaLM 2 (Google AI), achieved 67.2% and 86.5%, respectively, on medical question text summarization tasks with US Medical Licensing Examination–style questions. Newer LLMs like GPT-4, on the other hand, achieved an impressive 90% accuracy on US Medical Licensing Examination questions, outperforming human test-takers [5]. GPT-4 also ranked within the top 10% of all participants on German medical licensing exams among medical students [6]. Other models, such as Gemini (Google) [10,11] and OpenBioLLM (Aaditya Ura) [12,13], have also shown robust performance in analyzing medical data. Such results highlight LLMs' potential to support medical education and examination systems and aid health care practitioners in evidence-based decision support. However, despite these promising developments, LLM applications in health care remain primarily experimental. One of the critical limitations is hallucination, where LLMs generate content that is incoherent or factually incorrect [14,15]. This issue poses significant risks in clinical settings, as hallucinated outputs can lead to erroneous diagnoses, inappropriate treatments, mental distress, and reduced trust in AI-driven systems. Conventional similarity-based evaluation metrics, such as ROUGE [16] and BERTScore [17], are not able to detect hallucinations. Moreover, these similarity-based automatic evaluation metrics require expert-generated gold standard summaries. Compared with other domains, medical text annotation requires expertise from specialized health care professionals, making it significantly more expensive. With the success of the advancements of LLM models, there has been a growing interest in developing human-free automatic evaluation frameworks that can leverage LLM's capabilities.

This research is motivated by the growing need for accurate medical summaries, which are critical for clinical reviews, assessments for insurance, and audit processes. The vast volume of medical data generated every day, such as patient records and laboratory results, highlights the demand for advanced automatic summarization technologies. Traditional methods, such as manual summarization or rule-based systems, often struggle to efficiently extract relevant information, leading to delays or inaccuracies in clinical workflows.

To address these challenges, this study aims to answer the following primary research question: "How to build an AI system that can self-evaluate its performance across various medical summarization tasks?" It specifically explores the following key aspects:

1. How well can LLMs generate summaries from medical domain-specific data?
2. How do prompt design and position bias influence the reliability of LLM-based evaluations, and how to enhance the reliability?
3. How do LLMs perform compared with human experts in evaluating the generated summaries in terms of reliability?

To answer the above questions, this study focuses on developing an automatic medical question, dialog, and descriptive text summarization and evaluation system, multiagent summarization and auto-evaluation (MASA), which serves as a case study to explore how LLMs can improve the extraction of essential insights from complex, unstructured medical data. The key objectives include ensuring medical accuracy, relevance, and proper evaluation of the generated summaries, as a foundational step toward broadening AI applications in health care data processing. Notably, this work presents one of the first multiagent frameworks that integrates open-source summarization models (Llama [Meta AI] and Mistral [Mistral AI]) with an LLM as a judge (GPT-4), and evaluates its performance. We study its agreement with human experts across diverse medical summarization tasks using 5 distinct datasets (MEDIQA-QS, MeQSum, MEDIQA-ANS, MEDIQA-MAS, and MedDialog-EN). We also assess some of the newer LLMs, such as Llama 3 (Meta AI), Mixtral-Large (Mistral), and OpenBioLLM (Aaditya Ura) to provide a brief comparison of their performance as evaluators.



Methods

Overview

The overall architecture of our proposed system is illustrated in Figure 1, which represents a multilayer LLM agent network composed of 2 distinct layers. It is inspired by IBM's SOLOMON (System for Optimizing Language Outputs through Multi-agent Oversight Networks) framework [18]. The 2-layer approach implements a comprehensive processing pipeline that distills and validates medical information, contributing to more effective and timely health care decision support.

Summarization Layer

The network begins with a summarization layer, where LLM summarizers extract key information from unstructured data sources such as patient inquiries, doctor-patient conversations, and detailed question answers. This initial layer focuses on transforming lengthy and disorganized medical content into concise summaries that retain essential information for further analysis.

Evaluation Layer

Overview

The second layer, the evaluation layer, deploys LLM judges to assess the quality of the summaries generated by the summarization layer. Rather than using judges to grade each LLM's summaries sequentially, we implement a pairwise comparison strategy where LLM judges compare and evaluate a pair of summaries to determine the superior one. This approach enables judges to focus on the subtle differences between the 2 responses, highlighting strengths and weaknesses that might otherwise be overlooked, thereby enhancing the overall precision of the evaluation process.

We adopt the *Referenced Condorcet Assessment (RCA*) [19] approach to optimize the pairwise evaluation process. Instead of comparing every model's output against all others, RCA designates one "reference LLM" summarizer in the summarization layer and compares each model's output against this reference. In a general pairwise evaluation, n(n-1)2 comparisons are required for *n* LLM summarizers. With RCA, we significantly reduce the required number of comparisons to *n-1*, optimizing computational efficiency while maintaining accuracy in identifying high-quality summaries. By establishing a consistent reference point, RCA ensures consistent evaluation across different datasets. This approach provides reproducibility and improves the overall efficiency of the AI-evaluation layer.

Confidence and Bias in Evaluation

We implement a *majority voting mechanism* using multiple independent runs of the same LLM evaluator to enhance confidence in the decision. A final decision is reached when more than half of the evaluators agree; otherwise, the result is marked as a tie.

To address *position bias*, where the order of input summaries affects the evaluation outcome, we use a *swap-position strategy*. This involves evaluating each summary pair twice, the second time with reversed ordering. A summary is declared the winner only if it is preferred in both evaluations; otherwise, the outcome is considered a tie.

The name of the LLM summarizer is hidden in the evaluation process to promote anonymous and fair judgment. In the final step, when comparing outcomes with human experts, the same setting is used for human evaluators to ensure anonymity, fairness, and mitigate bias. Specifically, the source of each summary is anonymized, and the presentation order of summaries is randomized to minimize potential ordering and source biases.

LLM Model Selection

We select 2 open-source LLMs to generate summaries in the summarization layer. At the time of this study, Llama2 was the state-of-the-art (SOTA) open-source model, making the *Llama2-70B-chat-hf version* an ideal choice [20]. We also selected *Mistral-7B-Instruct-v0.1*, which was optimized for faster inference and demonstrated superior performance, surpassing the larger Llama2-13B model in some tasks [21]. By choosing 2 different LLMs, we benefit from both Mistral's strong performance and architectural diversity and reduce the risk of model-specific biases. We select GPT-3.5 (turbo) as the reference LLM for RCA because, compared with LLMs of similar generation in the Claude and Gemini families, GPT-3.5 (turbo) has been significantly more widely adopted in previous research and consistently used as a strong baseline in a variety of research [6,8].

For evaluation, we primarily selected the paid version of GPT-4 (turbo) as a judge, which was the SOTA LLM reasoning model at the time of this study [4]. Subsequently, we incorporated additional open source LLM evaluators, including Llama-3.3-70B-Instruct, Mixtral-large, and OpenBioLLM-70B. OpenBioLLM-70B [12] is a model trained on large-scale biomedical corpora. These models were used to examine variation in automated judgments and to assess their alignment with expert human evaluations. A summary of all the LLM models used in this study is illustrated in Table 1.

XSL•FO

[b]Sum: summarizers.

[c]Ref: reference models.

[d]Eval: evaluators.

Furthermore, 2 key aspects of the proposed architecture and methodology include the adaptability to use any LLM in each of the layers and the robust information processing framework.

Data Sources

We do not fine-tune any of the LLMs on the selected datasets. We validate our system for three distinct summarization tasks with different benchmark datasets presenting diverse challenges as described below. These datasets are commonly used in medical text analysis tasks [22].

Task 1: Consumer Health Question Summarization

Patients often ask detailed and complex health-related questions. The primary difficulty lies in reducing redundancy while preserving critical medical details. This challenge has been explored in benchmark datasets such as MEDIQA-QS [23] and MeQSum [24], both of which contain consumer health questions with gold-standard summaries crafted by medical experts. Consumer health question summarization can help to analyze service quality, consumers' needs and concerns, and thereby improve support quality.

MEDIQA-QS comprises deidentified consumer health questions sourced from the US National Library of Medicine. The *MeQSum* dataset contains 1000 consumer health questions to facilitate natural language processing (NLP) research specifically for the medical field.

Task 2: Biomedical Answer Summarization

Answers to biomedical queries from multiple sources or services must be aggregated to produce a coherent summary. This task poses 2 main challenges: first, extracting and generating relevant nonredundant information based on the input question, and second, ensuring consistency across diverse information sources. In this study, we focus on addressing the second challenge by aggregating and summarizing multiple relevant responses to a single medical query. We conduct our analysis using MEDIQA-ANS [25] and MEDIQA-MAS [23] datasets.

MEDIQA-MAS consists of collections of responses to specific health-related queries, along with summaries created by experts that integrate information from multiple answers into a single coherent summary. *MEDIQA-ANS* contains health questions asked by consumers, their corresponding answers, and expert-created summaries. The dataset is sourced from reliable organizations such as MedlinePlus and derived from questions submitted to the National Library of Medicine's CHiQA system.

Task 3: Dialog Summarization

Online medical advising uses interactive chat or voice to learn customer needs and provides appropriate responses based on expert knowledge. Key challenges in processing the data include handling informal expressions, identifying and filtering relevant medical information, and maintaining the temporal context of symptoms and events. Dialogue summarization is also important to learn about previous interactions with the same consumer to provide informed responses. We perform the task of producing a summary of a patient's medical condition from a dialogue between the patient and the doctor and validate our approach using the MedDialog-EN [26] dataset.

MedDialog-EN is an extensive collection of real-life anonymized medical consultations between patients and physicians. It covers a wide range of medical inquiries and responses, demonstrating a doctor's approach to various health problems.

We confirm that Tasks 1 and 2 datasets are published under the Creative Commons Attribution 4.0 International License (CC BY 4.0), which permits unrestricted use, distribution, and reproduction in any medium, provided the original work is properly cited. For Task 3, we have obtained explicit written permission from the original authors to reuse their content in this study, including its integration via the OpenAI application programming interface.

Prompt Design

We explore the impact of prompt design on the performance of LLMs across both layers in our framework, performing summarization and evaluation.

Prompt Design for Summarizer

For effective benchmarking and comparison with existing research for the summarizer, we leverage the established prompt templates proposed by Jahan et al [27] as a foundation. Examples of prompts are given in Multimedia Appendix 1. The designed constant prompt for all the summarizer LLMs serves

XSL•FO
RenderX

as a control variable and allows for the analysis of different prompt design approaches for the evaluator, ensuring that any variations in performance are attributed to the evaluator's prompt design rather than changes in the summarizer's prompt.

Prompt Design for Evaluator

Overview

For the evaluator, we introduce 2 custom prompt design approaches and systematically assess how variations in evaluator prompts influence the quality and reliability of the evaluation process. By comparing the prompts and outcomes, we aim to identify optimal strategies for leveraging LLMs as evaluators in summarization evaluation tasks.

Prompt Baseline

Our initial prompt design (Multimedia Appendix 1) for evaluator LLMs is inspired by the work of Zheng et al [28], which pioneers the use of LLM as a judge in evaluating the performance of other LLMs in primarily question-answering tasks. We adapt their approach for summarization tasks by enhancing the prompt to ensure that GPT-4 focuses on 4 key evaluation criteria commonly used by humans: *coherence*, *consistency*, *fluency*, and *relevance*. Additionally, we include statements in defining the baseline prompt for the evaluator LLMs to mitigate positional bias so that the order of summaries does not influence the LLM's judgment.

Prompt-Enhanced Guidance

Based on the observation of the performance of the baseline prompt, several aspects of the baseline prompt require improvements to make the prompt more focused and less ambiguous. In *prompt-baseline*, terms used to define the evaluation criteria, namely "coherence," "consistency," "fluency," and "relevance," lack clear operational definitions and lead to inconsistencies in evaluation. We propose *prompt-enhanced guidance* (EG), a significantly more comprehensive prompt template that provides clearer and more detailed instructions. The update includes detailed descriptions of the 4 key evaluation criteria and integrates a chain-of-thought [29] guideline, which guides GPT-4 through a structured, step-by-step evaluation process. Prompt-EG also introduces several new instructions for: (1) balancing brevity and detail to facilitate the selection of a high-quality summary; (2) detecting hallucinations to remove improper content from the generated summary, and (3) ensuring factual consistency, which is the most critical evaluation factor in the medical domain. The prompt template is explained in Multimedia Appendix 1.

Experiments

To evaluate the efficacy of our 2-layer framework, we perform rigorous experimentation on 3 summarization tasks using unstructured medical questions, dialogues, and long descriptive question answers. Examples of a few data samples used in the study are illustrated in Multimedia Appendix 2.

Evaluation by LLM

Each LLM evaluator compares a pair of anonymized summaries generated by 2 LLM assistants (A and B with no model names), and generates A, B, or a tie as the outcome. The same evaluation is conducted by human medical experts given the same summary data and evaluation criteria, and interrater agreements are analyzed.

Evaluation by Human Experts

A panel of 4 medical experts independently evaluated randomly selected 250 sample summary pairs, indicating their preferences based on clinical accuracy, completeness, and clarity. All experts received a standardized written guideline outlining the evaluation criteria, namely coherence, consistency, fluency, and relevance. For each pair, experts were instructed to select the better summary or mark them as a "tie" when both pairs were judged to be of equivalent quality. Experts were also allowed to abstain from evaluating specific pairs if the content was ambiguous, outside their area of expertise, or otherwise unsuitable for judgment. As a result, the final sample size included 246 evaluated summary pairs (47, 49, 50, 50, and 50 from the five datasets, respectively). All expert annotators participated voluntarily and did not receive financial compensation. Due to time and cost constraints, we could only recruit 4 human experts in this study. In addition to expert evaluation, 2 human annotators without formal medical education were recruited to assess the same summary pairs. These nonexpert annotators collaborated to reach a joint decision for each pair, using the same evaluation guidelines as the experts. This comparison allowed us to examine potential alignment and discrepancies between expert and nonexpert judgments. To assess the performance of the LLM judge, we compared the agreement rate (AR) between human annotators and the LLM judge for the summaries produced by LLaMA-2-70B and GPT-3.5.

Validation Criteria

We designed a comprehensive validation process that assesses the following capabilities of our 2-layer framework.

First, LLM-based summarization and evaluation were conducted by (1) evaluating the quality of the generated summaries, and (2) evaluating the impact of prompt design on evaluation consistency.

Second, inaccuracy detection (remove if not do) and bias mitigation were assessed by (1) inspecting task-specific trends and position bias; (2) analyzing the strengths and weaknesses of the framework's hallucination detection; (3) analyzing agreement patterns between the LLM evaluator and human experts when selecting the better summary from a pair; and (4) investigating causes of disagreement by examining alignment among human experts, nonexperts, and LLMs across summarization tasks with varying data complexity.

