Sadly, many digital health companies have yet to develop the guidelines and expertise needed to integrate AI effectively and maintain rigorous, ongoing evaluation. Without robust and continuous evaluation built in from the beginning, AI systems risk perpetuating errors, failing to meet stakeholder needs, and losing the trust of end-users. To address the shortcomings of current AI evaluations, including the emphasis on short-term KPIs, neglect of user-centered factors, and the lack of ongoing evaluations, its integration should be approached with a scientific mindset that prioritizes evidence-based methods and continuous learning. A recent clinical-trials-inspired framework emphasizes safety, efficacy, and monitoring, but translating high-level guidance into operational practice remains a challenge for digital health companies [15]. The purpose of this paper is to highlight the importance of embedding scientific evaluation as a core operational layer within AI workflows by providing practical guidelines for decision-makers (eg, C-suite leaders, product and operations leads, clinical directors, and AI implementation managers) in digital health companies. These guidelines are informed by over 35 years of cumulative experience in science, the digital health industry, and AI development. Adopting scientific practices offers digital health companies a pathway to strengthen their approach to AI integration, supporting more reliable and impactful outcomes in digital health care, differentiating themselves from competitors and contributing to revenue generation.

Guidelines for Integrating and Evaluating AI in Digital Health Companies

Overview

The following guidelines outline key steps and recommendations to support digital health company leaders in integrating evaluation processes throughout the life cycle of AI systems, enhancing their effectiveness, scalability, and trustworthiness. While conceptually aligned with implementation science frameworks used in AI–such as Consolidated Framework for Implementation Research, which highlights contextual and organizational factors that influence implementation [16], and Proctor's outcomes, which define success through measures like feasibility and sustainability [17]–these recommendations are tailored to the fast-paced, cross-functional environments in which AI is developed and deployed in digital health.

Evaluate Stakeholder Needs Before Implementation

Understanding the priorities and needs of stakeholders is a crucial first step to ensure AI systems align with real-world challenges and expectations. Stakeholders may include patients, clinicians, administrators, employees, and app users or consumers, depending on whether the system is designed for internal operations or as an external product. For example, evidence from intensive care settings highlights how involving diverse stakeholders in preimplementation assessments can significantly enhance the success of pilot testing, leading to better AI integration and usability [18]. This approach also facilitates a scientifically grounded evaluation of potential barriers to adoption, such as workflow disruptions or concerns about transparency, that might otherwise hinder long-term success. In addition, co-creation approaches, where stakeholders actively help design and refine AI systems, add value by going beyond traditional consultation [19-21]. These participatory approaches improve alignment with contextual knowledge, increase trust, and promote long-term adoption of AI tools in health care settings [22,23]. By applying scientific evaluation methods at this stage, behavioral and AI scientists, product developers, and operational leaders can systematically identify and address the specific needs and priorities of intended users, guiding the selection and design of AI systems that are both evidence-based and effective in meeting stakeholder requirements.

To assess stakeholder needs effectively, digital health companies should:

- Leverage collaborations and partnerships with industry experts and research scientists. These partnerships can help ensure that the AI system aligns with scientific standards while also remaining feasible for implementation within the company.
- Conduct qualitative and quantitative assessments with end-users to understand expectations, pain points, desired outcomes, and what AI platforms they may already use. Research and user experience teams can spearhead these efforts, leveraging a human-centered approach to ensure the system aligns with real-world needs and user priorities [24,25]. Qualitative methods offer in-depth insights, while quantitative approaches help capture broader trends across diverse user groups. For example, a digital health company could interview clinicians to uncover documentation challenges, then run a survey to assess anticipated usability, perceived efficiency, and readiness to adopt an AI tool.
- Use co-creation strategies, such as co-design workshops or participatory prototyping, to allow stakeholders to directly influence system functionality, content, and workflows. These methods surface context-specific needs that traditional assessments may miss and help improve usability, trust, and alignment with end-user expectations.
- Develop user personas and journey maps to understand how the AI system fits into existing workflows or end-user experiences. This approach can help teams visualize user interactions, surface potential friction points, and inform refinements that support usability and integration, especially when combined with direct stakeholder input gathered through participatory design activities.

Design AI Systems That Check Its Own Work

To ensure that AI systems are robust, effective, and user-centered throughout their life cycle, digital health companies should embed scientific evaluation mechanisms directly into their design. However, many companies currently underinvest in rigorous evaluation processes, leading to inconsistent progress, flawed AI tools that fail to meet business objectives, canceled projects, and wasted resources [26]. AI evaluations should balance traditional KPIs, such as accuracy and efficiency, with metrics that allow the system to monitor

XSL•FO
RenderX

and reflect on user experience, trust, usability, and satisfaction. By enabling AI tools to "check their own work," companies can create systems that not only meet company goals but also foster user trust and adoption—key factors for achieving sustained impact and scalability in health care settings. This includes designing systems that can detect uncertainty, surface potential issues, and escalate to human input when appropriate. Companies should consider the cross-functional work of teams such as engineering, technology, and science to ensure appropriate design, implementation, and evaluation of AI systems that align with stakeholder needs and operational goals.

In particular, digital health companies should integrate human-in-the-loop (HITL) methodologies, an approach that embeds human judgment into the training, validation, and deployment phases of AI tools. This enables teams to guide model development, intervene during deployment, and refine outputs in real-time, improving adaptability, safety, and trustworthiness [27,28]. HITL is distinct from broader governance or post-hoc audits in that it provides direct, real-time oversight within system workflows. This is especially important in clinical and behavioral health contexts, where ethical and contextual judgment cannot be fully automated.

Several scientific frameworks have been developed to evaluate AI tools, offering valuable guidance on embedding evaluation into the design process. Frameworks such as Standard Protocol Items: Recommendations for Interventional Trials-AI (SPIRIT-AI; [29]) and Consolidated Standards of Reporting Trials–AI (CONSORT-AI; [30]) focus on building transparency, trust, and rigor during the design and reporting phases of clinical trials for AI. While these frameworks emphasize preimplementation evaluation, others, such as Translational Evaluation of Healthcare AI (TEHAI; [31]) and Explainable AI (XAI; [32]), address specific aspects like performance, safety, ethical considerations, and user trust.

While these frameworks provide a strong foundation, they often focus on discrete stages of evaluation and may not fully incorporate HITL approaches that enable continuous input and oversight throughout the AI life cycle. Digital health companies must go further by embedding evaluation mechanisms into workflows to ensure continuous monitoring and improvement. Without such mechanisms, teams risk uneven progress, flawed implementations, and ultimately, AI tools that fail to meet stakeholder needs or achieve business goals [26].

When building AI systems that can monitor themselves, digital health companies should:

- Prioritize early investment in AI evaluation to build a strong foundation for assessing effectiveness throughout the AI tool's life cycle. This approach ensures potential challenges are proactively addressed, which supports smoother implementation and long-term adaptability. This may include consulting with behavioral or AI scientists to design evidence-based evaluation methods, identify potential biases, and refine AI system performance to align better with real-world needs.
- Consider existing scientific frameworks as a foundation for designing AI tools with transparency and rigor, while adapting them to include mechanisms for ongoing, real-world evaluation that captures both technical performance and comprehensive user experience metrics.
- Develop automated tools for ongoing evaluation that track metrics aligned with both user priorities and business objectives, such as technical accuracy, error rates, user satisfaction, and productivity. These evaluations streamline development by concentrating efforts on critical areas, increasing the likelihood of deploying AI systems that effectively meet organizational goals and end-user needs [26]. For example, automated tools could monitor user interactions on a mental health platform, such as response times, task completion rates, and drop-off points, allowing product teams and behavioral or AI scientists to identify areas for improvement and enhance user experience.
- Establish feedback loops that allow for end-users to provide feedback in real time, ensuring their perceptions are consistently captured and integrated into system updates.
- Embed HITL components such as human review panels, clinician-in-the-loop decision support, or structured escalation processes that ensure human judgment is available at key junctures. HITL differs from general human oversight or feedback mechanisms in that it places human judgment directly within the AI system's workflow, enabling real-time intervention to correct system drift, mitigate error propagation, and uphold ethical safeguards.
- Incorporate routine bias audits into evaluation workflows to assess whether the AI system performs equitably across user subgroups. This is particularly important in health settings where automated systems can unintentionally amplify disparities, especially among low-prevalence or underserved populations [33,34]. Regularly reviewing model outputs by demographic characteristics and edge cases can help teams identify and mitigate bias early in the deployment cycle.
- Establish human oversight to ensure accountability, mitigate potential biases, and validate performance. This includes establishing a scientific AI evaluation leader or multidisciplinary review teams to regularly assess the system's outputs, identify blind spots in automated evaluations, and ensure alignment with company goals and user needs. Human input is critical for addressing nuances and ethical considerations that AI alone may overlook, ensuring the system's outputs remain contextually appropriate and trustworthy. Oversight reinforces governance and long-term trust, complementing the real-time, embedded nature of HITL.