Finally, the applicability of the framework in real life was assessed by (1) analyzing agreement patterns between the LLM evaluator and human experts when selecting the better summary from a pair, and (2) investigating causes of disagreement by examining alignment among human experts, nonexperts, and LLMs across summarization tasks with varying data complexity.

Specific experimental setups are reported with the outcomes under the results section using a set of evaluation metrics as discussed below.

XSL•FO
RenderX

Evaluation Metrics

AR

We compute AR to show how often judges agree by selecting the same summary as the preferred one or a tie in pairwise evaluations. We compute AR between LLM and human judges as well as among different subgroups of judges, as human judges tend to disagree due to subjective opinions. AR reflects alignment in judgment and is mainly used to compare the consistency of LLM versus human preferences. A higher AR indicates stronger agreement. Formal definitions are provided in Multimedia Appendix 3.

Cohen κ Scores

We also compute pairwise Cohen κ scores for each dataset to assess interrater reliability among the 4 expert annotators' variation in judgments.

Win Rate

Win rate (WR) captures the proportion of evaluation instances in which one LLM's summary is preferred over another. This metric is used to compare the relative performance of summarization LLMs.

Bootstrapped CIs

We perform statistical tests (bootstrapping) and report the CIs to rigorously assess the significance of our evaluation results. For each test, we generate 10,000 resamples with replacement from the original 246 data samples. The following analyses are conducted:

First, prompt EG versus baseline (95% CI for AR difference): We conduct a bootstrap resampling test (10,000 iterations) to compare the ARs between prompt-EG and the baseline prompt. Specifically, we measure the proportion of bootstrap samples where Prompt EG's agreement with expert annotations is greater than or equal to the baseline's. We report the 95% CI for each prompt's AR.

Second, LLaMA 2 versus GPT-3.5 WR (95% CI for WR comparison): We similarly used bootstrap resampling to compare the WRs between LLaMA 2 and GPT-3.5. We computed the 95% CI, LLaMA 2 wins over GPT-3.5 under bootstrap resampling. This allows us to quantify the significance of LLaMA 2's performance advantage in a nonparametric manner.

Finally, agreement between 2 annotators (95% CI for AR): This bootstrap method estimates the 95% CI for the AR between any 2 sets of labels, regardless of whether they are from experts, nonexperts, or models. Through 10,000 resamples, we measure the variability in agreement to assess the consistency between raters and the robustness of the observed alignment.

Ethical Considerations

This study was reviewed and approved by the Queen's University Health Sciences and Affiliated Teaching Hospitals Research Ethics Board (Tools for Research at Queen's #6041269). The evaluation survey was administered through an approved secure online platform. An informed consent form outlining the study's objectives, procedures, and participants' rights was presented at the beginning of the survey. Participation was entirely voluntary, and respondents were informed of their ability to withdraw at any time before submission. All responses were collected anonymously and analyzed in aggregate to ensure privacy and confidentiality.

Results

Overview

To systematically assess the effectiveness of our proposed framework, we conducted a series of experiments designed to evaluate both the summarization and evaluation layers. These experiments provide a comprehensive assessment of LLMs' summarization capabilities in medical contexts while acknowledging inherent limitations. The results are organized and presented following the validation criteria discussed earlier. Examples of GPT-4's judgments are presented in Multimedia Appendix 2.

LLM-Based Summarization and Evaluation

Comparative Performance of Llama-2-70B and Mistral-7B Across Datasets

Our first experiment focused on comparing the summarization quality of Llama-2-70B and Mistral-7B across multiple medical summarization datasets. Table 2 presents WRs against GPT-3.5 as a reference point. Llama-2-70B consistently achieved higher WRs than GPT-3.5 across all datasets, whereas Mistral-7B generally performed below GPT-3.5. These comparative results suggest Llama-2-70B's superior performance in medical summarization tasks within our experimental framework. More detailed comparisons have been illustrated in Table 3. In Table 3, we ignored tie cases in order to provide a clearer comparative analysis. On average, Llama-2-70B achieved a WR of 65.9% against GPT-3.5 when judged by GPT-4, with a 95% CI of 48.7%-78.9%. Expert evaluations similarly favored Llama-2, with an average win rate of 68.3% and a 95% CI ranging from 50.2% to 85.2%. The expert interval lies entirely above the 50% threshold, indicating a statistically significant preference for Llama-2. While the GPT-4 interval extends above 50%, its lower bound of 48.7% is only marginally below the threshold, suggesting a favorable trend but not a statistically significant difference. Both intervals suggest that LLama-2 is more likely to outperform GPT-3.5 in real-world summarization tasks.

XSL•FO
RenderX

Table . Pairwise win rate (%) of Llama2-70b and Mistral-7b against GPT-3.5 as a reference across the different medical summarization datasets at the summarization layer of our framework. These summaries are then evaluated by GPT-4 and medical experts. The win rate indicates the percentage of instances where GPT-4 or medical experts determined that a given model produced a superior summary. The "tie" column represents cases where GPT-4 found no clear preference between the models.

[a]WR: win rate.

Impact of Prompt Design on Evaluation Consistency

Next, we examined how variations in prompt design affected the consistency of GPT-4's assessments with expert judgments. Section A in Table 4 compares ARs between GPT-4 and expert majority decisions across different prompt strategies. The prompt-EG approach generally outperformed the baseline strategy, achieving higher alignment with expert consensus for most datasets. This result highlights the importance of effective prompt engineering in improving LLMs' evaluation consistency, although the improvements vary by task type and dataset characteristics. While the bootstrapped 95% CIs for AR differences (prompt-EG−baseline) include zero in all cases, indicating that these improvements may not be statistically significant at the dataset level. However, baseline WR measures the proportion of bootstrap resamples where the baseline outperformed prompt-EG. The rate remained consistently low (eg, 7.6% on MEDIQA-QS and 14.6% on MedDialog-EN), suggesting that prompt-EG outperformed or matched the baseline in the vast majority of resampled scenarios. These findings reinforce the robustness and practical advantage of prompt-EG, even when absolute AR gains appear modest.

XSL•FO
RenderX

Table . Agreement rates between the GPT-4 judge and the majority decision of four human experts across 5 datasets, covering prompt strategies (baseline vs prompt-enhanced guidance), summarization models (GPT-3.5 and LLaMA2-70B), and position bias conditions. Section A compares agreement rates across prompts; section B reports the position bias ratio under prompt-enhanced guidance; and section C presents agreement rates for all samples and separately for samples with and without position bias. Full calculation details are provided in S1.4 in Multimedia Appendix 3.

Dataset	MEDIQA-QS	MeQSum	MEDIQA-ANS	MEDIQA-MAS	MedDialog-EN	Average, mean (SD)
Section A: prompt comparison						
Baseline AR[a]%	42.55	42.86	62.00	44.00	48.00	47.88 (8.19)
Prompt-EG[b] AR%	51.06	46.94	57.99	48.00	54.00	51.00 (4.52)
95% CI	−4.3to 21.3	−6.1 to 14.3	−16.0 to 8.0	−6.0 to 16.0	−6.0 to 18.0	−7.7 to 15.5

Inaccuracy Detection and Bias Mitigation

Inspecting Task-Specific Trends and Position Bias

Position bias, where the order of presented summaries influences evaluation outcomes, poses a methodological challenge in LLM-based assessments. To address this, we implemented a swap-position strategy, evaluating summaries in reverse order to detect and mitigate ordering effects.

Section B in Table 4 illustrates the position bias proportion for each dataset. Interestingly, position bias was much higher in answer summarization (eg, MEDIQA-ANS and MEDIQA-MAS) and dialogue summarization (eg, MedDialog-EN) tasks compared with question summarization tasks (eg, MEDIQA-QS and MeQSum). Our analysis indicates that GPT-4 exhibits greater variability in longer and more complex summarization tasks—particularly in answer summarization and dialogue summarization. These tasks often involve layered information, implicit reasoning, and multiple clinically relevant details, making evaluation more subjective and error-prone.

Section C in Table 4 illustrates agreement patterns under different sample conditions. Our analysis revealed task-dependent patterns in performance. For *question summarization* (eg, *MEDIQA-QS*) and *dialogue summarization* (eg, *MedDialog-EN*), ARs were higher for samples with position bias. Further investigation shows that in these position-biased samples, experts themselves often produced diverse evaluations, resulting in ties or divergent decisions. This diversity suggests that summary quality in these cases was subjectively equal, with no clear superior option. GPT-4's position bias likely stems from sampling different human perspectives from its pretraining knowledge—when summary quality is comparable, the model draws from the diverse human preferences encoded in its parameters, leading to different judgments when presentation order changes. This behavior demonstrates that GPT-4 is inconsistent as it aligns with differing human perspectives that exist within its knowledge base.

In contrast, the *answer summarization task* shows higher ARs for samples without position bias. This pattern likely stems from the more structured nature of answer summarization, which involves extracting answers directly from the provided document, thereby reducing variability in subjective interpretation. This observation is consistent with the data in Section C in Table 5, showing a higher proportion of expert consensus in answer summarization compared with the other tasks. Multimedia Appendix 4 presents illustrative examples demonstrating GPT-4's behavior to position bias. A comprehensive analysis of the hallucination detection component within the MASA framework is presented in Multimedia Appendix 5.

XSL•FO
RenderX

Table . Human evaluation of automatic factually incorrect hallucination detection by large language models presented in percentage. The upper row in each cell reports the evaluation result, and the lower row shows the 95% CI.

Dataset	Accuracy, % (95% CI)	Precision, % (95% CI)	Sensitivity, % (95% CI)	Specificity, % (95% CI)	F_1-score, % (95% CI)
Question summarization	93.0 (88.0 - 97.0)	96.4 (46.5 - 98.5)	65.0 (50.0, 81.2)	100 (100– 100)	71.2 (50.0 - 87.7)
Dialog summarization	98.0 (94.0 - 100)	99.0 (48.0 - 100)	83.3 (50.0 - 100)	100 (100 - 100)	89.5 (49.0 - 100)

In natural language generation, hallucinations refer to model-generated content that extends beyond or diverges from the information contained in the source text [15]. This broad definition often classifies even factually correct statements as hallucinations if they are not explicitly supported by the input. While this strict criterion ensures a conservative assessment of model outputs, it also conflates 2 fundamentally different cases: unsupported yet accurate domain knowledge and content that is genuinely false or misleading. To better capture this nuance, we conducted an additional evaluation focused specifically on detecting factually incorrect hallucinations (FIHs)—defined as model outputs that contradict the source text or introduce claims that conflict with established medical knowledge. Furthermore, 4 annotators collaboratively reviewed the LLM-generated summaries and resolved disagreements through discussion to determine the presence or absence of FIHs. Results are reported as macroaveraged values of FIH and non-FIH cases in terms of accuracy, precision, sensitivity, specificity, and F_1-score. CIs were estimated using 10,000 bootstrap resamples based on 100 samples from a consumer health question summarization task and 50 from a dialogue summarization task.

From Table 5, our framework consistently achieved high specificity and acceptable accuracy across both tasks, indicating its strength in minimizing false alarms and preserving clinically valid information. The sensitivity scores suggest that some FIHs were missed—reflecting an area for future improvement. The CIs are wide across all metrics. This is because hallucinations were rare in both datasets—only 10 out of 100 cases in question summarization and 3 out of 50 in dialogue summarization. With such low prevalence, each correct or incorrect prediction changes accuracy, precision, and sensitivity by several percentage points, leading to greater statistical uncertainty. These variations are mainly caused by the limited sample size, not inconsistency in the detection method or framework. Overall, the results demonstrate the reliability of the proposed framework in detecting clinically relevant FIH and provide a solid basis for future work to enhance sensitivity and generalize its use in broader medical AI evaluation settings. We include more details in Multimedia Appendix 5.

Applicability of the Framework in Real Life

Agreement Pattern Analysis of LLM Evaluator With Human Experts

To assess the effectiveness of LLMs as evaluators compared with humans, we computed GPT-4's average AR with (1) each human expert across all summarization tasks, (2) at least 1 human expert across all summarization tasks for each dataset, and (3) nonexperts lacking a professional medical background and education. Then, we explored (4) AR among human evaluators and possible reasons for disagreements. Finally, we applied (5) a cross-validation strategy to ensure a fair and consistent comparison across different LLM judges.

Agreement of GPT-4 With Each Human Expert

Table S2 in Multimedia Appendix 3 reveals significant variations in GPT-4's alignment with individual expert preferences when averaged over all datasets. The highest and lowest agreements of 50.54% and 36.65% with experts 3 and 4, respectively, demonstrate that LLMs inherently encapsulate diverse human perspectives from their training data and apply different viewpoints within their knowledge base when handling subjective tasks. The custom prompt-EG and models' parameter configurations (temperature, top-p, and top-k) further influence the outcomes. This observation suggests valuable opportunities for preference customization through advanced prompt engineering.

As illustrated in Table 6, the average Cohen κ values range from 0.04 to 0.24 across datasets, with the highest agreement observed on MEDIQA-ANS (Cohen κ=0.24), which contains structured, fact-based biomedical answers. In contrast, lower Cohen κ scores, including some negative Cohen κ values in other datasets, suggest that experts often applied differing interpretive evaluation criteria or preferences, leading to variation in judgments.

XSL•FO

Agreement of GPT-4 With at Least 1 Human Expert

To investigate the cause of misalignment of GPT-4's decisions against human experts and assess its potential as an evaluation tool, we measured its agreement patterns with the human experts for each dataset. Section A in Table 7 shows that GPT-4 achieves an average AR of 83.06% (95% CI 72.12% - 92.78%) with at least one of the medical experts across datasets. This finding is particularly meaningful when considered alongside the substantial disagreement observed among experts themselves. To better understand GPT-4's evaluation limits, we conducted a detailed error analysis on 16.94% (42/246) of cases where GPT-4 did not align with any expert. We found that 4.88% (12/246) of these nonalignment cases involved instances where GPT-4 returned a tie judgment and the expert panel was evenly split (2 experts preferred Summary A, and 2 preferred Summary B). Under majority voting, such a scenario would yield a tie; however, no individual expert selected "tie," as each expressed a definitive preference. Therefore, these cases are still considered nonalignments in this metric, as GPT-4's tie judgment did not match any expert's specific choice. In 9.34% (23/246) of cases, GPT-4 returned a tie while experts selected a definitive winner, often due to the summaries being extremely similar in quality, with minor differences in fluency or style. The remaining 2.8% (7/246) reflected true disagreement, where GPT-4 selected a different summary than all 4 experts, often due to overlooking nuanced clinical differences. These findings highlight the need for improved prompt strategies and clinical grounding to enhance the reliability of LLM-based evaluation.

Table . Agreement analysis among GPT-4, human experts, and nonexperts across 5 datasets in the preferred summary selection task. Section A reports the rate at which GPT-4 agrees with at least 1 expert. Section B compares agreement rates between GPT-4 and experts, GPT-4 and nonexperts, and between experts and nonexperts on simpler summarization tasks. Section C presents expert agreement rates, showing the proportion of samples where all 4 or at least 3 experts agreed. Calculation procedures are detailed in S1.2 and S1.4 in Multimedia Appendix 3.

Dataset	MEDIQA-QS	MeQSum	MEDIQA-ANS	MEDIQA-MAS	MedDialog-EN	Average rates
Section A: GPT-4 AR[a] with ≥1 expert						
GPT-4 AR%, (95% CI)	93.62 (85.1 - 100)	83.67 (73.5 - 93.9)	82 (70 - 92)	76 (64 - 88)	80 (68 - 90)	83.06 (72.12 - 92.78; SD 5.87)
Section B: ARs among experts, nonexperts, and GPT-4						
Expert versus GPT-4 AR%, (95% CI)	51.06 (36.2 - 66.0)	46.94 (32.7 - 61.2)	—[b]	—	54.00 (40.0 - 68.0)	50.67 (36.3 - 65.1; SD 2.90)
Nonexpert versus GPT-4 AR%, (95% CI)	57.45 (42.6 - 70.2)	75.51 (63.3 - 87.8)	—	—	60.00 (46.0 - 74.0)	64.32 (50.6 - 77.3; SD 7.98)
Expert versus Nonexpert AR%, (95% CI)	42.55 (27.7 - 57.4)	38.78 (26.5 - 53.1)	—	—	34.00 (22.0 - 48.0)	38.44 (25.4 - 52.8; SD 3.50)
Section C: expert agreement with 4 and ≥3 experts						
All 4 experts agree AR%, (95% CI)	12 (4.0 - 22.0)	16 (6.0 - 26.0)	28 (16.0 - 40.0)	18 (8.0 - 30.0)	22 (12.0 - 34.0)	19.2 (9.2 - 30.4; SD 5.46)
≥3 experts agree AR% (95% CI)	48 (34.0 - 62.0)	52 (38.0 - 66.0)	68 (54.0 - 80.0)	56 (42.0 - 70.0)	46 (32.0 - 60.0)	54.0 (40.0 - 67.6; SD 7.80)

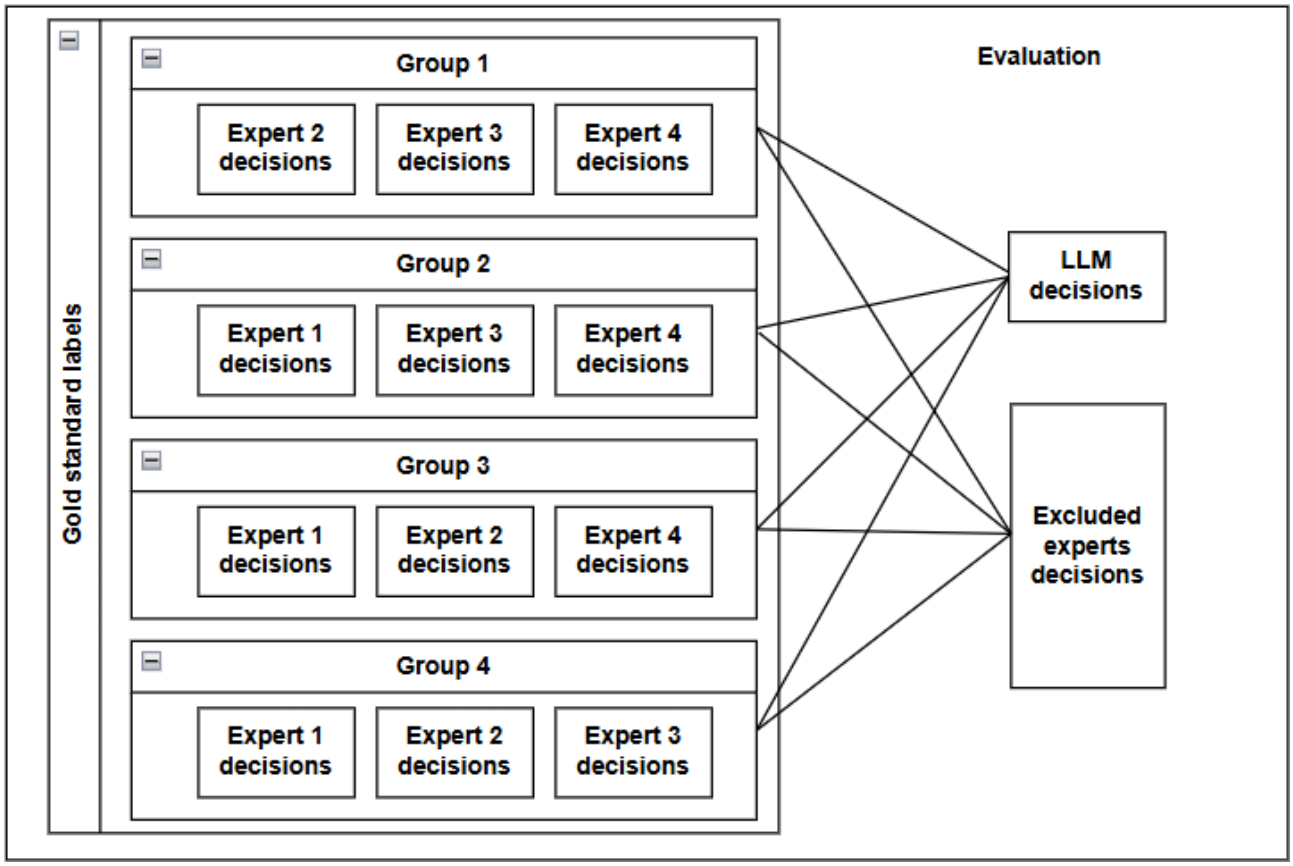
Agreement of GPT-4 With Nonexperts

In addition to expert evaluations, we conducted nonexpert reviews on the shorter and simpler datasets to assess the generalizability, accessibility, and usability of the generated summaries for a broader audience. Nonexperts are identified as individuals without any professional medical background or education. While medical experts provide critical insights into accuracy and relevance, nonexperts offer a valuable perspective on clarity and comprehensibility for individuals without specialized medical knowledge. This dual evaluation approach is particularly important in health care settings, where patients and caregivers often rely on the summary of medical information. Since the nonexperts reported difficulty in identifying factual inaccuracies due to limited medical expertise for the long documents in MEDIQA-ANS and MEDIQA-MAS during the review process, we excluded these datasets in this experiment. This way, we could demonstrate the general understanding of the nonexpert population compared with the experts and GPT-4 in summarization tasks.

Section B in Table 7 reveals that GPT-4's judgments align more closely with nonexperts (AR=64.32%, 95% CI 50.6% - 77.3%) than with experts (AR=50.67%, 95% CI 36.3%-65.1%), which is expected. This differential alignment can be attributed to GPT-4's training methodology. During fine-tuning, GPT-4 was likely optimized using nonexpert human feedback that prioritized general comprehensibility and user satisfaction. However, GPT-4's pretraining on diverse datasets, including medical corpora, provided it with domain knowledge that enables partial alignment with expert judgments. This explains why the AR between GPT-4 and experts (AR=50.67%, 95% CI 36.3% - 65.1%) exceeds that between experts and nonexperts (AR=38.4%, 95% CI 25.4% - 52.8%), suggesting GPT-4 occupies a middle ground between specialized and general regarding evaluation perspectives. Further analysis revealed that when GPT-4 and nonexperts favored a different summary than the experts, their preferences were often driven by surface-level detail or fluency improvements. In contrast, experts prioritized clinical fidelity over stylistic clarity. This pattern highlights the need to craft evaluation prompts that explicitly instruct LLMs to prioritize clinical accuracy alongside linguistic quality, especially in medical contexts.

Agreement and Disagreement Among Human Experts and Nonexperts

Section C in Table 7 highlights the variability in consensus across different expert group sizes. Notably, the average AR where all 4 experts agree with each other is only 19.2% (SD 5.46), with a 95% bootstrap CI of 9.2% - 30.4% based on 10,000 resamples. However, this rate significantly increases to 51.6% (95% CI 40% - 67.6%) when considering cases where at least 3 experts agree. This disparity underscores potential differences in expert interpretation or judgment, reflecting the complexity of achieving unanimous agreement in this task. Expert consensus was generally higher for answer summarization tasks (eg, MEDIQA-ANS and MEDIQA-MAS) than for question summarization tasks (eg, MEDIQA-QS and MeQSum), likely due to the latter's brevity and informality, which limited content differentiation and led to more subjective and variable expert preferences.



XSL•FO
RenderX

Cross-Validation Strategy

To establish a fair evaluation of ARs, we used cross-validation by systematically excluding 1 expert at a time from the group of 4, as illustrated in Figure 2. This process generated 4 groups, with the majority decision of the remaining 3 experts serving as the reference or gold standard annotation for each data point. We then compared both GPT-4's decisions and the excluded expert's decisions against this reference, allowing us to assess how individual human evaluators and the LLM perform relative to the same benchmark. This methodology serves multiple purposes, such as evaluating the stability of judgment distributions, identifying potential outliers within the expert group, and providing a consistent framework for comparing human and LLM performance.

Table 8 illustrates that expert 1 (excluded from group 1) achieved the highest AR of 49.87% (95% CI 36.1% - 63.3%) with other experts, while expert 3 (excluded from group 3) exhibited the lowest AR of 40.49% (95% CI 27.1% - 54.3%). The absence of extreme outliers suggests a natural distribution of expert perspectives rather than anomalous judgments. Notably, excluded experts achieved an average AR of 45.1% (SD 3.48), compared with GPT-4's 46.95% (SD 3.44). This demonstrates that GPT-4's evaluation capability approximates human-level consistency in this experimental context. We assessed a few newer open-source models, including Llama-3.3 and Mistral-Large, finding their performance (43.72% and 43.52%, respectively) to be slightly below GPT-4 but still within the range of human variation (lowest 40.49%). These findings suggest that current LLMs can function as supplementary evaluation tools in scenarios where expert resources are limited, although they should not be considered as replacements for human judgment.

Figure 2. The cross-validation framework. In each iteration, 1 expert is excluded from the group of 4, and the decisions of the remaining 3 experts are used as the gold standard. GPT-4's decisions and the excluded expert's decisions are then compared against this gold standard, enabling a fair assessment of performance and individual alignment across all groups. LLM: large language model.

RenderX

Table . Agreement rates between GPT-4 and excluded experts in the cross-validation framework. The table shows that the excluded expert achieves a slightly higher average agreement rate (47.38%) compared with GPT-4 (46.95%), highlighting GPT-4's close approximation to human-level performance in selecting better summaries.

Annotation group	Excluded expert, AR[a]% (95% CI)	GPT-4, AR% (95% CI)	Llama-3.3, AR% (95% CI)	Mixtral-Large, AR% (95% CI)	OpenBioLLM, AR% (95% CI)
Group 1	49.87 (36.1 - 63.3)	46.02 (31.8 - 59.8)	42.62 (29.2 - 56.4)	48.71 (32.1 - 60.5)	39.80 (26.4 - 54.0)

Group 3	40.49 (27.1 - 54.3)	44.63 (30.8 - 58.9)	39.17 (26.6 - 53.0)	38.57 (27.2 - 54.4)	29.97 (18.2 - 43.4)
Group 4	43.54 (30.1 - 57.4)	52.81 (38.6 - 66.6)	49.74 (35.9 - 63.1)	42.19 (32.8 - 60.8)	42.98 (29.2 - 56.8)
Average	45.10 (31 - 58.3; SD 3.48)	46.95 (32.9 - 61.0; SD 3.44)	43.72 (30.3 - 57.4; SD 3.82)	43.52 (30.0 - 57.6; SD 3.69)	38.32 (25.1 - 52.1; SD 4.96)

[a]AR: agreement rate.

Additionally, we explored OpenBioLLM-70B [12], a SOTA biomedical language model. Previous studies have reported its superior performance across a variety of biomedical NLP benchmarks, often outperforming models such as GPT-4, Gemini, Meditron-70B, Med-PaLM-1, and Med-PaLM-2. However, in our evaluation of subjective summary preference tasks, OpenBioLLM-70B achieved the lowest AR with expert judgments (38.32%), despite its domain specialization. These results suggest that while OpenBioLLM may excel in traditional biomedical NLP benchmarks, it may not be equally effective in subjective evaluation tasks, such as summary preference judgments, which require not only domain knowledge but also alignment with human evaluative heuristics like coherence and fluency. This suggests that extensive domain adaptation may come at the expense of general analytical and comparative reasoning capabilities, which are essential for tasks like pairwise summary evaluation. This trade-off highlights the importance of balancing domain expertise with general reasoning abilities when selecting or designing LLM-based evaluators.

Discussion

Key Observations and Implications

This study introduces a multiagent framework designed to enhance medical summarization and evaluation tasks using LLM. The first layer, the summarization layer, focuses on extracting concise and essential information from unstructured medical data, such as patient inquiries and doctor-patient conversations. This transformation enhances data clarity and prepares it for further assessment. The second layer, the evaluation layer, uses LLM judges for pairwise comparison of summaries, leveraging strategies like the *Referenced Condorcet Assessment* to reduce comparison workload and enhance accuracy. A majority-based decision-making approach, coupled with a swap-position method to mitigate position bias, ensures consistent and unbiased evaluations. This 2-layer design creates a robust framework for efficient medical summarization and evaluation, contributing to improved health care decision support.

Our findings reveal variable ARs between GPT-4 and medical experts across datasets, reflecting both the inherent subjectivity of summary evaluation and the diversity of expert perspectives. Rather than indicating a failure of the evaluation system, this variation demonstrates that qualitative assessments of summary lack a single "ground truth" even among human experts. GPT-4's ability to align with different expert viewpoints suggests it can access multiple perspectives within its knowledge base—a capability that could be leveraged to customize and personalize evaluation systems that align with specific user preferences or institutional guidelines. Future systems can enhance robustness by incorporating multiple expert viewpoints into both the summarization and evaluation processes through prompt designs that reflect diverse reasoning patterns or ensemble-style LLM configurations that aggregate outputs from varied prompts. These techniques can reduce the impact of subjective bias and increase the reliability of automated medical NLP systems in real-world settings.