Testing and Refinement Before Implementation

AI systems should undergo beta, feasibility, and pilot testing, which involves the collaboration of research (ie, behavioral and AI scientists), user experience, product, engineering, and operations teams, to ensure they are ready for real-world implementation. These phases allow opportunity to identify potential issues related to usability, performance, and integration within real-world workflows before full implementation. For example, beta testing helps gather quick feedback from real-world users to refine usability and make early improvements. Feasibility can be used to evaluate resource requirements and alignment with the business goals of the

XSL•FO
RenderX

company, ensuring practical deployment and sustainability. Pilot testing can also be used to further refine the AI tool and assess initial outcomes for viability. For instance, pilot testing has been essential in improving the intuitiveness of health care chatbots [35,36].

To effectively test and refine before implementation, digital health companies should:

- Conduct feasibility tests early to assess whether the AI tool aligns with business objectives, technical infrastructure, and resource availability. This ensures the AI is viable and positioned for successful implementation.
- Engage diverse stakeholders, such as clinicians, administrators, and end-users during testing and refinement to gather comprehensive feedback. For example, when testing an AI-powered clinical decision support tool, a company could engage physicians to ensure recommendations align with clinical guidelines, administrators to assess integration with existing electronic health record systems, and nurses to evaluate usability and workflow compatibility.
- Iterate, based on findings, by using the feedback from these testing stages to refine the AI system, addressing issues such as workflow integration and potential user resistance. Structured reviewer input or user flagging mechanisms, when embedded into the system's operation, can function as HITL approaches that support more responsive and ethical refinement. AI scientists and operations teams should work closely with behavioral scientists to ensure the system evolves based on real-world insights.

Implement With Real-Time Monitoring and Data Collection

Implementing an AI tool is an important opportunity for digital health companies to gather actionable insights about how they perform in real-world settings. Real-time monitoring and data collection allow companies to identify emerging issues, refine workflows, and validate that AI tools meet both technical and user-centered expectations. For example, LinkedIn leveraged a deep-learning-based monitoring system to track the health of its AI models, identifying issues in real-time to improve business outcomes [37]. This proactive approach supports scalability and long-term adoption by addressing challenges early in deployment. Engineering, operations, and research (eg, behavioral and AI scientists and data analysts) should collaborate to establish monitoring systems and analyze findings.

To implement real-time monitoring and data collection effectively, digital health companies should:

- Deploy automated, self-check monitoring systems to continuously track both traditional KPIs (eg, accuracy, response times, and error rates) and user experience metrics (eg, task completion rates, interaction frequency, and perceived usability). Leverage the evaluation mechanisms embedded during the AI system's design.
- Analyze incoming data to systematically identify patterns or recurring issues that may impact the AI's performance or user engagement. Structured analyses, conducted by the company's data analysts and behavioral scientists, help prioritize areas for improvement and ensure resources are allocated effectively. For example, by analyzing user interaction patterns, a company might find that users tend to leave an AI-powered chat when provided with lengthy responses, prompting the need to shorten message length to improve engagement.
- Implement strategic refinements based on monitored insights to address significant challenges or adapt the AI system to evolving user needs and company priorities. Postlaunch updates should be carefully planned and aligned with long-term goals. Where appropriate, HITL mechanisms can support these refinements by enabling human input in ambiguous, high-stakes, or ethically sensitive situations.

Continue Evaluation and Iterative Improvement After Implementation

Once an AI system is implemented, ongoing evaluation becomes essential to ensure it continues to meet company goals and user expectations. AI tools often experience performance degradation over time as changes in usage patterns, data inputs, workflows, user needs, and external factors (eg, regulatory changes, updates to clinical guidelines) require them to adapt to maintain their effectiveness and relevance. For example, generative AI models (eg, ChatGPT) present unique challenges due to their inherent randomness, making repeated evaluations essential to ensure reliable performance [38]. Additionally, the dynamic nature of AI, particularly generative AI, requires digital health companies to continuously adopt and adapt to rapidly improving models with enhanced capabilities and significant cost fluctuations. Recent benchmarking data from Epoch shows that once models reach certain levels of computing power, they experience significant jumps in performance on tasks [39]. Furthermore, when GPT-4 was initially released in March 2023, it cost US $36 per million tokens (ie, units of text used to process input and generate output), but by late 2024, this price had dropped to just $0.25 per million tokens—a staggering 99% reduction [40]. This sharp drop in cost highlights how quickly AI technology evolves, making advanced tools more affordable over time. For digital health companies, this means they must regularly evaluate whether adopting updated models is both practical and beneficial, ensuring they use the most effective and cost-efficient solutions while staying aligned with their goals and user needs. Product teams, behavioral and AI scientists, and operation specialists should collaborate to monitor performance, gather user feedback, and adapt systems to evolving needs and guidelines.

To continuously evaluate and improve AI systems, digital health companies should:

- Conduct regular audits to assess technical metrics, such as accuracy and reliability, alongside user experience metrics, including satisfaction and usability. These audits help identify whether the system is meeting its intended objectives and uncover opportunities for optimization. They should also maintain broader human oversight (beyond HITL mechanisms), which could include a scientific AI evaluation leader and/or a multidisciplinary team
- Incorporate usability testing as a continuous process to regularly identify pain points and opportunities for

XSL•FO
RenderX

improvement among diverse user groups. Regularly engaging with end-users ensures that the system adapts to their evolving needs and remains intuitive and efficient. For example, ongoing usability testing for an AI-driven mental health platform could involve observing end-users as they navigate key features, such as finding a therapist or accessing self-help tools, to identify usability challenges and inform iterative design improvements.

- Prioritize publishing and reporting on AI performance, user experiences, and trust-building metrics throughout AI integration (ie, from beta testing to post-launch). Reporting on technical metrics alongside user-focused insights offers a holistic view of AI system effectiveness. For example, companies can conduct retrospective analyses of de-identified conversation content and usage patterns to identify trends and gaps, guiding future improvements. While peer-reviewed outputs are valuable, resource-constrained teams may benefit from alternative dissemination methods, such as implementation briefs, open-access case reports, webinars, or practice-based repositories, that enable rapid, practical knowledge-sharing. By sharing these findings, companies contribute to greater accountability, advance innovation, and guide the development of AI tools that meet user and company needs.
- Maintain human oversight that could include a scientific AI evaluation leader or a multidisciplinary team of technical, clinical, and operational experts. Human oversight is needed to ensure that AI systems can continuously adapt to new data, address unforeseen issues, and uphold ethical and performance standards in dynamic health care settings.

Conclusions

The integration of AI into digital health presents a transformative opportunity to enhance care delivery, optimize operations, and improve patient outcomes. However, its success hinges on a commitment to continuous, scientifically grounded evaluation. Scientific evaluation is not just a checkpoint—it is an operational layer that should be embedded into workflows to ensure trust, scalability, and measurable impact. While not developed through a formal consensus process or systematic review, the guidelines outlined in this paper are informed by over 35 years of cumulative experience across science, the digital health industry, and AI development. They advocate for incorporating scientific evaluation processes that balance technical performance with user-centered metrics, enabling digital health companies to ensure their AI tools remain effective, adaptable, and trustworthy over time. This approach may enhance the reliability and scalability of AI systems and drive revenue growth by improving user satisfaction, increasing adoption rates, and streamlining operations. Achieving these outcomes requires cross-functional collaboration between behavioral and AI scientists, data analysts, product teams, engineers, and operations staff. Together, these teams can ensure AI solutions are aligned with business objectives, meet stakeholder needs, and deliver meaningful, scalable impact in digital health care. A key future direction is to formally build on these recommendations through a structured, cross-disciplinary consensus process.

Abstract

Background: Mental disorders are frequently evaluated using questionnaires, which have been developed over the past decades for the assessment of different conditions. Despite the rigorous validation of these tools, high levels of content divergence have been reported for questionnaires measuring the same construct of psychopathology. Previous studies that examined the content overlap required manual symptom labeling, which is observer-dependent and time-consuming.

Objective: In this study, we used large language models (LLMs) to analyze content overlap of mental health questionnaires in an observer-independent way and compare our results with clinical expertise.

Methods: We analyzed questionnaires from a range of mental health conditions, including adult depression (n=7), childhood depression (n=15), clinical high risk for psychosis (CHR-P; n=11), mania (n=7), obsessive-compulsive disorder (n=7), and sleep disorder (n=12). Two different LLM-based approaches were tested. First, we used sentence Bidirectional Encoder Representations from Transformers (sBERT) to derive numerical representations (embeddings) for each questionnaire item, which were then clustered using k-means to group semantically similar symptoms. Second, questionnaire items were prompted to a Generative Pretrained Transformer to identify underlying symptom clusters. Clustering results were compared to a manual categorization by experts using the adjusted rand index. Further, we assessed the content overlap within each diagnostic domain based on LLM-derived clusters.

Results: We observed varying degrees of similarity between expert-based and LLM-based clustering across diagnostic domains. Overall, agreement between experts was higher than between experts and LLMs. Among the 2 LLM approaches, GPT showed greater alignment with expert ratings than sBERT, ranging from weak to strong similarity depending on the diagnostic domain. Using GPT-based clustering of questionnaire items to assess the content overlap within each diagnostic domain revealed a weak (CHR-P: 0.344) to moderate (adult depression: 0.574; childhood depression: 0.433; mania: 0.419; obsessive-compulsive disorder [OCD]: 0.450; sleep disorder: 0.445) content overlap of questionnaires. Compared to the studies that manually investigated content overlap among these scales, the results of this study exhibited variations, though these were not substantial.

Conclusions: These findings demonstrate the feasibility of using LLMs to objectively assess content overlap in diagnostic questionnaires. Notably, the GPT-based approach showed particular promise in aligning with expert-derived symptom structures.

Introduction

Mental health questionnaires are essential tools to assess psychological and psychiatric conditions, offering insights into symptom presence, severity, frequency, and duration [1]. Over the last decades, a wide range of questionnaires has been developed, each requiring rigorous validation of its validity and reliability [2]. Particularly, the analysis of a questionnaire's content is crucial in order to assure that it validly measures the intended construct [3]. However, a surprising degree of content divergence has been reported among questionnaires designed to measure the same construct [1,4-11]. For example, a comparison of 4 depression questionnaires revealed that while items assessing general, somatic, and positive symptoms were consistently included, 4 factors (anxiety, positive emotions, interpersonal functioning, and performance impairment) were unique to individual questionnaires [4]. A more detailed analysis of the content overlap of 7 depression questionnaires revealed only a weak similarity among the questionnaires, with 40% of symptoms appearing in just one questionnaire [6]. Similar results have been reported for questionnaires of childhood depression, clinical high risk for psychosis (CHR-P), mania, obsessive-compulsive disorder (OCD), and sleep disorder [7-11]. Thus, it is questionable if questionnaires designed to measure the same construct can be used interchangeably [12]. This lack of interchangeability has important implications, as it may compromise comparability across studies, affect the reproducibility of findings, and introduce bias in clinical practice and research.

These more detailed analyses of questionnaire similarity quantified the content overlap by determining whether items of different questionnaires assess the same symptoms, following a method proposed by Fried [6]. This is done through a manual categorization of questionnaire items, where researchers assign each questionnaire item (eg, "Trouble concentrating on things, such as reading the newspaper or watching television") to a symptom category (eg, "cognitive deficits"). This process is both time-consuming and observer-dependent, leading to inconsistencies and limiting the scalability and reliability of content overlap assessments. Therefore, an objective and more automated process is needed to make the evaluation of content overlap more accessible.

With advances in artificial intelligence, large language models (LLMs) have emerged as powerful tools for analyzing and generating text [13-15]. A key feature of LLMs is their ability to transform text into numerical representations within a high-dimensional vector space, so-called embeddings [14]. Sentences with similar content typically have embeddings that are in close proximity to each other within this vector space. For example, "I have trouble concentrating" is expected to be located closer to "I find it hard to focus" than to "I feel sad." Thus, LLMs offer an effective method for capturing the underlying semantic structure and quantifying the semantic similarities of sentences [16]. Combined with clustering, an unsupervised machine learning technique, embeddings can be used to group texts with semantically similar content [13,17,18]. In addition to embedding generation, LLMs can also be guided through prompting, that is, eliciting meaningful text outputs by providing specific instructions or questions to the LLM [19]. Although static embeddings generated without prompting are consistent, they often lack interpretability; in contrast, the more flexible approach of prompting produces auto-generated, interpretable results but can be inconsistent and depends heavily on the quality of the prompt [20-23]. LLMs' capability of text analysis has been of interest in psychological research, for example, to validate constructs of psychological questionnaires, to predict the relationship between questionnaire items, and to generate new questionnaires [24-29]. Given their ability to quantify semantic similarities, LLMs present a promising alternative for automating and standardizing the assessment of questionnaire content overlap.

Thus, in this study, we used LLMs to objectively quantify the content overlap of mental health questionnaires that have previously been analyzed through manual categorization. Therefore, we first evaluated whether LLMs can group questionnaire items in a manner comparable to clinical experts by using two approaches. First, we used a state-of-the-art LLM [14] to derive static embeddings of questionnaire items and used unsupervised machine learning to group items assessing similar symptoms. Second, prompting was used to determine symptoms underlying questionnaire items. In a second step, we assessed the content overlap across mental health questionnaires based on the LLM-derived groupings. Our goal is to demonstrate that LLMs can effectively cluster questionnaire items based on symptoms, thereby improving our knowledge about mental health questionnaires with a focus on their heterogeneity.

Methods

Questionnaires

This analysis was based on a selection of mental health questionnaires that have been previously investigated with respect to their content overlap [6-11]. This included questionnaires for adult depression (n=7) [30-36], childhood depression (n=15) [30,37-50], CHR-P (n=11) [51-61], mania (n=7) [62-68], OCD (n=7) [69-75], and sleep disorder (n=12) [76-86]. The questionnaires were included based on their frequency in literature, inclusion in reviews, and citation count. The full details about the selection process can be found in the previous publications. A summary of all questionnaires can be found in Table 1. It has to be noted that the Depression and Anxiety in Youth Scale (DAYS) [87], the Multiscore Depression Inventory for Children (MDI-C) [88], the Reynolds Adolescent Depression Scale (RADS) [89], and the Eppendorf Schizophrenia Inventory (ESI) [90] were neither publicly available nor purchasable. Hence, these questionnaires could not be included in the analysis. Further, we did not include the Child Behavior Checklist and Youth Self Report [91] as these are not specifically designed to assess the risk for psychosis.

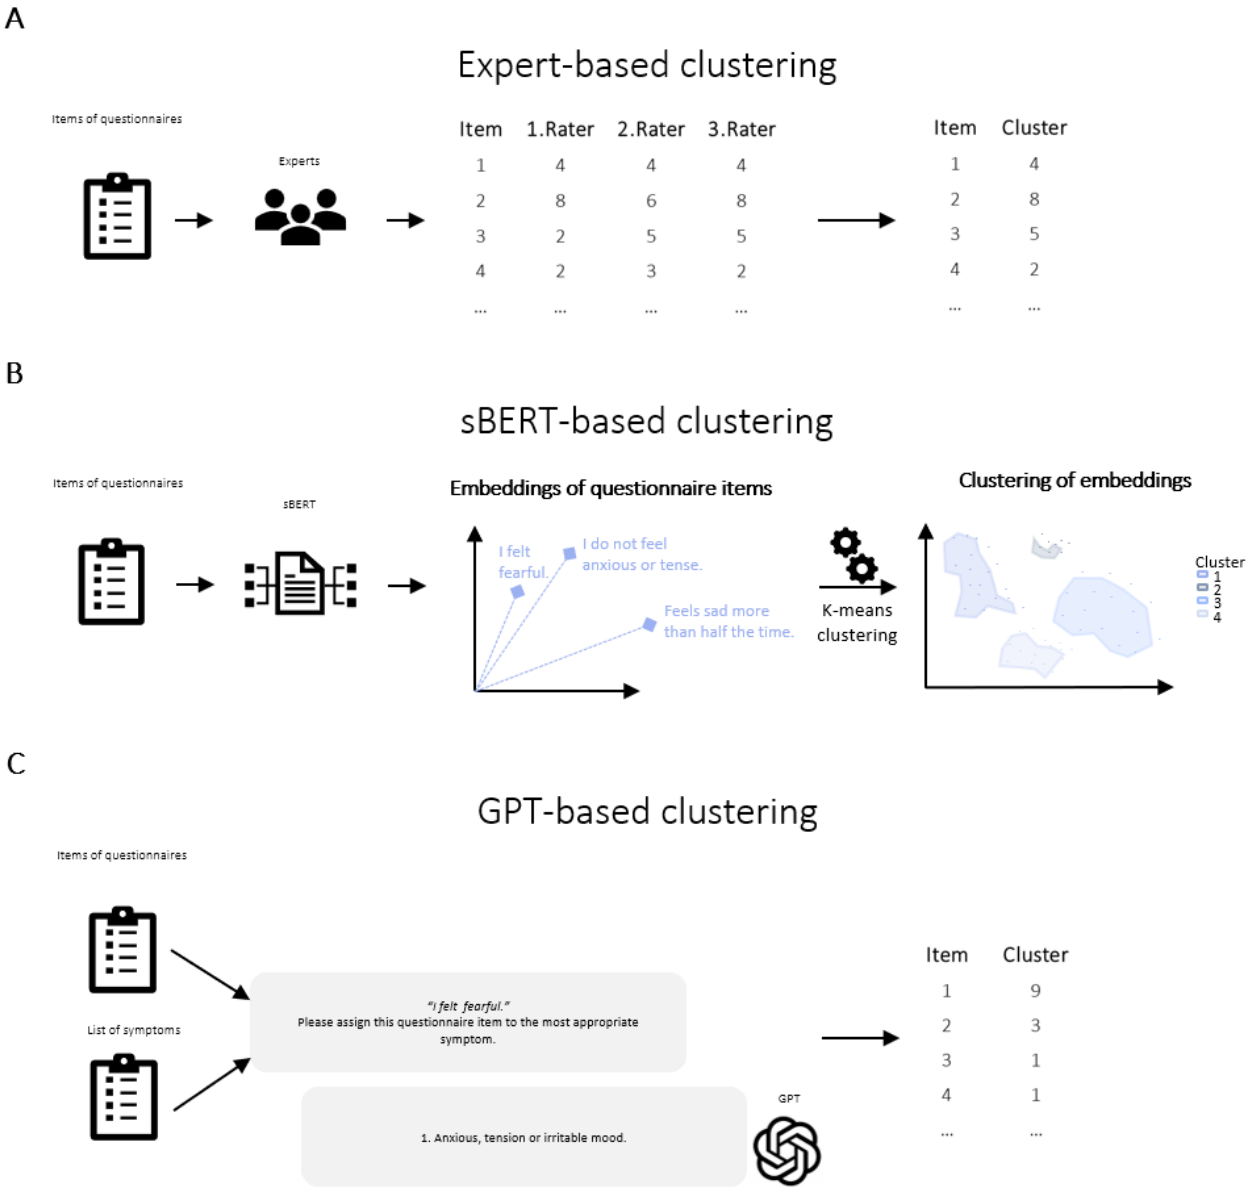
[a]SR: self-rating.