Due to the small sample size per dataset (50 samples each), we recognize that individual dataset trends should be interpreted with caution, as minor fluctuations in ARs may not be statistically meaningful. To mitigate this limitation, our study was designed to include 3 summarization tasks across 5 distinct datasets (total n=246 samples) to allow a more task-level and prompt-level comparison. Across this broader evaluation, prompt-EG consistently demonstrated improved or comparable alignment with expert judgments relative to the baseline prompt. While a slight dip was observed on the MEDIQA-ANS dataset, we consider this within the margin of expected variance given the small sample size. Importantly, the overall performance across tasks favors prompt-EG, supporting its design goal of promoting more consistent and structured evaluation across different medical summarization contexts.

Cross-validation results demonstrate that GPT-4's ARs (45.1%) closely approximate those of individual experts when compared against the same reference standard (47.38%). This finding suggests that current LLMs can achieve human-comparable consistency in evaluation tasks, although with important limitations. In addition to GPT-4, we also evaluate several open-source models to assess their potential as transparent and controllable alternatives. While these open-source models do not surpass GPT-4 in cross-validation, the gap between their performance is relatively modest. This suggests that with task-specific tuning or further alignment, open-source evaluators may serve as viable alternatives in future clinical NLP applications where transparency and control are essential. The high alignment rate (83.06%) with at least 1 expert further

XSL•FO
RenderX

indicates that GPT-4 can capture perspectives within the natural distribution of human judgment, making it potentially valuable as a complementary evaluation tool rather than a replacement for human expertise. However, in real-world clinical use, false positives (selecting hallucinated or inaccurate summaries) can mislead decision-making and compromise patient safety. False negatives (failing to identify clinically useful summaries) may result in missed insights or delayed responses. These risks underscore the need for cautious deployment, continuous human oversight, and further refinement of LLM evaluation frameworks in medical contexts.

Our findings should be interpreted in the context of medical summarization tasks—the observed alignment patterns may not generalize to other domains with different subjectivity profiles. The framework's performance demonstrates the feasibility of LLM-assisted evaluation in specialized domains, particularly when human resources are limited or when rapid and scalable assessments are required.

The scalability and adaptability of the proposed multiagent framework make it well-suited for real-world deployment in both clinical and commercial health care environments. For instance, the summarization modules could be integrated into electronic health record systems to help clinicians rapidly review patient histories and incoming referrals. In the context of insurance and billing, the framework could enhance audit workflows by condensing extensive clinical documentation for claim validation. Furthermore, the LLM-based evaluation layer could act as a quality control module, which can identify the summaries that lack clarity or medical consistency, coherence, fluency, and relevance. Textbox 1 presents a summary of the key findings and recommendations.

Textbox 1. Summary of key findings and recommendations.

Key findings

- GPT-4 demonstrates alignment levels comparable with individual medical experts and captures a range of expert viewpoints.
- Prompt-enhanced guidance improves evaluation consistency compared with the baseline prompts, especially in structured summarization tasks.
- Even experts' discussion cannot align with each other.

Recommendations

- Large language models comparable with GPT-4 can complement expert reviewers in clinical or admin workflows.
- GPT-4 can support doctors by streamlining summary review and reducing workload.

Limitations

Despite the promising results, several limitations need to be considered.

First, our study involved a limited number of medical experts, which may not capture the full diversity of professional opinions in medical summarization tasks. We aimed to recruit as many experts as possible, based on the understanding that a larger and more diverse panel could help establish more robust human agreement benchmarks. However, we encountered significant challenges during recruitment. These included scheduling conflicts, limited availability, and the high cognitive effort required for detailed evaluation. As a result, only 4 experts participated in this study. This limitation highlights the need for scalable expert engagement strategies in future work.

- We evaluated a limited set of LLMs. As model architectures and training methodologies evolve rapidly, expanding the range of assessed models would provide more comprehensive insights into the capabilities and limitations of different approaches.
- While our framework shows promise for evaluation tasks, the quality of generated summaries remains variable. Enhancing summary quality through domain-specific fine-tuning, retrieval-augmented generation (RAG), hybrid human-AI workflows, or leveraging our evaluation system as a reward signal for reinforcement learning approaches to automatically improve the quality of summaries presents important directions for future research.

Second, we evaluated a limited set of LLMs. As model architectures and training methodologies evolve rapidly, expanding the range of assessed models would provide more comprehensive insights into the capabilities and limitations of different approaches.

Third, while our framework shows promise for evaluation tasks, the quality of generated summaries remains variable. Enhancing summary quality through domain-specific fine-tuning, retrieval-augmented generation, hybrid human-AI workflows, or leveraging our evaluation system as a reward signal for reinforcement learning approaches to automatically improve the quality of summaries presents important directions for future research.

Fourth, although prompt-EG was designed to output confidence levels (ie, low, medium, and high) alongside its pairwise judgments, these confidence scores were not analyzed in this study. We acknowledge that a confidence estimate could serve as a valuable signal in future evaluation pipelines. For example, confidence scores might be used to weight the strength of individual judgments, which can resolve conflicts among multiple evaluators. Incorporating and systematically analyzing these confidence levels present a promising direction for future research.

Fifth, while the evaluation metrics were computed over a randomly selected set of 50 instances per dataset, these results are intended to illustrate relative performance patterns rather than make definitive statistical generalizations. Future work

XSL•FO
RenderX

could expand the evaluation set and incorporate confidence intervals or statistical testing to strengthen robustness claims.

Sixth, our evaluation metrics focus primarily on ARs rather than more nuanced measures for evaluating various qualitative aspects of summaries. Developing multidimensional evaluation frameworks that assess factual accuracy, coherence, relevance, and accessibility separately could provide more granular insights into model performance.

Finally, this study is limited to English-language datasets primarily originating from US-based clinical and consumer health sources. Therefore, the generalizability of the proposed framework to other languages and health care systems remains an open question.

Conclusions

This study presents a multiagent framework, MASA, leveraging LLMs for medical summarization and evaluation. By integrating a summarization layer and an evaluation layer, our system addresses key challenges in processing unstructured medical data and ensuring accuracy, coherence, and relevance in generated summaries. The introduction of the *Referenced Condorcet Assessment*, swap position approach, and enhanced prompt designs like prompt-EG demonstrates how methodological refinements can mitigate common issues such as position bias.

Our findings demonstrate that current LLMs can achieve evaluation consistency comparable with individual human experts, although with important limitations and context dependencies. This suggests the feasibility of LLM-assisted evaluation in specialized domains, particularly when human resources are limited or when rapid, scalable assessment is required.

Future work should focus on expanding expert panels, evaluating diverse LLM architectures, enhancing summary quality through domain-specific techniques, and developing more nuanced evaluation metrics. By addressing these challenges, we can move toward more robust, transparent, and effective AI systems for medical information processing—systems that complement rather than replace human expertise while maintaining alignment with evolving capabilities in language model technology.

Abstract

Background: The proliferation of both general purpose and health care–specific large language models (LLMs) has intensified the challenge of effectively evaluating and comparing them. Data contamination plagues the validity of public benchmarks, self-preference distorts LLM-as-a-judge approaches, and there is a gap between the tasks used to test models and those used in clinical practice.

Objective: In response, we propose CLEVER (Clinical Large Language Model Evaluation–Expert Review), a methodology for blind, randomized, preference-based evaluation by practicing medical doctors on specific tasks.

Methods: We demonstrate the methodology by comparing GPT-4o (OpenAI) against 2 health care–specific LLMs, with 8 billion and 70 billion parameters, over 3 tasks: clinical text summarization, clinical information extraction, and question answering on biomedical research.

Results: Medical doctors prefer the medical model–small LLM trained by John Snow Labs over GPT-4o 45% to 92% more often on the dimensions of factuality, clinical relevance, and conciseness.

Conclusions: The models show comparable performance on open-ended medical question answering, suggesting that health care–specific LLMs can outperform much larger general purpose LLMs in tasks that require understanding of clinical context. We test the validity of CLEVER evaluations by conducting interannotator agreement, interclass correlation, and washout period analysis.

Introduction

Challenges in Trustworthy Large Language Model Evaluation

The emergence of large language models (LLMs) has transformed natural language processing (NLP) across numerous fields. Recent innovations, particularly LoRA (Low-Rank Adaptation) [1], have markedly improved these models' accessibility and adaptability. LoRA's approach of minimizing trainable parameters enables the efficient adaptation of large models to specific domains with limited computational resources, often yielding results that match or exceed those of full fine-tuning.

This parameter-efficient method not only expedites the adaptation process but also helps prevent overfitting, especially when dealing with scarce domain-specific data. Consequently, these refined, more compact models can potentially outperform their larger, general purpose counterparts in specialized areas without encountering issues such as catastrophic forgetting [2]. The advent of such techniques has democratized LLM deployment, empowering a wider array of researchers and organizations to harness these powerful tools without requiring substantial computational infrastructure. This accessibility has opened new avenues for innovation and application across diverse domains, fostering a more inclusive landscape in artificial intelligence (AI) research and development.

However, while the ability to create domain-specific LLMs has expanded, the challenge of effectively evaluating their performance remains. LLMs evaluation is challenging due to the complexities of scoring and the difficulties associated with reproducibility. Current evaluation methods include multiple-choice questions, heuristics, and string matching, using other language models for assessments (LLM as a judge), and

XSL•FO
RenderX

hiring human annotators. While multiple-choice evaluations are a cost-effective and straightforward approach, they do not accurately reflect real-world performance and often oversimplify the evaluation process. This method fails to adequately assess a model's capability to generate longer sequences or engage in chain-of-thought reasoning. Furthermore, it is not compatible with real-world scenarios where open-ended responses are required, as users expect models to generate answers rather than select from given options [3].

Additionally, while it is possible to measure log likelihood when using multiple-choice questions, this method only measures the truthfulness of the only token generated by the model and cannot provide an in-depth evaluation. The limitations of current evaluation methods become even more pronounced when considering the need for sophisticated techniques capable of assessing linguistic accuracy, relevance, and potential impact in specialized fields such as medicine, where errors can have serious consequences. Perplexity is another metric that can be used to measure a model's predictive capabilities by assessing how well it fits a given distribution. However, perplexity may not be suitable for instruction-tuned models and can be distanced from actual model quality in real-world generation scenarios. Moreover, both log likelihood and perplexity are tokenizer-specific metrics that require careful tuning and consideration of implementation details [4].

In real-world scenarios, text generation remains a crucial area of focus, especially for applications such as summarization and open-ended question answering (QA). However, evaluating free-form text generation is inherently difficult. Typically, evaluated models are forced to resort to heuristics for answer extraction to make them measurable, leading to outputs that can be partially correct or follow specific patterns without fully addressing the intended task. This creates challenges in determining the quality of responses. Another significant concern in evaluations is reproducibility. Ideally, published results should provide sufficient detail for others to replicate findings within a narrow margin of error. However, reproducibility can be compromised by standard evaluation libraries and test sets that may not adequately reflect real-world scenarios.

At first glance, one may assume that LLMs can effectively tackle the challenges associated with evaluating open text generation, given their capacity to simulate human evaluation. However, this approach introduces a potential circular validation issue, as the judging LLM must also be evaluated for domain accuracy. If an LLM were adequately trained for specialized domain evaluations, it would be more advantageous to apply it directly to these tasks rather than using it as a judge. Some efforts have been made to use multiple LLM judges to boost capabilities, such as in the study by Badshah and Sajjad [5]; however, it is predominantly confined to question-answering datasets, where judge LLMs provide binary true or false verdicts on candidate LLM outputs on generic tasks, leaving a gap in addressing the complexities of real-life medical scenarios and the open-ended nature of text generation. Moreover, these evaluations are generally benchmarked against human evaluations, underpinning the idea of relying on human judgment for complex tasks, since it is generally acknowledged that LLMs cannot surpass the performance of subject-matter experts in tasks that necessitate subjective reasoning. Despite the higher costs and scalability challenges associated with human evaluations, they are often regarded as the gold standard due to their capacity to provide nuanced assessments and an in-depth understanding of subject matter.

The authors of this paper acknowledge that while human evaluation is often considered the gold standard, its effectiveness is contingent upon the evaluators possessing domain-specific expertise. LLMs expand across various applications—from consumer electronics to heavy machinery—the need for tailored evaluation methods becomes increasingly critical. Each domain-specific LLM should undergo unique evaluation processes, particularly in sensitive fields such as health care, where accuracy and reliability are paramount. Medical evaluations must be conducted by medical experts who can assess the clinical relevance and factual accuracy of LLM outputs, ensuring that these models meet the stringent requirements of real-world medical practice. This approach is essential not only to validate the performance of LLMs but also to address the complexities and nuances inherent in specialized domains, thereby fostering trust and effectiveness in their deployment.

In light of the aforementioned principles, a review of current medical LLM evaluation methods reveals significant shortcomings. Existing evaluations have primarily relied on multiple-choice examination questions and synthetic datasets. While these methods are useful for assessing medical knowledge representation and reasoning, they fail to capture the complexities of real-world clinical applications. Critical aspects such as comprehension of complex patient cases from semistructured documents, understanding medical jargon and abbreviations, information reformulation for tasks such as summarization, and open-ended QA are often overlooked. Recent studies have also highlighted issues with data contamination in popular benchmarks such as MMLU (Massive Multitask Language Understanding) [6], raising concerns about their validity. Notably, most evaluations have not used clinical text datasets that differ significantly from quiz questions in terms of structure, language, and length. Although some benchmarks such as DR.BENCH (Diagnostic Reasoning Benchmark) [7] focus on clinical documents, they primarily consist of traditional encoder model tasks, limiting their suitability for comprehensive LLM evaluation. Recent attempts to create datasets from electronic health records or fictive patient cases have not yet been used to evaluate biomedical LLMs. These limitations underscore the need for a more comprehensive and clinically relevant evaluation framework for medical LLMs [8].

Similarly, in a parallel study, Bedi et al [9] conducted a systematic review of 519 studies on LLMs in health care, revealing significant gaps in current evaluation practices. Only 5% of studies used real patient care data, with most focusing on medical knowledge tasks (44.5% on medical licensing examination questions) and diagnostic tasks (19.5%). In terms of NLP and natural language understanding tasks, QA dominated (84.2%), while summarization (8.9%) and conversational dialog (3.3%) were infrequent. The review also identified several key

XSL•FO
RenderX

shortcomings in existing evaluations: there was an overemphasis on accuracy metrics, with 95.4% of studies using accuracy as the primary evaluation dimension, which led to the introduction of "factuality" as an additional evaluation dimension to assess the truthfulness of LLM outputs by the authors. Moreover, medical specialties were unevenly represented, with most studies focusing on generic health care applications [9].