[b]OR: observer-rating.



[c]CHR-P: clinical high risk for psychosis.

[d]OCD: obsessive-compulsive disorder.

For each diagnostic domain (adult depression, childhood depression, CHR-P, mania, OCD, and sleep disorder) we identified the respective core symptoms based on the *Diagnostic and Statistical Manual of Mental Disorders, 5th edition (DSM-5*) [92]. For CHR-P symptoms, we extracted the core symptoms from the Structured Interview for Psychosis-Risk Syndromes (SIPS) [8]. Thereby, symptom features were listed as individual symptoms (eg, from the *DSM-5* item "Feelings of worthlessness or excessive or inappropriate guilt," the symptoms "Feelings of worthlessness" and "Feelings of guilt" were extracted). Each questionnaire item was assigned to one of the core symptoms by 3 of 10 clinical experts independently (Figure 1A). All experts are working in the field of mental health as clinicians, psychotherapists, and researchers. Questionnaires were assigned to experts according to their field of expertise. Each element of a questionnaire to which a participant or observer must respond was considered as an item. Thereby, subitems were consolidated into one item. Items that were not related to symptoms but to assessment quality (eg, "These answers represent my honest feelings") were removed from the analysis. If an item assessed multiple core symptoms, symptoms were combined and categorized with a more general symptom (eg, "There is no change from my usual appetite" can refer to both "decreased appetite" and "increased appetite," which were combined as "changes in appetite"). In case an item could not be assigned to a core symptom from the *DSM-5* or SIPS, an additional symptom was added to the list of core symptoms (eg, "I feel very bored" refers to "boredom").

(C) Generative Pretrained Transformer–based clustering. GPT: Generative Pretrained Transformer; sBERT: Sentence-Bidirectional Encoder Representations from Transformers.

Similarity of Expert- and Embedding-Based Item Grouping

For each diagnostic domain, 3 clinical experts were independently provided with a list of questionnaire items and were instructed to assign each item to one of the core symptoms. Questionnaire items were assigned to core symptoms based on the highest agreement among expert ratings. In case no clear consensus was reached, the raters discussed and agreed upon the most appropriate categorization. Based on this, all items of questionnaires of the same diagnostic domain were clustered.

To cluster items by underlying symptoms using LLMs, we used 2 approaches. First, sentence embeddings of questionnaire items were derived from the pretrained sentence Bidirectional Encoder Representations from Transformers (sBERT) model "all-mpnet-base-v2" [14] (Figure 1B). The open-access sBERT model, trained on 160 gigabytes of English text corpora, was selected based on its superior performance in sentence encodings across 14 benchmark tasks and its recognition as one of the best validated models [93]. The resulting sentence embeddings of a fixed dimensionality of 768 were clustered using k-means clustering. The number of clusters was set to the same number as in the expert-based analysis. Second, OpenAI's third-generation Generative Pretrained Transformer (GPT) model "GPT-3.5-Turbo-0125" [94] was used to assign each questionnaire item to a corresponding symptom (Figure 1C). Its wide availability, computational efficiency, and high performance at comparatively low cost made it a suitable choice for this study [95]. Each item was presented to the model alongside the list of core symptoms, and the model was prompted to assign the item to the most appropriate symptom. Based on the model's responses, items of each diagnostic domain were grouped according to their assigned symptom.

Similarity of clustering within each diagnostic domain, among the 3 experts and between the experts' highest-agreement cluster (hereafter referred to as expert-based clustering) and the two

XSL•FO
RenderX

LLM-based clustering approaches, was quantified using the Adjusted Rand Index (ARI), a widely used metric for evaluating agreement between clustering solutions [96,97]. The ARI ranges from -0.5 to 1.0, where negative values indicate clustering discordance lower than chance, values near zero suggest random clustering, and values approaching one reflect near-perfect agreement. In the absence of established guidelines for interpreting the strength of the ARI, we applied the classification used for correlation coefficients: very weak (0.00 - 0.19), weak (0.20 - 0.39), moderate (0.40 - 0.59), strong (0.60 - 0.79), and very strong (0.80 - 1.00). First, we evaluated the similarity in ratings for each pair of raters and computed the mean similarity within each diagnostic domain. Second, the similarity between expert-based and both the sBERT- and GPT-based clustering solutions was evaluated across the diagnostic domains using the ARI. Given that both self- and observer-rated questionnaires were included in the analysis and the rating types of questionnaires exert a strong influence on how items are phrased, we additionally examined the similarity between the expert-based clusterings and both LLM-based clusterings separately for rating types. As a control of the sBERT-based approach, sentence embedding vectors were randomly permuted, and the analysis was repeated (1000 repetitions) as described before.

Content Overlap of Questionnaires

In a second step, the content overlap of questionnaires within each diagnostic domain was calculated based on the method introduced by Fried [6] but using the GPT-based clustering approach. Specifically, for each diagnostic domain, the Jaccard index was calculated for each pair of questionnaires to determine their overlap of content. The Jaccard index is calculated by dividing the number of shared items between 2 clusters by the total number of items present in both clusters. The resulting values range from 0, indicating no overlap, to 1, representing complete overlap. Similar to Fried [6], we defined the strength of the Jaccard index as follows: very weak (0.00 - 0.19), weak (0.20 - 0.39), moderate (0.40 - 0.59), strong (0.60 - 0.79), and very strong (0.80 - 1.0).

Ethical Considerations

This study did not involve human participants, medical records, patient information of any kind, or secondary data analyses. Thus, the study did not meet the criteria for a review by an institutional review board, and no ethical approval was required.

Results

Questionnaires

A total of 23 symptoms of adult depression, 30 symptoms of childhood depression, 40 symptoms of CHR, 29 symptoms of mania, 27 symptoms of OCD, and 45 symptoms of sleep disorder were identified in the questionnaires based on core criteria from the *DSM-5* or SIPS (Table S1 inMultimedia Appendix 1). A more detailed graphical representation of the number of items assigned to each cluster by the 3 clustering approaches can be found in Figures S1-6 in Multimedia Appendix 1. It should be noted that defining the expert-based clustering solution based on the highest agreement among experts and limiting the analysis to self-rating (SR) or observer-rating (OR) questionnaires reduced the number of identified symptoms in some of the diagnostic domains (Table 2).

XSL•FO

[a]sBERT: Sentence-Bidirectional Encoder Representations from Transformers.

[b]GPT: Generative Pretrained Transformer.