Another challenge roots from the widespread use of mainstream benchmarks for evaluating LLMs, posing a significant risk of benchmark leakage. Models may have been exposed to evaluation data during training, which in turn can lead to inflated metrics and unrealistic test outcomes, favoring larger models trained on extensive corpora. Recent research has shown that many open-source LLMs have indeed been exposed to benchmark datasets during training, resulting in potentially unreliable performance scores.

On another note, research by Ni et al [10] in their paper "Training on the Benchmark Is Not All You Need" reveals that many prominent open-source LLMs have been exposed to benchmark datasets during their training process. This exposure can lead to inflated and potentially unreliable performance scores, obscuring the true capabilities of these models and making it challenging to accurately assess their performance on real-world tasks outside the benchmark context. In a parallel study, Deng et al [11] found that ChatGPT (OpenAI) was able to guess missing options by 57% in the MMLU benchmark, with the model demonstrating a remarkable ability to predict masked choices in test sets, raising significant concerns about potential data contamination in modern evaluation benchmarks.

Similarly, Oren et al [12] proved in a study that test set contamination in language models can be detected by analyzing the likelihood of canonical orderings compared to shuffled examples, demonstrating this method's effectiveness even in models as small as 1.4 billion parameters and on test sets of only 1000 examples. AI2 ARC on Mistral (Mistral AI), which does return a low *P* value of .001, could suggest some contamination. "Benchmarking Benchmark Leakage in Large Language Models" created a unified methodology from atomic detection metrics [13].

Using a unique dataset for evaluating LLMs is essential for obtaining accurate and relevant performance insights tailored to specific domains. This approach minimizes bias from pre-existing benchmarks that models may have encountered during training, ensuring a fair assessment of their true capabilities. Additionally, a custom dataset allows for the identification of domain-specific challenges, leading to more effective implementations and improvements in real-world applications. By adhering to these principles, we aim to provide a more robust and meaningful evaluation of LLMs in the medical domain, avoiding the pitfalls highlighted by the Goodhart law: "When a measure becomes a target, it ceases to be a good measure" [14]. This adage is particularly relevant in the context of LLM evaluation, where mainstream benchmarks on known datasets carry a high risk of having been consumed during model training, which can create inflated metrics and unrealistic test outcomes, favoring larger models trained on extensive corpora.

Introducing CLEVER

Overview

Recognizing these limitations and the unique requirements of medical LLMs, we developed a comprehensive evaluation framework, CLEVER (Clinical Large Language Model Evaluation–Expert Review), specifically tailored for assessing LLM performance in medical applications.

Assembling a Panel of Medical Experts

We formed a diverse panel of medical experts from various specialties, including internal medicine, oncology, and neurology. This multidisciplinary approach ensured that our evaluation process incorporated a wide range of clinical perspectives and expertise. The involvement of these specialists, who also possess extensive knowledge of NLP and practical experience in its application, was crucial for assessing the clinical relevance and factual accuracy of the LLM-generated outputs in the context of real-world medical practice.

Assessment of LLM Performance Across Key NLP Tasks

To effectively evaluate the capabilities of the language models, we conducted a thorough assessment across 4 critical medical NLP tasks: medical summarization, QA in clinical notes, biomedical research, and open-ended QA (closed-book) in medical context. Each task was selected based on its relevance to clinical workflows and its potential impact on patient care. Our evaluation framework was grounded in 3 fundamental pillars: factuality, which assesses the accuracy of information; clinical relevance, which evaluates the applicability of the information to real-world scenarios; and conciseness, which measures how effectively the models convey necessary information without unnecessary verbosity.

Mitigating Data Contamination Issues

To address concerns regarding data contamination and ensure an unbiased evaluation, we created 500 novel clinical test cases specifically tailored for LLM tasks from scratch, paying specific attention to avoid any overlap with existing benchmark datasets that may have been used during model training. We reserved 100 test cases for interannotator agreement (IAA) analysis to be evaluated by subject-matter expert physicians. All clinical test cases were created from scratch, guided by established clinical practice guidelines and real-world medical documentation formats (eg, discharge summaries, pathology reports, and research abstracts). Medical experts constructed cases to resemble authentic clinical scenarios while explicitly avoiding overlap with existing benchmarks or copyrighted material.

Dataset and Test Cases

Topics were chosen to reflect a broad spectrum of medical specialties, including internal medicine, oncology, and neurology, ensuring diversity of subject matter and clinical complexity.

Guidelines for Test Case Creation

All test cases were created de novo to ensure originality, clinical authenticity, and fairness in evaluation. The design process adhered closely to established clinical practice guidelines and

XSL•FO
RenderX

incorporated the structure and style of real-world medical documentation formats, such as discharge summaries, pathology reports, and research abstracts. To prevent bias and inflated performance metrics, explicit care was taken to exclude any overlap with existing benchmark datasets (eg, MMLU and MedQA) or copyrighted materials. By constructing the cases from scratch, the dataset was purpose-built to mitigate risks of data leakage while providing an unbiased foundation for evaluating LLM performance in clinically realistic contexts.

Expert-Driven Design and Validation

Test case development followed a rigorous, expert-driven process to ensure clinical accuracy, realism, and task appropriateness. Initial drafts were created by medical doctors with expertise across multiple specialties, drawing on deidentified electronic health records, clinical case reports, and peer-reviewed biomedical literature. Each case was subsequently reviewed by at least 2 additional physicians not involved in drafting, who evaluated the content for accuracy, clarity, and suitability for the intended task, such as summarization or focused QA. Feedback from these reviews guided iterative refinements until consensus was reached among all reviewers. This multistep process ensured that the final dataset was both clinically valid and methodologically rigorous, providing high-quality test material for evaluating LLM performance in real-world medical contexts.

Composition of the Test Set

The test set was designed to comprehensively evaluate medical NLP performance by encompassing a balanced range of narrative and structured items across 4 task categories. A total of 500 cases were developed, distributed in roughly equal proportions (approximately 125 per category) among clinical summarization (CS), clinical information extraction, biomedical research QA, and open-ended medical QA. CS tasks required condensing complex patient cases from semistructured narratives, while information extraction focused on answering diagnostic or management questions from patient notes (eg, “What were the bone marrow smear findings?”). Biomedical research QA tasks involved interpreting abstracts and short scientific reports, and open-ended medical QA items assessed broader medical knowledge in a closed-book setting. Input length and complexity were intentionally varied across cases to reflect the heterogeneity of challenges encountered in real-world medical practice, from short diagnostic prompts to extended case narratives requiring integrative reasoning.

Ensuring Scientific Rigor

To uphold scientific rigor throughout the evaluation process, we used a randomized, blind experimental design incorporating multiple comparative tests to minimize bias and enhance reliability. Evaluators were blinded to the source of each response, ensuring they were unaware of which model had generated the outputs under assessment. To further validate the integrity of the results, several measures were implemented, including IAA analysis to assess consistency among expert raters, intraclass correlation coefficient (ICC) calculations to quantify reliability across evaluators, and washout period assessments to evaluate the stability of model performance over time, thereby offering insights into reproducibility.

For IAA analysis, 100 cases were selected from the full dataset using random stratified sampling. This approach ensured proportional representation across all 4 task categories, coverage of the multiple medical specialties included in the dataset, and incorporation of diverse case types, ranging from simple to complex and short to long scenarios. This sampling strategy preserved the heterogeneity of the evaluation dataset and prevented bias toward any specific task or medical specialty.

Blinding and randomization procedures were applied during evaluation to eliminate potential sources of bias. All test cases were stripped of identifiers and randomized in order before being presented to both the models and the human experts. Through this rigorous, multilayered process, the test cases remained novel, free from contamination, clinically authentic, and representative of the practical challenges encountered in medical NLP—ultimately providing a robust foundation for the fair and meaningful evaluation of LLM performance.

This study presents the results of applying CLEVER to compare GPT-4o [15], trained by OpenAI, with 2 health care–specific LLMs trained by John Snow Labs: medical model–small (MedS) [16], which has 8 billion parameters, and medical model–medium (MedM), which has 70 billion parameters. The results demonstrated that after fine-tuning on a domain-specific dataset, these specialized LLMs outperformed GPT-4o in the measured tasks, notably using a model with <10 billion parameters that can be deployed on-premise. These findings validate our proof of concept for evaluations, confirming that our methodology is effective. Furthermore, they support the theory that smaller models trained with domain-specific data can indeed surpass larger models, a hypothesis that has been proven through our rigorous benchmarking process.

Through a randomized blind study conducted with medical doctors as evaluators, we assessed LLM performance based on 3 essential dimensions—factuality, clinical relevance, and conciseness. This approach aligned with best practices in clinical research and acknowledged the inherent complexity of medical information, necessitating comprehensive evaluation metrics. Our CLEVER methodology aimed to transform these theoretical insights into actionable practices within health care. By providing a structured framework for evaluation, CLEVER not only facilitated the effective integration of LLMs into clinical workflows but also highlighted critical areas for enhancement, ensuring that these models could reliably support health care professionals in delivering high-quality patient care.

Methods

Medical Experts

Medical professionals are essential for evaluating medical LLMs due to their superior accuracy, domain-specific expertise, and ability to assess potential harm. Research by Avnat et al [17] demonstrates that medical experts significantly outperform LLMs in diagnostic accuracy and clinical decision-making, with professionals achieving 82.3% accuracy compared to 64.3%

XSL•FO
RenderX

for Claude3 (ANTHROPIC PBC) and 55.8% for GPT-4 (OpenAI) on identical medical questions.

This substantial performance gap underscores the critical need for expert evaluation to ensure patient safety. Furthermore, medical professionals possess deep domain-specific knowledge that allows them to identify subtle nuances, context-specific information, and potential errors that may elude nonexpert evaluators or automated systems. Expert qualifications enable them to assess the potential for harm in LLM outputs, identifying dangerous advice, misinformation, or inappropriate recommendations that could pose risks to patient health if implemented in clinical settings. Consequently, the involvement of medical professionals in evaluating medical LLMs is crucial for maintaining high standards of accuracy, reliability, and safety in health care applications.

For our research, we convened a diverse panel of medical experts with combined expertise in clinical practice and medical AI solutions. The board included:

- A professor of human pathophysiology (MD, PhD) with 25 years of clinical experience and 2 years in AI solutions
- A neurologist (MD) with 1 year of clinical practice and 3 years in AI solutions
- An ECFMG (Educational Commission for Foreign Medical Graduates)–certified hematologist-oncologist (MD) with 3 years of clinical experience and 3 years in AI solutions

This multidisciplinary team brought deep medical knowledge and AI expertise to the evaluation. All physicians were externally hired with no prior exposure to our models or training data, ensuring unbiased assessments. Their sole role was to prepare evaluation data and objectively evaluate model outputs, independent of model familiarity. This approach guarantees that the evaluation reflects an accurate measure of model performance on unseen data.

Evaluation Rubrics

In our study, we developed a comprehensive evaluation framework for assessing the performance of LLMs in medical contexts. This framework is built upon 3 key rubrics: factuality, clinical relevance, and conciseness, which were carefully selected to address the unique challenges and requirements of medical information processing and dissemination.

The first rubric, factuality, can be defined as the extent to which the information provided is accurate, truthful, and consistent with established medical knowledge. It means the response is free from factual errors or misleading content that could negatively impact clinical understanding or decisions. Factuality focuses on the accuracy and correctness of the LLM-generated answers. This criterion is of paramount importance in the medical field, where misinformation can have severe consequences. Evaluators were instructed to assess the veracity of the information provided, drawing upon their extensive medical knowledge and referencing current literature and established clinical guidelines.

The assessment of factuality not only considers the presence of correct information but also the absence of false or misleading statements. This approach aligns with recent research [18-21] emphasizing the critical nature of factual consistency in medical AI applications.

Clinical relevance, the second rubric, is defined as the degree to which the information is meaningful and useful in a clinical context. It reflects how well the response supports health care providers in making informed medical decisions and addresses relevant clinical issues. This rubric evaluates the applicability and utility of the LLM-generated information in real-world clinical settings. This criterion addresses a crucial aspect of medical AI: the ability to provide actionable insights that can inform patient care and clinical decision-making. Evaluators were tasked with assessing how well the LLM's responses addressed the specific medical questions or tasks presented, and to what extent the information could be practically applied in clinical scenarios. This rubric acknowledges that even factually correct information may not always be clinically useful, a distinction that is vital in the context of medical practice.

The third rubric, conciseness, is defined as the ability to communicate necessary information clearly and succinctly, avoiding unnecessary verbosity or jargon. It emphasizes delivering complex medical information in a way that is easy to understand and quickly digestible for efficient application in clinical practice. Conciseness assesses the LLM's ability to convey necessary information succinctly and clearly. In the fast-paced environment of clinical practice, the ability to quickly digest and apply information is crucial. Evaluators were instructed to consider how effectively the LLM summarized complex medical concepts without sacrificing essential details. This rubric also takes into account the clarity of expression and the avoidance of unnecessary jargon or verbosity. The importance of conciseness in medical communication has been highlighted in several studies [22-25], noting its impact on information retention and application in clinical settings.

Tasks

The 500 cases were distributed across the 4 task categories: CS, clinical information extraction (QA from notes), biomedical research QA, and open-ended medical QA. Each category was represented in roughly balanced proportions (approximately one-quarter of the dataset per task type), with variation in input length and complexity to reflect the range of challenges encountered in real clinical practice.

CS is a critical task in health care that involves distilling and synthesizing complex medical information into concise, accurate, and actionable summaries. CS produced by a well-adapted LLM can match the expertise of medical professionals [26], enabling health care providers to efficiently interpret patient information and make informed decisions [27].

One of the focal points of CS evaluation is information synthesis, which tests the models' ability to extract and combine relevant details from diverse sources, such as electronic health records, laboratory results, and clinical notes, which plays a vital role in creating comprehensive summaries reflecting the complexity of patient cases.

Effective CS requires a deep understanding of domain-specific knowledge, including medical terminology, procedures, and the relationships between various health factors. Language

XSL•FO
RenderX

models must demonstrate proficiency in these areas to generate summaries that are not only accurate but also clinically relevant. The ability to condense extensive medical histories into brief yet comprehensive narratives highlights the models' effectiveness in prioritizing the most pertinent information for clinical decision-making.

Additionally, effective CS often involves understanding the chronology of medical events and their implications for patient care, further underscoring the need for temporal reasoning capabilities within these models. Furthermore, evaluating how well models perform across different medical specialties—from general practice to specialized fields such as oncology or neurology—can provide insights into their adaptability and robustness in diverse clinical contexts.

Clinical QA tasks are essential for evaluating language models in the medical domain. This task involves answering specific clinical questions based on the provided medical context. It assesses the model's ability to extract relevant clinical information and apply it effectively to answer focused inquiries. For example, questions such as "Given the clinical note, what were the bone marrow smear findings?" or "Given the surgical note, what procedures did the patient undergo?" require the model to interpret complex clinical data accurately. Additionally, questions such as "Based on the provided case report, did Anlotinib benefit the patient?" test the model's understanding of treatment efficacy and patient outcomes. The ability to answer these questions demonstrates a model's comprehension of medical terminology, procedural knowledge, and clinical reasoning, making it a vital evaluation criterion for language models intended for use in health care settings.

Biomedical research QA tasks focus on evaluating language models' capabilities in interpreting scientific literature and research findings. This task requires models to answer questions related to biomedical studies, such as "Given the report, what biomarkers are commonly negative in acute promyelocytic leukemia (APL) cases?" or "Given the note, why is chemotherapy the main treatment used in triple-negative breast cancer (TNBC) patients?" These inquiries test the model's ability to synthesize information from research articles and clinical guidelines while demonstrating an understanding of disease mechanisms and treatment rationales. Furthermore, questions such as "Given the article, what is serum neurofilament light chain (sNFL) used for?" assess the model's knowledge of specific biomarkers and their applications in clinical practice. By evaluating models on biomedical research QA tasks, researchers can gauge their proficiency in handling complex medical information and their potential utility in supporting health care professionals with evidence-based decision-making.

Open-ended QA tasks evaluate language models' abilities to provide comprehensive responses to broader medical inquiries that may not have straightforward answers. This task encompasses a wide range of questions, such as "What biopsy techniques confirm malignant bone tumors?" or "Are there any favorable mutations in acute lymphoblastic leukemia?" These types of questions require models to integrate knowledge from various medical domains and provide well-rounded answers based on existing literature and clinical guidelines. Additionally, inquiries such as "Are there any over-the-counter sleep aids that contain barbiturates?" challenge models to synthesize information about pharmacology and regulations surrounding medications. The open-ended nature of these questions tests a model's depth of understanding and its ability to navigate complex topics while delivering accurate and relevant information.

Test Setup

We conducted randomized blind evaluations to mitigate potential bias in our assessments, particularly because the medical evaluators are employees of our organization and may be influenced by familiar patterns. Shuffling the order of model responses for each question in comparative evaluations, we aimed to reduce various forms of bias, such as order bias and expectation bias, while also preventing evaluators from memorizing specific models' styles. By enhancing objectivity and reliability in the assessment process, we compelled evaluators to judge each response solely on its merits without knowledge of its source. Furthermore, by eliminating external cues and preconceptions, we facilitated a fairer comparison between models and revealed genuine preferences, increasing the statistical validity of our results. Ultimately, shuffling model responses contributes to a more robust and trustworthy evaluation of the relative performance of different language models, ensuring that the assessment is based on the quality of the outputs rather than extraneous factors.

Our preferred method for testing model success was pairwise comparison between GPT-4o, MedS, and MedM. Pairwise comparison offers numerous advantages in evaluating complex options, particularly in the context of language model assessment. This method simplifies the evaluation process by breaking it down into manageable comparisons between 2 options at a time, reducing cognitive load and making it easier for evaluators to make decisions. It is especially useful for long lists of items and mimics real-life decision-making processes, potentially leading to more accurate research results. Pairwise comparison can generate quantitative results from qualitative data, handle incomplete comparison data, and minimize biases through randomization. In the context of blind testing language models, this approach allows evaluators to focus on the content of each response without being influenced by knowledge of which model produced it. This leads to a more objective and statistically valid assessment of the models' relative performance. The method's simplicity, flexibility, and ability to reduce bias make it an excellent choice for comparing language model outputs, ensuring a fair and thorough evaluation process. A recent study by Liu et al [28] justifies our pairwise comparison approach, demonstrating that pairwise preference methods inspired by reinforcement learning from human feedback can leverage LLMs' inherent ranking abilities to produce more robust, transitive, and efficient evaluations that align better with human judgments.

We augmented the pairwise comparison method with the inclusion of 4 options (model A vs model B, neutral, and none) to provide several advantages and reflect a nuanced understanding of the complexities involved in comparing

XSL•FO
RenderX

language model outputs. First, our augmented comparison allows evaluators to accurately indicate their preference when 1 model clearly outperforms others while accommodating scenarios where each model might excel in different aspects. The "neutral" option recognizes that in some cases, the outputs from different models may be very similar in quality or content, without a clear advantage, thus preventing forced choices when differences are negligible and leading to more accurate overall results. Additionally, the "none" option is crucial as it enables evaluators to indicate when none of the responses meet the required standards of factuality, clinical relevance, or conciseness, which is particularly important in medical contexts where accuracy and relevance are paramount. This 4-option framework helps prevent false positives; without the "none" option, evaluators might feel pressured to select the "least bad" option even if all responses are inadequate, potentially leading to misleading results. Furthermore, the distribution of choices across these 4 options can provide rich insights into the relative strengths and weaknesses of each model and highlight areas where all models struggle (high "none" selections) or perform similarly well (high "neutral" selections). Ultimately, this method enhances evaluator confidence in their assessments because they are not forced into binary choices that may not reflect their true judgments.

About IAA

From the full dataset, 100 cases were selected for IAA evaluation using random stratified sampling. This ensured proportional representation of all 4 task categories and coverage of multiple specialties. The sampled cases also included a mix of simple and complex examples, as well as shorter and longer inputs, to capture the diversity of the dataset while avoiding bias toward any specific task or medical domain.

In our study, we used a rigorous methodology to assess IAA among medical experts evaluating language model outputs. We used the ICC, specifically calculating ICC1, ICC2, ICC3, and their average measures counterparts ICC1k, ICC2k, and ICC3k [29].

ICCs are commonly denoted using a system that reflects both the statistical model and the reliability type being assessed. The notation ICC1, ICC2, and ICC3 refers to 1-way random effects, 2-way random effects, and 2-way mixed effects models, respectively. These are further specified with either "1" or "k" to indicate whether the reliability is for a single rater (1) or the average of k raters (k). For instance, ICC(2,1) represents a 2-way random effects model for single rater reliability, while ICC(3,k) indicates a 2-way mixed effects model for the average reliability of k raters.

ICC1 is used when subjects are assessed by different sets of randomly selected raters, ICC2 when all subjects are assessed by the same randomly selected raters, and ICC3 when the raters are the only ones of interest. This notation system allows researchers to precisely communicate the type of ICC used in their analyses, facilitating accurate interpretation and replication of results.

This comprehensive approach was applied to 3 distinct comparison scenarios: (1) MedS versus GPT-4o, (2) MedM versus GPT-4o, and (3) MedS versus MedM versus GPT-4o.

Our approach involved 3 qualified physicians independently annotating a seed dataset of 100 diverse medical queries, adhering to a predefined rubric focusing on factuality, clinical relevance, and conciseness. The ICC was selected over traditional methods such as Cohen κ or Spearman rank correlation due to its ability to handle multiple raters and continuous data, as well as its robustness across various data types and study designs.

The selection of multiple ICC forms (ICC1, ICC2, ICC3, ICC1k, ICC2k, and ICC3k) allowed us to account for different aspects of our study design:

- ICC1 and ICC1k: appropriate for scenarios where each subject is rated by different, randomly selected raters.
- ICC2 and ICC2k: suitable when the same set of randomly selected raters assesses all subjects.
- ICC3 and ICC3k: Used when a fixed set of raters evaluates all subjects. This comprehensive ICC analysis provided insights into both single-measure and average-measure reliability estimates, offering a nuanced understanding of the consistency in expert evaluations across different model comparisons.

The ICC's statistical framework contributes to its accuracy in reflecting measurement scale reliability, particularly in handling missing data and varying sample sizes common in real-world research scenarios. Furthermore, its wide acceptance in health measurement, as recommended by the COSMIN (Consensus-Based Standards for the Selection of Health Measurement Instruments) guidelines, lends credibility to its use in medical research [30].

The results of this IAA analysis served as a crucial metric for validating the reliability of our annotation process and identifying areas for potential refinement in our evaluation methodology. This rigorous validation step is essential for ensuring the development of accurate and trustworthy AI models in health care applications, particularly in the context of NLP for medical information retrieval and dissemination.

Washout Evaluation

To assess the temporal stability and intrarater reliability of expert annotations, we implemented a washout period analysis. This 2-phase annotation process involved a carefully selected 2-week interval between assessments, strategically chosen to minimize memory effects while ensuring consistent evaluation criteria. Expert annotators evaluated an identical set of questions at 2 distinct time points, without access to their previous responses during the second session. This design allowed us to quantify the consistency of individual annotators' decisions over time.

To measure intrarater reliability, we calculated the percentage of unchanged responses for each annotator and used the ICC to account for agreement occurring by chance. This analysis facilitated the identification of potential ambiguities in our annotation schema and provided a robust measure of the temporal consistency of expert judgments, offering insights into the reproducibility of expert assessments and highlighting areas for potential refinement of evaluation criteria or additional annotator training.

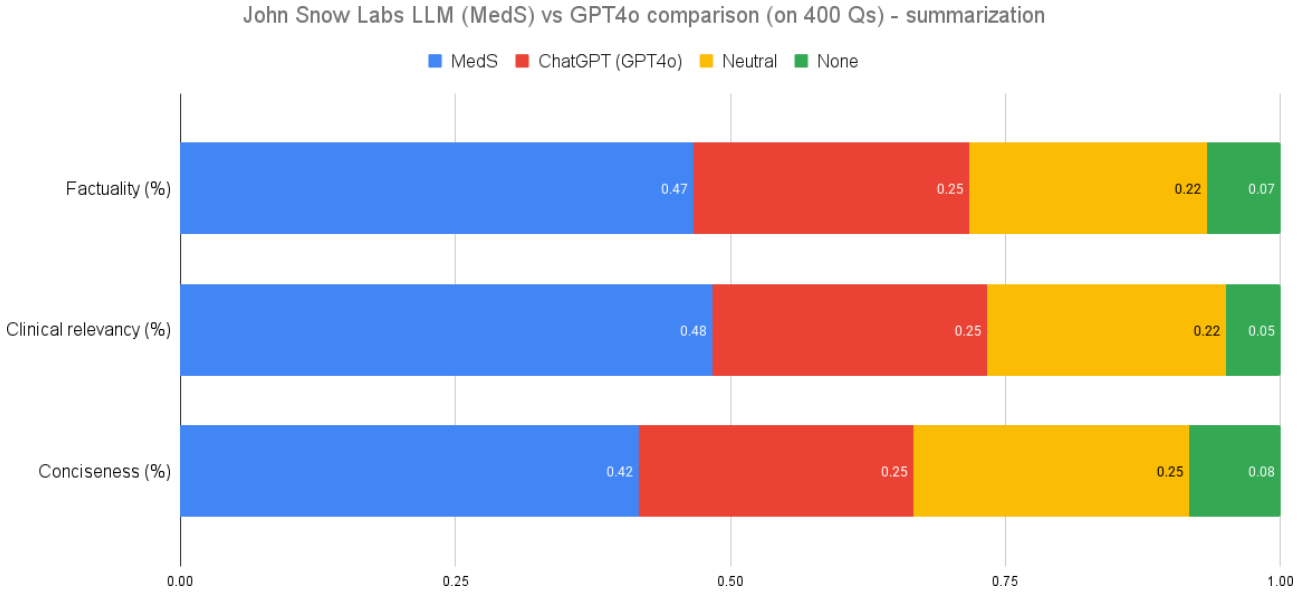
Ethical Considerations



This study did not involve human participants, animals, or any identifiable personal data. Therefore, institutional and local research ethics policies did not require ethics board approval for this type of study.

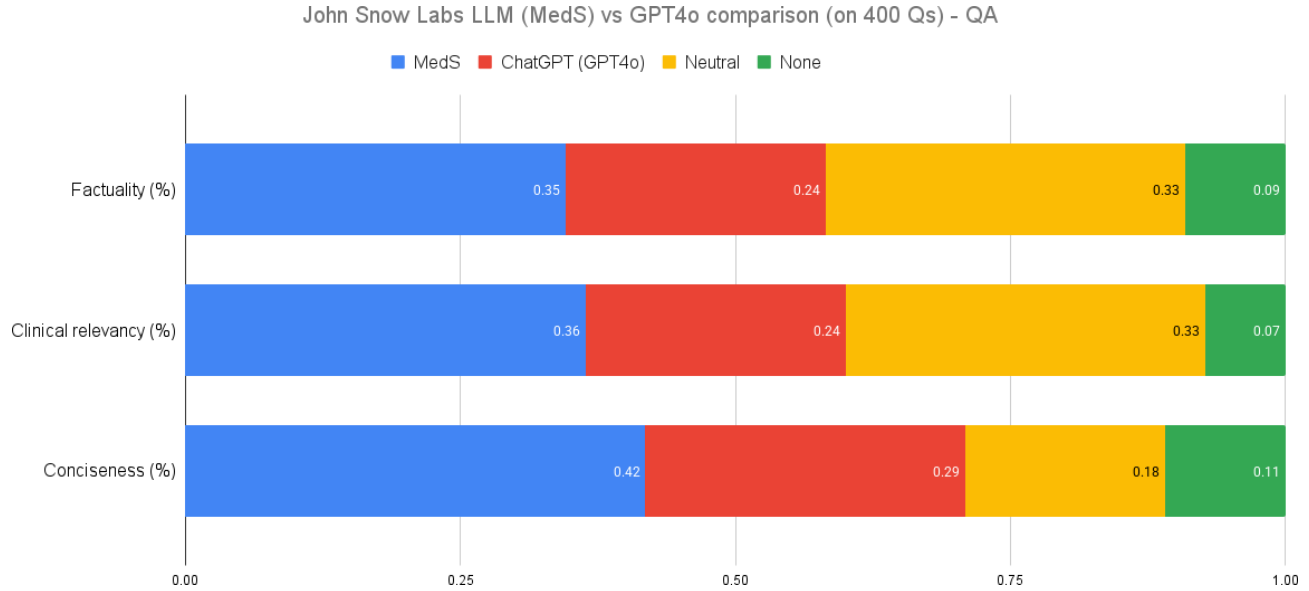
Results

Clinical Text Summarization

CS assessment helps ascertain whether these models can be trusted to support health care providers in high-stakes environments where errors can have significant consequences. Our comparative analysis of an 8 billion parameter model fine-tuned on medical data and GPT-4o revealed significant differences in performance across several key metrics, as illustrated in Figure 1.

Figure 1. Clinical text summarization performance comparison. LLM: large language model; MedS: medical model–small; Q: question.