[c]CHR-P: clinical high risk for psychosis.

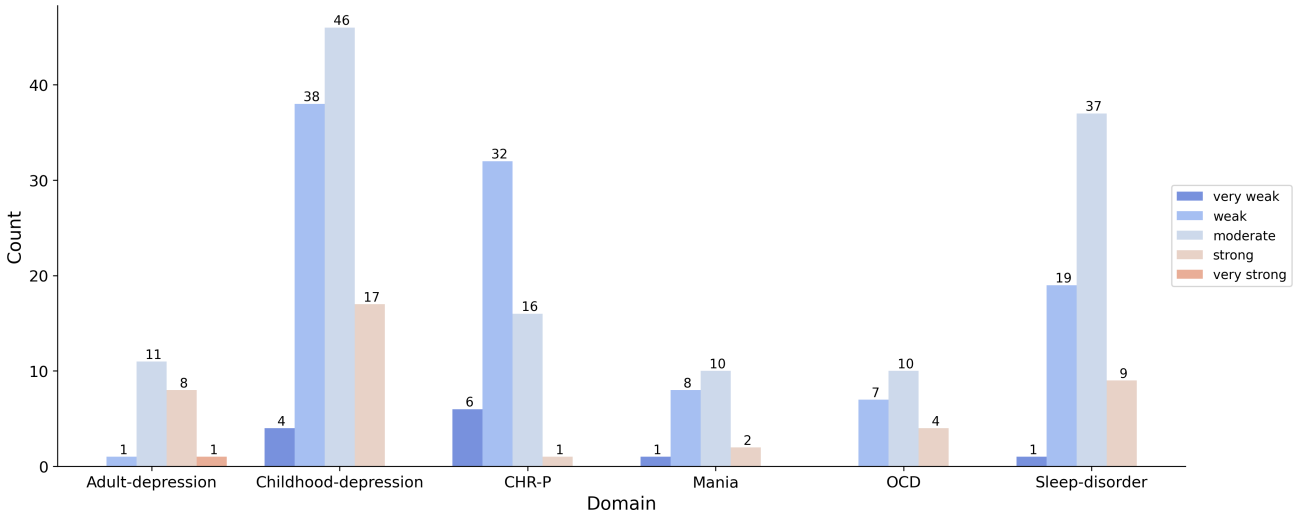
[d]OCD: obsessive-compulsive disorder.

[e]SR: self-rating.

[f]OR: observer-rating.

Similarity between expert-based and sBERT-based clusterings varied across the diagnostic domains. The ARI ranged from 0.188 (for childhood depression questionnaires) to 0.371 (for adult depression questionnaires), indicating a very weak to weak similarity (Table 3). Including solely SR items, the mean ARI ranged between a very weak (0.143 for mania questionnaires) and weak similarity (0.366 for adult depression). For OR questionnaires, we observed a similarity lower than chance (ARI: −0.023) for childhood depression questionnaires. Across the other domains, we observed ARIs in the range of a weak (0.286 for OCD questionnaires) to moderate similarity (0.589 for CHR-P questionnaires). Irrespective of diagnostic domains and rating types, the mean ARI exceeded the 95% CI indicating agreement above chance level, with the exception of the childhood depression OR questionnaires.

Additionally, we observed a varying similarity between expert-based and GPT-based clustering solutions. We observed a very weak (0.195 for sleep disorder questionnaires) to strong (0.694 for adult depression questionnaires) similarity across the different diagnostic domains (Table 3). When focusing on SR items, the ARI varied from 0.195 (for sleep disorder questionnaires) to 0.651 (for adult depression questionnaires), indicating again a very weak to strong similarity. Including solely OR items, we observed a weak (0.378 for CHR-P questionnaires) to strong (for adult depression questionnaires) similarity.



Content Overlap of Questionnaires

Using the method introduced by Fried [6] but adapted to the GPT-based clustering approach to assess the content overlap of questionnaires, we observed a weak content overlap for CHR-P questionnaires (mean Jaccard index: 0.344) and a moderate content overlap for adult depression questionnaires (mean Jaccard index: 0.574), childhood depression questionnaires (mean Jaccard index: 0.443), mania questionnaires (mean Jaccard index: 0.419), OCD questionnaires (mean Jaccard index: 0.457), and sleep disorder questionnaires (mean Jaccard index:

XSL•FO
RenderX

0.461). An overview of the observed content overlap within each diagnostic domain is presented in Figure 3. Interactive sunburst plots showing a more detailed overview of the content overlap of the questionnaires in each diagnostic domain can be found on GitHub [98].

Figure 3. Content overlap of questionnaires within each diagnostic domain. CHR-P: clinical high risk for psychosis; OCD: obsessive-compulsive disorder.

As similarity between the expert-based and GPT-based clustering was highest for adult depression questionnaires, we focused on the content overlap of these questionnaires in greater detail. The number of symptoms and the average Jaccard index per questionnaire can be found in Table 4.

Table . Average overlap of clusters across adult depression questionnaires.

Questionnaire	Number of items	Number of symptoms	Mean Jaccard index
BDI-II[a]	21	12	0.549
CES-D[b]	20	15	0.601
HDRS[c]	17	11	0.445
IDS[d]	60	14	0.623
MADRS[e]	10	8	0.567
QIDS[f]	32	12	0.653
SDS[g]	20	13	0.579

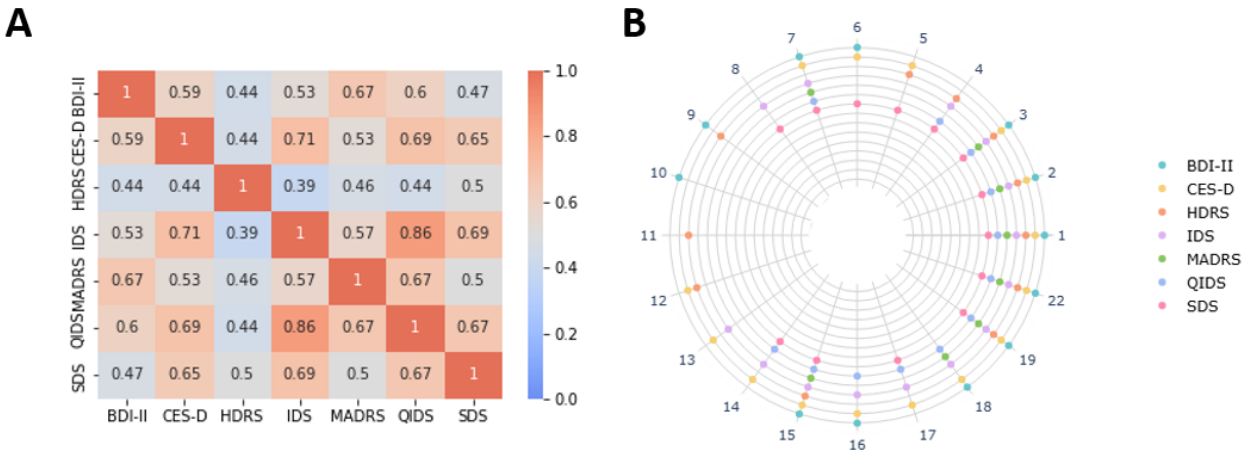
[a]BDI-II: Beck Depression Inventory.

[b]CES-D: Center of Epidemiological Studies Depression Scale.

[c]HDRS: Hamilton Rating Scale for Depression.

[d]IDS: Inventory of Depressive Symptoms.

[e]MADRS: Montgomery-Åsberg Depression Rating Scale.



[f]QIDS: Quick Inventory of Depressive Symptoms.

[g]SDS: Zung Self-Rating Depression Scale.

A total of 20 symptoms were found in questionnaire items of adult depression questionnaires using GPT-based clustering. Of these, 15/20 symptoms (75%) were found in the CES-D. Around 8/20 symptoms (40%) were identified in the Montgomery-Åsberg Depression Rating Scale (MADRS). Six symptoms were featured across all questionnaires (Figure 3). One symptom was exclusively represented in the BDI-II, while another item appeared only in the Hamilton Rating Scale for Depression (HDRS). Across all adult depression questionnaires, the mean content overlap was 0.574. For a detailed overview of the Jaccard indices, see Table 4 and Figure 4A. The content overlap of Inventory of Depressive Symptoms (IDS) and Quick Inventory of Depressive Symptoms (QIDS) was highest, whereas the lowest overlap was found between IDS and HDRS. Details of symptoms found in questionnaires can be found in Figure 4B.

BDI-II: Beck Depression Inventory; CES-D: Center of Epidemiological Studies Depression Scale; HDRS: Hamilton Rating Scale for Depression; IDS: Inventory of Depressive Symptoms; MADRS: Montgomery-Åsberg Depression Rating Scale; QIDS: Quick Inventory of Depressive Symptoms; SDS: Zung Self-Rating Depression Scale.