- In terms of factuality, the MedS model was preferred 47% of the time, compared to 25% for GPT-4o, with the models being deemed equal in 22% of cases.
- Regarding clinical relevance, the MedS model was favored in 48% of instances, while GPT-4o was preferred in 25%.
- The MedS model also outperformed in conciseness, with a preference rate of 42% versus 25% for GPT-4o.



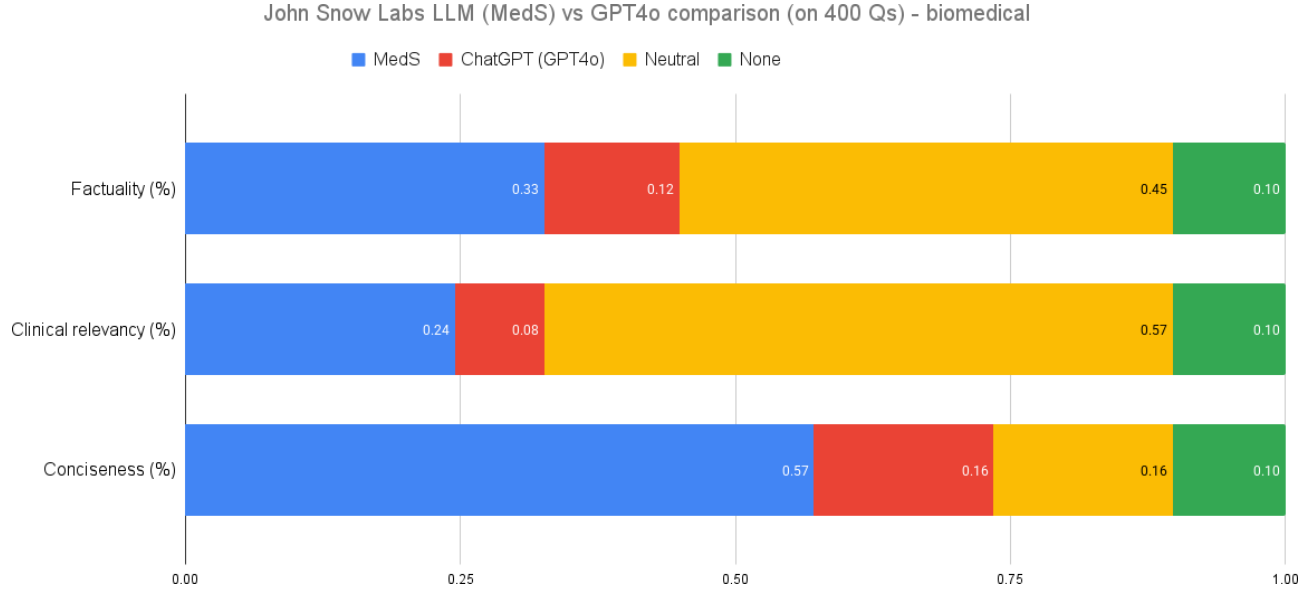
Evaluations were based on the models' responses to specific medical summarization tasks. Sample questions posed to the models included: summarize the patient's medical history and initial presentation, and summarize the final diagnosis of the lesion and the patient's follow-up and recovery after surgery. These results suggest that domain-specific fine-tuning can lead to substantial improvements in performance, particularly in specialized fields such as medicine, even when compared to larger, more general models such as GPT-4o.

Clinical Information Extraction

Our analysis of an 8 billion parameter model fine-tuned on medical data compared to GPT-4o revealed notable performance differences, as illustrated in Figure 2.

XSL•FO
RenderX

Figure 2. Clinical information extraction performance comparison. LLM: large language model; MedS: medical model–small; Q: question; QA: question answering.

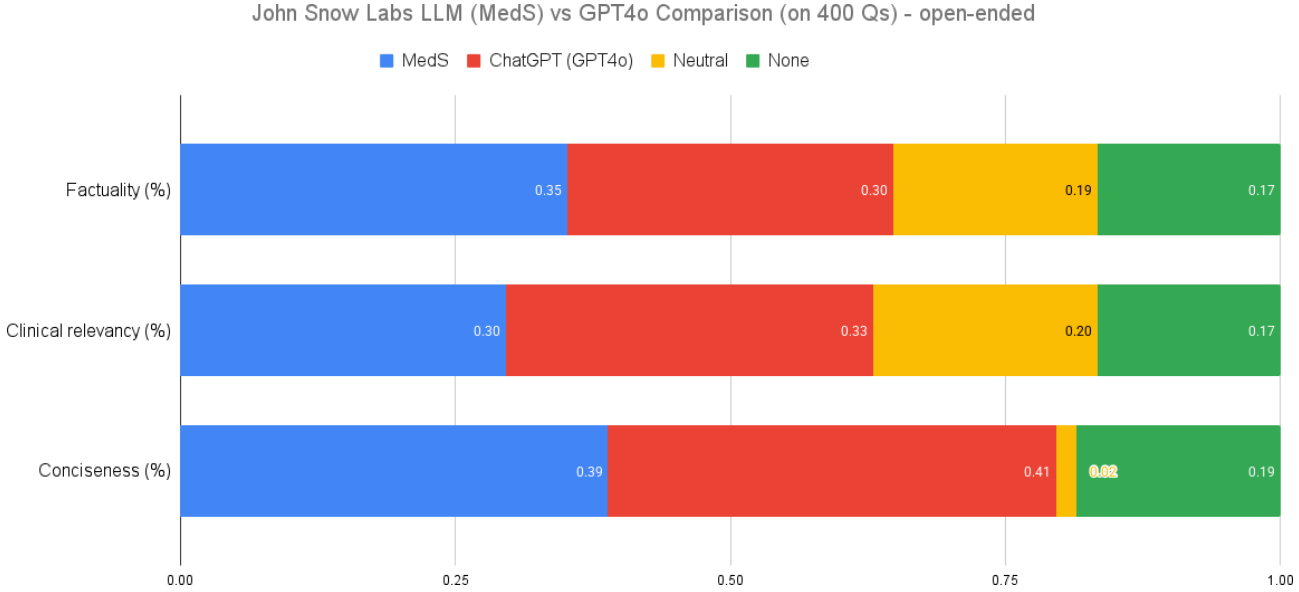


- The MedS model exhibited a 10% advantage in factuality (35% vs 24%), with 33% of evaluations deemed neutral.
- In terms of relevance, the MedS model had a 12% advantage, while conciseness showed a 13% lead over GPT-4o.

Biomedical QA

In biomedical research, the performance delta is significantly larger for our 8 billion parameter model, which has been fine-tuned on clinical and biomedical contexts as well as question-answering and summarization tasks, as demonstrated by Figure 3. Evaluations often involve providing an article or PubMed paper and asking specific questions or abstracting information directly from a short paragraph. In terms of factuality, MedS outperforms GPT-4o by a substantial margin. While clinical relevance assessments frequently yield neutral preferences—indicating similar performance between models—the enhanced training of our model enables it to excel in factual accuracy and contextually relevant tasks. This underscores the importance of specialized fine-tuning in achieving superior results in biomedical applications.

Figure 3. Biomedical question answering performance comparison. LLM: large language model; MedS: medical model–small; Q: question.



Open-Ended Medical QA

By assessing performance on open-ended QA tasks, researchers can evaluate a model's overall medical knowledge and its readiness for real-world applications in clinical practice. In our evaluation of clinical relevance for open-ended medical questions without provided context, our 8 billion parameter model was unable to surpass GPT-4o's performance. This outcome is understandable given the nature of the task and the models' respective training. GPT-4o, being a more generalist model trained on a significantly larger dataset, has a broader knowledge base that proves advantageous in answering diverse medical questions without specific context. Our model, while excelling in targeted biomedical tasks, faces limitations in

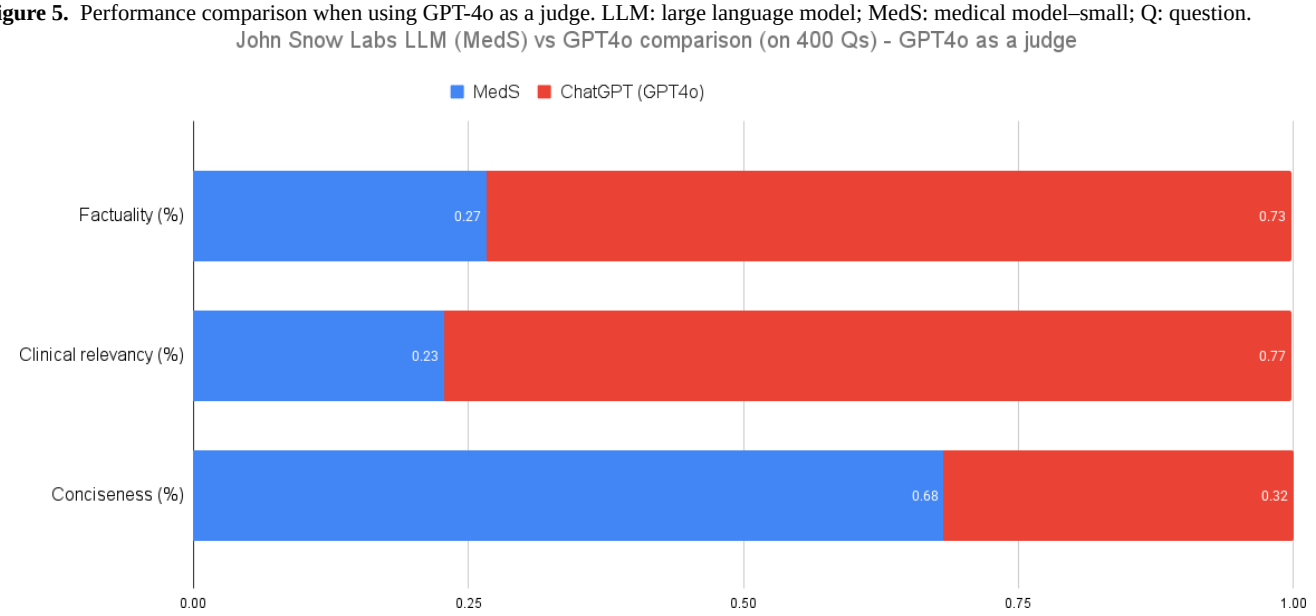
XSL•FO
RenderX

covering the entire spectrum of global medical knowledge. Despite this, it is noteworthy that our model still outperformed GPT-4o in factuality by 5 percentage points, highlighting its strength in accuracy within its specialized domain, as seen in Figure 4. This comparison underscores the trade-offs between specialized and generalist models, emphasizing the importance of context and task-specific training in AI model performance.

Figure 4. Open-ended medical question answering performance comparison. LLM: large language model; MedS: medical model–small; Q: question.

LLM as a Judge

In our study, we used a novel evaluation framework incorporating both human expertise and LLM judgment. Specifically, in addition to 4 medical professionals, we used GPT-4o as a fifth evaluator.



For each test case, GPT-4o received the input clinical case or question, anonymized outputs from all candidate models (MedS, MedM, and GPT-4o), and the following instructions: “Rank the outputs based on factual accuracy, clinical relevance, and conciseness, from the perspective of a practicing physician who must make reliable decisions efficiently.” Conciseness was explicitly emphasized because, in real-world clinical settings, physicians need rapid, actionable summaries without redundant information. All models were treated identically, so GPT-4o could rank any model highest if it best satisfied these criteria.

Prioritizing conciseness reflects real clinical utility rather than introducing bias. Guiding the judge model with clinically meaningful criteria ensures the evaluation aligns with end user priorities. The preference observed for MedS indicates that, under these criteria, domain-specific models can generate outputs that better meet physician needs, even when evaluated by a larger general purpose model.

As depicted in Figure 5, our findings revealed a significant discrepancy between GPT-4o’s ratings and those of the human reviewers when analyzed independently. We hypothesize that this divergence may be attributed to the LLM’s capacity to recognize its own generated responses, potentially leading to a favorable bias during the evaluation process. This observation aligns with recent research on LLM self-recognition and preference biases [31,32] and self-enhancement bias [33]. Our results underscore the importance of careful consideration when implementing LLM-based evaluation methods, particularly in domains requiring specialized knowledge, such as medicine.

RenderX

Figure 5. Performance comparison when using GPT-4o as a judge. LLM: large language model; MedS: medical model–small; Q: question.

ICC Assessment

Overview

Table 1 ICC1 (absolute agreement) shows negative agreement because raters' exact scores differ, and there is poor agreement on the absolute values of the ratings. In contrast, ICC2 and ICC3 (consistency-based agreement) show positive agreement because the raters are consistent in their rankings or pattern of ratings, even though exact values may be different. This suggests that raters may not give identical scores, but they tend to be consistent in their relative assessment of the targets. Therefore, consistency exists, despite consensus.

Table . Factuality over MedS[a] versus GPT-4o: ICC[b] results: ICC (assessing the reliability or agreement among raters). Please note that raters are consistent in their assessment, but do not agree with each other all the time.

Type	Description	ICC	*F* test (*df*)	*P* value	95% CI
ICC1	Single raters absolute	−0.095	0.739 (49, 1.0E+02)	.88	−0.22 to 0.07
ICC2	Single random raters	0.076	1.501 (49, 9.8E+01)	.045	−0.03 to 0.21
ICC3	Single fixed raters	0.143	1.501 (49, 9.8E+01)	.045	−0.02 to 0.33
ICC1k	Average raters absolute	−0.353	0.739 (49, 1.0E+02)	.88	−1.16 to 0.19
ICC2k	Average random raters	0.198	1.501 (49, 9.8E+01)	.045	−0.09 to 0.45
ICC3k	Average fixed raters	0.334	1.501 (49, 9.8E+01)	.045	−0.07 to 0.6

[a]MedS: medical model–small.

[b]ICC: intraclass correlation coefficient.

For ICC evaluation tables depicting reliability or agreement among raters for MedS versus GPT-4o, MedM versus GPT-4o, and MedS versus MedM versus GPT-4o please refer to Section S3 in Multimedia Appendix 1.

Factuality

This shows inconsistent reliability, with both negative and positive ICC values. The agreement improves somewhat with more raters, but the fluctuations suggest that the raters might not consistently agree on this dimension. When it comes to 3-way comparison, factuality also shows less variability and more consistency.

Clinical Relevance

Displays steady improvement in agreement as the number of raters increases, starting from poor reliability and reaching moderate levels. There is a clear upward trend, indicating that reliability improves with more raters.

Conciseness

The most reliable dimension, with ICC values indicating moderate to strong agreement among raters. The progression is steady and shows consistent improvement with more raters, suggesting that this dimension is easier to evaluate consistently. In general, conciseness appears to be the most reliable dimension, followed by clinical relevance, while factuality shows significant variability, making it the least reliable.