Discussion

Principal Findings

To the best of our knowledge, this is the first study to use LLMs to assess the content overlap of mental health questionnaires. First, we aimed to compare expert-based clustering of questionnaire items to two observer-independent automatic approaches using LLMs: (1) clustering sentence embeddings generated by sBERT using k-means, and (2) prompting the questionnaire items directly to the GPT model. Across the different diagnostic domains, we found a moderate to very strong agreement between expert raters. Although similarity between expert-based and sBERT-based clustering was above chance, GPT-based clustering was in general more aligned with expert-based clustering except for sleep disorder questionnaires. In a second step, we calculated the content overlap of questionnaires within each diagnostic domain based on the GPT clustering. We observed weak (CHR-P questionnaires) to moderate (adult depression, childhood depression, mania, OCD, and sleep disorder questionnaires) content overlap.

Similarity of Expert- and Embedding-Based Item Grouping

Generally, our findings demonstrate that LLMs such as sBERT and GPT can be effectively used to cluster questionnaire items based on content. Both models have previously been used to assess the validity of questionnaires and surveys [24,25,29]. Using a fine-tuned sBERT model to generate semantic embeddings of the International Personality Item Pool questionnaires, Wulff and Mata [29] demonstrated that these embeddings can predict a questionnaire's empirical internal structure, convergent and divergent validity, and detect its structural fidelity. Similarly, the fine-tuned sBERT model SurveyBot3000 was able to infer correlations between questionnaire items and the intercorrelation of questionnaires of the American Psychological Association (APA) PsycTests corpus [24]. Further, Huang et al [25] used a GPT model to generate semantic embeddings of two gratitude questionnaires. Similarity between each questionnaire pair was then clustered to infer semantic similar items and identify redundancy within questionnaires. Our study extends these applications by highlighting LLMs' utility in assessing content overlap in mental health questionnaires. Notably, we found that directly prompting items to GPT is particularly effective for generating meaningful content-based groupings of questionnaire items. Similarly, Petukhova [16] observed that GPT models outperform static embedding models like sBERT in clustering and semantic understanding tasks. Specifically, when combined with prompt engineering, GPT models offer advantages in generative reasoning over the fixed representations generated by sBERT [23]. Compared to methods that require generating and clustering embeddings from static models like sBERT, GPT prompting is not only more flexible but also easier to implement, as it does not require additional preprocessing or fine-tuning. Thus, GPT prompting appears to be a promising tool for rapidly obtaining an overview of the content overlap in mental health questionnaires. This application will likely further improve with future GPT models, as newer versions show increased ability to detect psychological constructs [99].

Content Overlap of Questionnaires

Compared to previous studies, we observed a higher overlap between the questionnaires with the exception of sleep disorder questionnaires [6-11]. This is likely due to differences in the number of identified symptoms. Compared to previous studies, we identified fewer symptoms across all diagnostic domains, which may have resulted in a less fine-grained analysis and, consequently, an increased apparent content overlap. However, using more nuanced symptoms was not feasible, as some items

XSL•FO
RenderX

lack specificity; for example, “I sleep a lot less than usual” can reflect both initial and middle insomnia. Nevertheless, we observed a substantial heterogeneity between questionnaires across all diagnostic domains, which strengthens previous observations of content divergence between questionnaires. Such heterogeneity of content is not inherently problematic. On the contrary, variability across questionnaires can be beneficial; it allows clinicians and researchers to capture complementary information, adapt to different contexts, and contribute to scientific advancement [100,101]. However, to fully leverage this variability, it is essential to understand the distinct strengths and applications of each questionnaire. This study demonstrates a method for facilitating the identification of content overlap, thereby making this process more accessible.

Focusing on the content overlap of adult depression questionnaires in greater detail revealed that the overlap of questionnaires is moderate (0.574), indicating that the results from one questionnaire may only partially generalize to others. In line with the observations of Fried [6], the content of the QIDS demonstrated the highest mean similarity with other questionnaires, but we observed the lowest mean similarity for the HDRS, not the CES-D. Related to this, we identified idiosyncratic items in the HDRS (and BDI-II) but not in the CES-D. Several studies have reported that the HDRS and BDI-II capture idiosyncratic symptoms [4,6,101]. In line with Fried [6], our GPT-based clustering identified only items related to feelings of punishment in the BDI-II, whereas items related to hypochondriasis appeared exclusively in the HDRS. However, additional idiosyncratic symptoms were identified in other questionnaires, and these differ from those reported by Shafer [4]. These differences may again be attributed to a less fine-grained symptom structure. Overall, our findings demonstrate that GPT-based content overlap analysis of questionnaires is not only feasible but also fast and computationally efficient, making it a promising approach for large-scale questionnaire comparisons. In the future, this approach will facilitate an extended investigation of questionnaire content overlap by incorporating additional instruments and enable broadening the analysis to questionnaires assessing other mental health disorders, such as anxiety disorders or posttraumatic stress disorder.

Limitations

Several limitations have to be addressed. First, the number of items and symptoms was not consistent across the diagnostic domains. The discrepancy in the number of identified clusters may have influenced the results. However, reducing the number of clusters, and thus the number of identified symptoms, would decrease the specificity of symptoms and thus lower the accuracy of the content overlap analysis [6]. Further, the semantic representation of an LLM is influenced by its training data [25]. Both LLMs used in this study were trained on publicly available texts (eg, web pages, books, or Wikipedia) but not clinical datasets (eg, diagnostic manuals). This might have influenced the model’s representation of questionnaire items. However, both LLMs were shown to contain reliable general psychiatric knowledge and were able to classify mental health conditions without fine-tuning [102-104]. In future work, it would be valuable to compare the clustering performance of pretrained and fine-tuned models. Moreover, while the present study as well as several previous publications indicate that semantic embeddings can capture some aspects of medical terms and psychological concepts [26,102,105], it needs to be acknowledged that such LLM-based representations are most likely far from complete and can potentially be biased due to a number of reasons [106]. Thus, although LLMs can facilitate efficient and low-effort creation of questionnaire content, human expertise remains essential for reviewing and interpreting their outputs. Finally, only English-language questionnaires were included in this study. Whether LLMs can effectively cluster questionnaire items in other languages remains to be tested.

Conclusion

In summary, our study demonstrates the feasibility of using LLMs to assess the content overlap in mental health questionnaires. In particular, prompting GPT models provides a novel and objective approach for evaluating similarity across questionnaires. It is important to note that human expertise remains essential for reviewing and interpreting the outputs of LLM. Although our findings differed somewhat from previous content overlap analyses, these differences were not substantial. Future content analysis could benefit from LLMs fine-tuned on a corpus of psychological text data. Nonetheless, this study demonstrates a novel application of LLMs in the field of mental health research.

Abstract

Background: This study examines the capability of large language models (LLMs) in detecting medical rumors, using hemangioma-related information as an example. It compares the performances of ChatGPT-4o and DeepSeek-R1.

Objective: This study aimed to evaluate and compare the accuracy, stability, and expert-rated reliability of 2 LLMs, ChatGPT-4o and DeepSeek-R1, in classifying medical information related to hemangiomas as either "rumors" or "accurate information."

Methods: We collected 82 publicly available texts from social media platforms, medical education websites, international guidelines, and journals. Of the 82 items, 47/82 (57%) were labeled as "rumors," and 35/82 (43%) were labeled as "accurate information." Three vascular anomaly specialists with extensive clinical experience independently annotated the texts in a double-blinded manner, and disagreements were resolved by arbitration to ensure labeling reliability. Subsequently, these texts were input into ChatGPT-4o and DeepSeek-R1, with each model generating 2 rounds of results under identical instructions. Output stability was assessed using bidirectional encoder representations from transformers–based semantic similarity scores. Classification accuracy, precision, recall, and F_1-score were calculated to evaluate the performance. Additionally, 2 medical experts independently rated the model outputs using a 5-point scale based on clinical guidelines. Statistical analyses included paired *t* tests, Wilcoxon signed-rank tests, and bootstrap resampling to compute confidence intervals.

Results: In terms of semantic stability, the similarity distributions for the 2 models largely overlapped, with no statistically significant difference observed (mean difference=−0.003, 95% CI −0.011 to 0.005; P=.30). Regarding classification performance, DeepSeek-R1 achieved higher accuracy (0.963) compared to ChatGPT-4o (0.910), and also performed better in terms of precision (0.978 vs 0.940), recall (0.957 vs 0.894), and F_1-score (0.967 vs 0.916). Expert evaluations revealed that DeepSeek-R1 significantly outperformed ChatGPT-4o on both "rumor" items (mean difference=0.431; P<.001; Cohen d_z=0.594) and "accurate information" items (mean difference=0.264; P=.045; Cohen d_z=0.352), with a particularly pronounced advantage in rumor detection.