Washout Period Analysis

Temporal Stability Assessment

Revisiting the same questions 2 weeks later allowed for an assessment of how consistently raters maintain their evaluations over time and whether they change their minds. The results indicate that annotators generally do not alter their assessments significantly during this period, suggesting a high level of stability and reliability in their evaluations, as depicted in Table

XSL•FO
RenderX

2. Additionally, the higher agreement observed in averaged ratings implies that collective evaluations are more consistent than those of individual raters. Among the participants, rater-1 demonstrated the highest reliability, exhibiting minimal changes in responses over the 2-week washout period. In contrast, rater-2 and rater-3 showed weaker agreement, with rater-3 being identified as the least consistent. Nevertheless, all raters exhibited statistically significant agreement, indicating that they largely maintained consistency in their answers over time. These findings underscore the importance of temporal stability in assessments and suggest that raters can provide reliable evaluations within a structured framework.

Table . ICC[a] values and statistics per rater.

Type	Description	Rater 1	Rater 2	Rater 3
ICC1	Single raters absolute	0.927	0.653	0.601
ICC2	Single random raters	0.927	0.653	0.600
ICC3	Single fixed raters	0.928	0.657	0.596
ICC1k	Average raters absolute	0.962	0.790	0.751
ICC2k	Average random raters	0.962	0.790	0.750
ICC3k	Average fixed raters	0.963	0.793	0.747

[a]ICC: intraclass correlation coefficient.

Classification Report

As an alternative method, we assessed the consistency of raters across multiple evaluation rounds by treating the first evaluation as the ground truth. The analysis focused on how much raters changed their assessments in subsequent evaluations, with changes indicating lower F_1-scores (Table 3). Rater-1 emerged as the most consistent overall, exhibiting high F_1-scores and ICC values across most models and criteria, particularly demonstrating strong reliability in both conciseness and factuality. In contrast, rater-2 displayed greater variability, especially in factuality, where lower F_1-scores indicated more frequent changes in judgment. However, rater-2 performed well in clinical relevance for certain models, suggesting that their consistency is criterion-dependent. Rater-3 also showed commendable performance, particularly in factuality, where their F_1-scores were among the highest, consistent with the moderate to strong ICC values observed in the washout analysis. The findings indicate that factuality presents challenges for some raters—especially rater-2—while conciseness tends to be evaluated more consistently across all raters. The correlation between F_1-scores and ICC values reinforces the reliability of these metrics as measures of rater consistency. This study highlights the importance of understanding how raters' evaluations evolve and suggests that training or calibration may be beneficial, particularly for dimensions such as factuality, where variability is more pronounced. Future research should further explore the factors influencing rater decision-making and aim to enhance consistency across all evaluation criteria. This version emphasizes the classification aspect of your analysis while maintaining a scientific tone suitable for a paper.

XSL•FO
RenderX

Table . Rater F_1-scores for different model comparisons: intrarater stability. We treated the first annotation round as the reference and compared each rater's second-round labels against it. For each rater, we computed (1) the proportion of unchanged labels (identical labels in round-2 vs round-1) and (2) conventional classification metrics (precision, recall, and F_1-score) where round-1 labels were treated as ground truth and round-2 as predictions.[a]

Comparison	Rater 1	Rater 2	Rater 3
MedS[b] versus MedM[c]			
Clinical relevance	0.910	0.816	0.890
Conciseness	0.849	0.880	0.851
Factuality	0.901	0.756	0.875
MedS versus GPT-4o			
Clinical relevance	0.842	0.920	0.842
Conciseness	0.819	0.859	0.819
Factuality	0.862	0.859	0.814
MedM versus 3			
Clinical relevance	0.840	0.880	0.737
Conciseness	0.800	0.907	0.814
Factuality	0.849	0.859	0.746
Model 1 versus MedM versus GPT-4o			
Clinical relevance	0.826	0.809	0.812
Conciseness	0.824	0.772	0.860
Factuality	0.864	0.747	0.821

[a]The proportion unchanged is defined as the number of identical labels in both rounds divided by the total labels. Averaging across the 3 raters, the proportion unchanged was ≈0.83 (83%), implying ≈17% of labels differed between rounds; we conservatively reported this as "around 20%" in the main text. Importantly, F_1-scores (reported in Section S5 in Multimedia Appendix 1) are a different statistic—they measure the harmonic mean of precision and recall for the target class when treating round-1 as ground truth—and can remain high (>0.8) even if a modest fraction of labels change, especially under class imbalance. We therefore report both measures (percent unchanged and F_1-score) to provide a fuller picture of rater stability: percent-unchanged captures exact label repeatability, while F_1-score captures reproduction of key classes (precision or recall performance).

[b]MedS: medical model–small.

[c]MedM: medical model–medium.

Discussion

Limitations and Future Work

Overview

While this study provides valuable insights into the reliability and consistency of language model evaluations, several limitations should be acknowledged, and potential avenues for future research identified.

Weighting of Evaluation Dimensions

The current study assigned equal weight to all rubrics (factuality, clinical relevance, and conciseness). However, in clinical applications, these dimensions may not be equally important. Factuality, for instance, may be of paramount importance in medical contexts, while conciseness might be considered less critical. Future studies should consider implementing a weighted scoring system that reflects the relative importance of each dimension in real-world applications.

Evaluator Bias Mitigation

Evaluators affiliated with the model-developing organization could introduce subconscious bias, so multiple safeguards were implemented. All medical experts were hired as external contractors and had no hand in model development, testing, or access to model outputs before the blinded evaluation study. The models evaluated were not publicly available, ensuring evaluators had no familiarity with their outputs. Though evaluators had worked with the organization before, all medical doctors were asked to blindly review all tasks, regardless of their specialty. Model outputs were anonymized and randomized, and evaluators received bias-awareness training focused on rubric-based scoring. IAA and ICC analyses ensured scoring consistency; a washout period helped measure intrarater reliability and minimize memory effects. These measures substantially reduced subconscious bias, supporting that evaluations reflected intrinsic model quality rather than organizational affiliation. Future research should consider fully independent audit teams for even greater credibility.

Medical Expertise and Specialization

The study revealed instances of numerous "neutral" responses, particularly in specialized medical areas. This suggests a potential limitation in the breadth of expertise among the evaluators. Future studies should consider expanding the evaluation panel to include a wider range of medical specialists,

XSL•FO
RenderX

ensuring that each evaluated task is assessed by experts in the relevant field.

Evaluation Methodology

The current study used pairwise comparisons. While effective, this method may not capture the full spectrum of model performance. Future research could explore alternative methodologies, such as ranking-based evaluations, which might provide a more nuanced understanding of relative model performance across a broader range of tasks.

Time and Cost Considerations

The evaluation process, including the washout period, resulted in a significant time lag between model output and final assessment. Additionally, the use of human experts incurs substantial costs. Future research could explore methods to streamline the evaluation process and investigate cost-effective alternatives that maintain high reliability.

Model Training Bias

The superior performance of our models in conciseness may be attributed to specific training focusing on brevity. This highlights the importance of considering model training objectives when interpreting comparative results. Future studies should either ensure comparable training objectives across all models or explicitly account for these differences in the analysis.

Potential for AI-Assisted Evaluation

To mitigate human bias and potentially reduce costs, future research could explore the use of advanced language models as impartial judges. This approach would need to be carefully validated against human expert evaluations to ensure reliability and fairness.

Longitudinal Consistency

While this study included a washout period to assess short-term consistency, future research could benefit from longer-term longitudinal studies to evaluate the stability of assessments over extended periods and across different versions of the models.

Generalizability

The current study focused on specific models and medical contexts. Future research should aim to replicate these findings across a broader range of language models and diverse medical specialties to establish the generalizability of the evaluation framework.

Quantitative Analysis of Qualitative Feedback

In addition to numerical ratings, future studies could incorporate a more structured analysis of qualitative feedback from evaluators. This could provide deeper insights into the reasoning behind ratings and identify specific areas for model improvement.

Further Investigation

Factors influencing rater variability and strategies to enhance consistency among raters, particularly for those demonstrating lower reliability, should be investigated. A deeper understanding of rater dynamics over time and potential avenues for improving evaluation processes in various research contexts may be researched.

By addressing these limitations and exploring these future directions, subsequent research can further refine the methodology for evaluating medical language models, enhancing the reliability, objectivity, and practical applicability of such assessments in clinical settings.

Conclusions

In our study, we aimed to bring a new methodology for benchmarking clinical LLMs. We observed that our methodology is effective, and as a positive side effect, we found that John Snow Labs' health care–specific LLMs, trained on domain-specific data, outperformed GPT-4o. We evaluated our methods' performance using these specialized LLMs as a test bed against GPT-4o on a range of medical tasks.

The results demonstrated that after fine-tuning on a domain-specific dataset, these specialized LLMs outperformed GPT-4o in the measured tasks. Notably, this superior performance was achieved using a model with 8 billion parameters, which can be deployed on-premise. This characteristic allows for private and efficient operation, addressing critical concerns in health care regarding data privacy and computational resource requirements. Moreover, the success of this small-sized model underscores a paradigm shift in model optimization, where targeted fine-tuning enables smaller models to rival and even surpass the performance of much larger generalist counterparts such as GPT-4o. Achieving a 5% advantage in factuality—a metric of paramount importance in medical applications—and outperforming GPT-4o by over 10% in conciseness demonstrates that strategic specialization can yield remarkable results. These findings challenge the assumption that scale alone dictates performance and highlight the potential of smaller, efficient models to deliver task-specific excellence in resource-constrained and privacy-sensitive domains.

The evaluation was conducted as a randomized, blind study, with medical doctors serving as evaluators. While interrater agreement was not strong, the evaluators demonstrated consistency in their observations across all questions. This methodology aligns with best practices in clinical research, emphasizing the importance of blinding in randomized trials assessing nonpharmacological treatments. Our assessment of LLM performance was conducted across multiple dimensions, including accuracy, correctness, and conciseness. This multifaceted approach acknowledged the complexity of medical information and the need for comprehensive evaluation metrics. The subjective nature of LLM evaluations underscores the importance of developing robust metrics, carefully crafted questions, and well-designed evaluation strategies. Furthermore, the evaluation process revealed that identifying certain errors required nuanced clinical knowledge, emphasizing the critical role of medical expertise in assessing AI models for health care applications.

This study encountered several challenges in the evaluation process, including issues with IAA, assessing fit for specific tasks, and determining model performance on unique data

XSL•FO
RenderX

distributions. Additionally, the research team noted potential pitfalls in the analysis phase, particularly the risk of misattributing results if careful attention was not paid to model aliases and their corresponding data rows. This observation highlighted the importance of meticulous data management and analysis protocols in AI evaluation studies.

These findings contributed to the growing body of literature on the development and evaluation of AI models for health care applications. They underscored the potential of specialized LLMs in medical contexts while also highlighting the complexities and challenges inherent in their evaluation. Future research should focus on refining evaluation methodologies and metrics to ensure robust and clinically relevant assessments of AI models in health care.

Acknowledgments

We would like to extend our deepest gratitude to John Snow Labs, not only for their development of the Spark NLP (natural language processing) library but also for their continued support throughout this research endeavor. The availability and robustness of their library have made this study possible. Their openness and dedication to facilitating our work and allowing us to share our results with the broader community have been invaluable. We appreciate their commitment to advancing health care and medical research through their technological contributions.

Data Availability

The CLEVER (Clinical Large Language Model Evaluation–Expert Review) dataset used in this study is publicly available and can be accessed at the John Snow Labs website [34]. Abstract

Artificial intelligence (AI) is revolutionizing digital health, driving innovation in care delivery and operational efficiency. Despite its potential, many AI systems fail to meet real-world expectations due to limited evaluation practices that focus narrowly on short-term metrics like efficiency and technical accuracy. Ignoring factors such as usability, trust, transparency, and adaptability hinders AI adoption, scalability, and long-term impact in health care. This paper emphasizes the importance of embedding scientific evaluation as a core operational layer throughout the AI life cycle. We outline practical guidelines for digital health companies to improve AI integration and evaluation, informed by over 35 years of experience in science, the digital health industry, and AI development. It describes a multistep approach, including stakeholder analysis, real-time monitoring, and iterative improvement, that digital health companies can adopt to ensure robust AI integration. Key recommendations include assessing stakeholder needs, designing AI systems that can check its own work, conducting testing to address usability and biases, and ensuring continuous improvement to keep systems user-centered and adaptable. By integrating these guidelines, digital health companies can improve AI reliability, scalability, and trustworthiness, driving better health care delivery and stakeholder alignment.

industry; AI integration; user-centered design; health care delivery; digital health; workflow; scientific evaluation; artificial intelligence

Introduction

Digital health companies are increasingly leveraging artificial intelligence (AI) tools to transform care delivery and improve internal operations. AI is being used to develop customer-facing products, such as mental health chatbots and symptom-checking platforms, and to enhance efficiency within organizations, such as accelerating provider documentation workflows [1]. AI adoption has surged globally, with the International Business Machines (IBM) Corporation reporting 35% adoption in 2022 [2], and McKinsey & Company finding this figure had risen to 72% by 2024 [3]. This rapid growth underscores the transformative potential of AI, particularly generative AI (ie, technology that creates new content by learning from existing patterns), which is projected to contribute up to $4.4 trillion in economic value in the coming years [4]. The American Psychological Association named AI as one of the top 10 trends in shaping the field of mental health, recognizing its growing influence [5].

However, AI tools often fail to meet their potential. A recent study highlighted that symptom-checking chatbots frequently provide inaccurate or unhelpful recommendations, eroding user trust and raising patient safety concerns [6]. Similarly, AI-powered transcription tools have been shown to fabricate information or introduce critical errors into clinical documentation, jeopardizing their reliability in real-world settings [7]. Even in research, where AI can support aspects like code automation and study stimuli creation, challenges such as false outputs and breached ethics raise concerns [5]. Additionally, unclear definitions of trust in health care AI contribute to these challenges, hindering ethical and effective translation into practice [8]. These issues underscore the importance of integrating robust, scientifically grounded evaluations into AI tools to enhance their reliability, safety, and effectiveness. The evaluations of AI systems currently tend to prioritize key performance indicators (KPIs) such as efficiency for internal tools and technical performance for customer-facing products to demonstrate return on investment, neglecting essential factors such as usability, transparency, trust, and long-term reliability [9-12]. This fragmented approach to AI evaluation results in several challenges, as internal tools frequently face resistance due to poor design or lack of clarity, and external systems often lose user trust when they fail to perform reliably in real-world contexts [13]. Additionally, the absence of ongoing evaluation and iterative refinement leaves AI systems unable to adapt to evolving needs, which compounds inefficiencies and reduces their long-term impact [13,14]. These

gaps undermine the adoption and scalability of AI solutions and jeopardize their potential to drive sustainable change in digital health care.