Conclusions: DeepSeek-R1 demonstrated greater accuracy and rationale in detecting medical rumors compared with ChatGPT-4o. This study provides empirical support for the application of LLMs and recommends optimizing accuracy and incorporating real-time verification mechanisms to mitigate the harmful impact of misleading information on patient health.

medical rumors; large language models; hemangioma; semantic similarity; classification performance; artificial intelligence; AI

Introduction

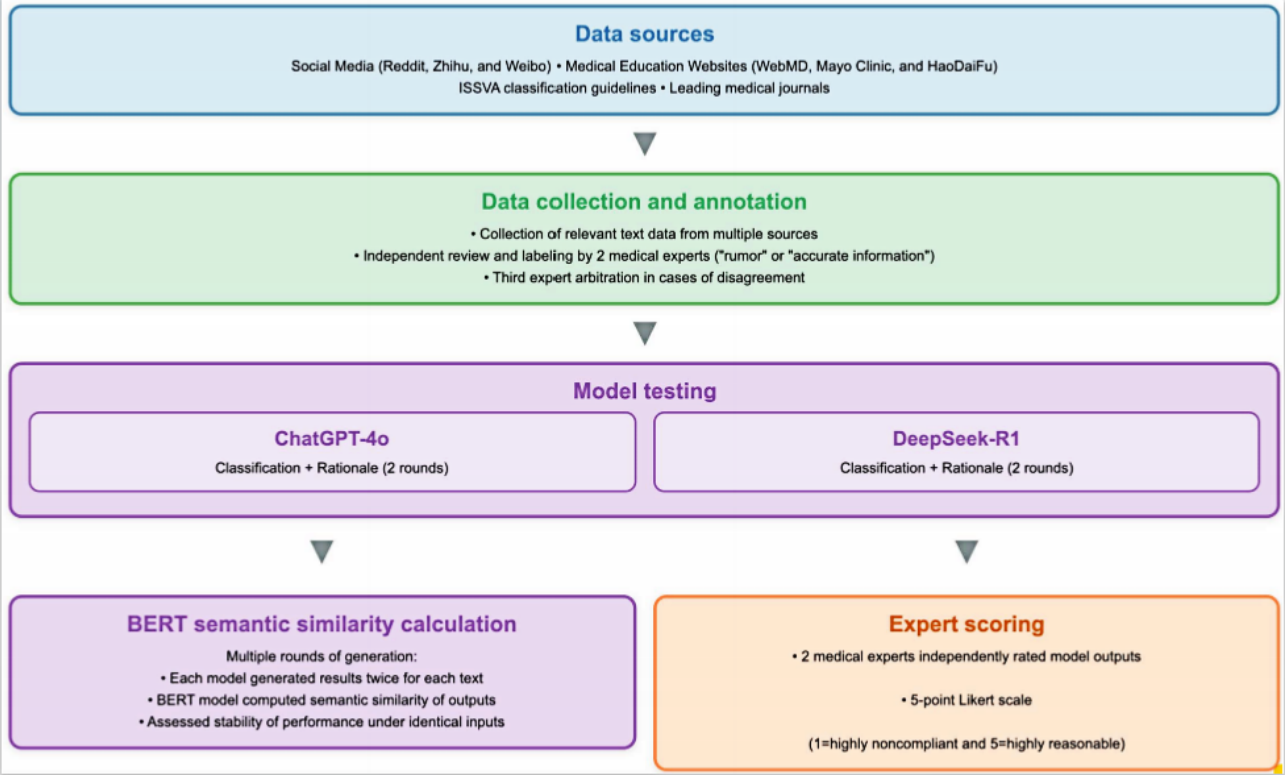
In recent years, artificial intelligence (AI) has drawn considerable attention in detecting medical and health-related rumors [1,2]. Some studies have conducted systematic reviews on the application of AI technologies, such as text mining and machine learning, for the automatic identification of health misinformation [3]. Nonetheless, recognizing medical rumors remains a challenge due to the scarcity of high-quality specialized datasets and the extensive effort required by medical experts for annotation [4,5], making it difficult to train highly accurate rumor detection models. Moreover, as conversational AI assistants become increasingly integrated with and partially replace traditional search engine functionalities, more

XSL•FO
RenderX

individuals are turning to chatbots for medical information [6,7]. However, current large language models (LLMs) lack robust verification mechanisms and often struggle to differentiate genuine from false medical information, frequently producing factually incorrect or imprecise answers—commonly known as "hallucinations" [6,8,9]. In the medical field, the risks posed by misinformation are particularly severe, as misleading content can undermine trust in health care systems, alter treatment decisions, and even lead patients to delay or reject scientifically validated therapies, opting instead for unsupported and potentially harmful treatments [10].

To ground our investigation concretely, we focused on vascular tumors and malformations—a field where rapidly evolving medical classifications often cause significant public confusion and misinformation [11]. The International Society for the Study of Vascular Anomalies classification is continuously updated, with the 2025 edition significantly revising its 2018 predecessor by introducing a new category, potentially unique vascular anomaly, incorporating multiple genetic syndromes into the classification framework, and implementing extensive terminology revisions. Such frequent updates complicate both clinical diagnosis and public comprehension [11,12]. A prominent example is the lesion previously termed "cavernous hemangioma," which has now been redefined as a subtype of "venous malformation." However, outdated terminology persists widely in patient forums and online sources, creating a gap between current medical standards and lay perceptions. This misinformation can lead directly to clinical risks, such as misdiagnosis, delayed treatments, or unnecessary interventions, highlighting the critical need to address inaccuracies and outdated information [13].

In this context, our study selected 2 widely adopted conversational AI models—OpenAI's ChatGPT-4o and the open-source DeepSeek-R1—as research subjects [14,15]. This combination not only represents the 2 primary development trajectories (closed-source versus open-source) of contemporary LLMs but also establishes a baseline task for subsequent benchmarking, allowing future studies to incorporate additional LLMs and facilitate longitudinal comparability. We conducted a classification evaluation of medical statements concerning hemangiomas and vascular malformations, focusing particularly on the models' ability to identify incorrect medical claims (rumors). By comparing the performance of these 2 models on relevant statements, our research aims to evaluate the current capabilities and limitations of AI models in verifying medical information and to provide insights for enhancing rumor-detection capabilities in medical AI systems in future work.



Methods

Study Design and Overview

Our study used publicly available texts from global social media platforms (eg, Reddit, Zhihu, and Weibo); medical education websites (eg, WebMD, Mayo Clinic, and HaoDF or HaoDaifu Online), the International Society for the Study of Vascular Anomalies classification resources, relevant guidelines, and medical journals (Multimedia Appendix 1). In total, 82 statements were collected, with 47 (57%) classified as "rumors" and 35 (43%) as "accurate information." These statements covered key educational aspects of patients with hemangiomas and vascular malformations, including (1) nomenclature and classification, (2) pathogenesis and natural history, (3) risk stratification and complications, (4) assessment and referral, (5) treatment and peritreatment issues, and (6) prognosis and follow-up. All texts collected were independently reviewed by medical experts and labeled as either "rumors" or "accurate information," based on guideline-supported factual accuracy. Figure 1 provides an overview of the study workflow.

Ethical Considerations

This study used only publicly available, nonidentifiable text data and did not involve clinical interventions, access to medical records, or collection of personal identifiers. In accordance with the Measures for the Ethical Review of Life Science and Medical Research Involving Humans, research using lawfully obtained public data or anonymized information may be exempt from ethics review (Article 32). Therefore, an ethics application was not required for this study [16]. Since the data were public and nonidentifiable, informed consent was not required. No compensation was provided to any individuals in relation to this study.

Data Collection and Annotation

Two medical experts specializing in vascular anomalies (with 5 and 10 y of clinical experience, respectively) independently reviewed and labeled each statement as either "rumor" or "accurate information." To minimize bias, all items were anonymized by removing source identifiers and engagement metrics prior to labeling, and annotators remained double-blinded to each other's decisions. In cases of disagreement, arbitration was conducted by a third medical expert with 15 years of clinical experience, resulting in a unified set of labels and ensuring labeling reliability. Potential biases were mitigated through independent dual review, third-party arbitration, and prespecified labeling guidelines.

Model Testing

After labeling, the texts were input into 2 LLMs—ChatGPT-4o and DeepSeek-R1—for testing. The process is presented in Textbox 1.

Textbox 1. Model testing process.

- Prompts and outputs: to minimize bias introduced by variations in prompting and to highlight baseline comparability, both models received the identical concise instruction: "evaluate the following statement for accuracy and reliability in the context of hemangioma and vascular malformation treatment." Each model classified the texts as either "rumor" or "accurate information," accompanied by a brief rationale (Multimedia Appendix 2).
- Multiple rounds of generation: to reduce the effects of random output, each model generated results twice for each text. A bidirectional encoder representations from transformers model was then used to compute the semantic similarity of these 2 outputs to assess the stability of the model's performance under identical inputs.

Expert Scoring

In addition to classification results, 2 medical experts independently assessed the compliance of each model's output with clinical guidelines. Evaluations were performed using a 5-point Likert scale (1= highly noncompliant, 5=highly reasonable). The medical experts remained blinded to both the model identities (ChatGPT-4o vs DeepSeek-R1) and each other's scores. Detailed scoring criteria are provided in Multimedia Appendix 3.

XSL•FO
RenderX

Statistical Analysis

Semantic Similarity and Stability

Semantic stability was assessed by calculating bidirectional encoder representations from transformers (BERT)–based similarity scores between 2 independently generated outputs for each statement (see Multimedia Appendix 4 for detailed code). Descriptive statistics, including means, SDs, medians, and IQRs, were reported. Differences between models were compared using paired Wilcoxon signed-rank tests (due to partially nonnormal distributions). Additionally, 95% bias-corrected and accelerated CIs for mean differences were computed via 10,000 bootstrap resamples to ensure robust interval estimation.

Classification Performance

Classification accuracy, precision, recall, and F_1-scores were calculated based on standard definitions, with error distributions visualized using confusion matrices. This approach allows comprehensive evaluation of global and class-specific performance and is particularly suitable for scenarios involving class imbalance.

Expert Ratings

Two clinical experts independently provided ratings on a 5-point Likert scale for each of the 82 statements (47 rumors and 35 accurate statements) in 2 separate rounds. The mean rating for each item was computed as the final score. For each model, descriptive statistics such as mean (SD) and 95% CIs were calculated, treating each statement as an independent unit. Between-model comparisons were performed using paired 2-tailed *t* tests (assuming normality of differences) supplemented by Wilcoxon signed-rank tests as a robust alternative, with Cohen d_z effect sizes reported. Within-model comparisons between "rumors" and "accurate information" were conducted using Welch *t* test to account for unequal sample sizes and potential variance heterogeneity. Reviewer agreement and reliability were assessed using Cronbach α and interclass correlation coefficients (ICCs), ICC(2,1)/ICC(2,k). All tests were 2-tailed, with statistical significance defined as $P<.05$.

Results

Overview

This study systematically compared the performance of ChatGPT-4o and DeepSeek-R1 in classifying statements related to hemangiomas and vascular malformations across three dimensions: (1) the stability of 2 independent outputs, assessed using BERT-based semantic similarity metrics; (2) classification performance, evaluated by accuracy, precision, recall, and F_1-score; and (3) clinical appropriateness of model outputs as rated by experts on a 5-point scale. For expert ratings, statistical inference was conducted using a paired design with Wilcoxon signed-rank tests, effect sizes (r), and 95% bias-corrected and accelerated CIs.

Semantic Similarity Analysis

To evaluate the semantic similarity between the model-generated responses, we used a BERT-based scoring approach (detailed in Multimedia Appendix 5). Multimedia Appendix 6 shows the distribution of the scores for ChatGPT-4o and DeepSeek-R1. Overall, the distributions for both models exhibited substantial overlap, with ChatGPT-4o displaying a slightly narrower distribution, while DeepSeek-R1 showed a marginally wider range. During paired comparisons, 1 pair with identical observations was excluded, resulting in 81 (99%) paired samples for analysis. The Wilcoxon signed-rank test indicated no significant difference in stability between the 2 models (W=1440.5; $z=-1.036$; $P=.30$), with a mean difference of only −0.003 (95% bootstrap CI −0.011 to 0.005, r=−0.115) as shown in Table 1. These findings suggest comparable semantic similarity and stability performance between the 2 models.

Table . Stability comparison between ChatGPT-4o and DeepSeek-R1 based on bidirectional encoder representations from transformers semantic similarity scores.[a]

Model and comparison	Mean (SD)	Median (IQR)	Range
ChatGPT-4o (N=82)	0.9000 (0.0250)	0.9060 (0.8870 - 0.9180)	0.8250 - 0.9400
DeepSeek-R1 (N=82)	0.8970 (0.0320)	0.9010 (0.8850 - 0.9140)	0.7800 - 1.0000

[a]Paired difference (DeepSeek-R1 − ChatGPT-4o; n=81; of the original 82 pairs, 1 pair with identical values [tie] was excluded automatically during the Wilcoxon test, resulting in an effective sample size of 81): mean difference=−0.0030; 95% bias-corrected and accelerated CI −0.0110 to 0.005; Wilcoxon W=1440.5000; $z=-1.0360$; $P=.30$; $r=-0.1150$.

Classification Performance Evaluation

Classification performance for hemangioma and vascular malformation statements was evaluated by examining confusion matrices (Figure 2A) and key performance metrics. Confusion matrix analyses indicated no substantial differences in misclassification distribution between the 2 models, with overall good stability. In terms of the overall classification accuracy (Figure 2B), DeepSeek-R1 achieved 0.963, which was notably higher than ChatGPT-4o, which reached approximately 0.910. Additionally, DeepSeek-R1 surpassed ChatGPT-4o in terms of other metrics, including precision, recall, and F_1-score. Specifically, DeepSeek-R1 demonstrated a precision of approximately 0.978, recall of 0.957, and an F_1-score of 0.967, each marginally higher than the corresponding values for ChatGPT-4o (Figure 2C). These results highlight the superior classification accuracy of DeepSeek-R1.

RenderX

Expert Rating Analysis

In qualitative assessments, both models demonstrated strong performance regarding the clinical appropriateness of their outputs, with subtle yet meaningful differences observed. Expert ratings (Multimedia Appendices 7 and 8) indicated that for statements classified as "rumors" (47/82, 57%), DeepSeek-R1 scored significantly higher with a mean (SD) of 4.39 (0.59) and 95% CI 4.21 - 4.56 compared to ChatGPT-4o with a mean of 3.96 (SD 0.81) and 95% CI of 3.72 - 4.20; the mean difference was 0.431 (95% CI 0.218 - 0.644); paired t_{46}=4.071; P<.001; Wilcoxon P<.001; and effect size Cohen d_z=0.594.

For statements labeled as "accurate information" (35/82, 43%), DeepSeek-R1 with a mean of 4.44 (SD 0.37) and 95% CI of 4.32 - 4.57 also significantly outperformed ChatGPT-4o with a mean of 4.18 (SD 0.69) and 95% CI of 3.94 - 4.41; the mean difference was 0.264 (95% CI 0.007 - 0.522); paired t_{34}=2.085; P=.045; Wilcoxon P=.046; and Cohen d_z=0.352.

These findings demonstrate significant superiority of DeepSeek-R1 over ChatGPT-4o in evaluating both "rumors" and "accurate information," with a particularly pronounced advantage in detecting "rumors."

DeepSeek-R1 performed slightly better than ChatGPT-4o across multiple evaluation dimensions, exhibiting higher output stability and classification accuracy. This finding suggests that DeepSeek-R1 holds greater potential for medical information classification tasks.

Discussion

This study compared ChatGPT-4o and DeepSeek-R1 in the task of identifying medical rumors, with hemangioma-related misinformation serving as the focal point [17,18]. Overall, both models demonstrated robust language comprehension capabilities but differed markedly in their approaches to recognizing inaccurate statements about hemangiomas. DeepSeek-R1 excelled at pinpointing erroneous claims and clearly categorizing them as rumors, showing its strength in explicit rumor detection and confident classification. In contrast, ChatGPT-4o demonstrated superior semantic similarity and exhibited more consistent stability in understanding nuanced languages, yet tended to approach rumor identification cautiously, often resorting to ambiguous wording rather than decisively refuting false information. Although these observed differences may stem from variations in training data, model architecture, and fine-tuning strategies, existing evidence from other studies suggests that specialized fine-tuning with medical information could further enhance the capability of LLMs in accurately and effectively detecting medical misinformation [19].

In our task, overly cautious responses—specifically, the failure to decisively refute rumors (false negatives)—may perpetuate harmful misconceptions, causing caregivers to delay specialist referrals or discontinue evidence-based treatments in favor of unproven remedies. Conversely, overconfidence—erroneously labeling accurate guidance as rumors (false positives)—may lead to unnecessary anxiety, undermine trust in clinicians, or impede appropriate interventions. In hemangioma treatment, such misclassification could negatively impact decisions regarding timely assessment (eg, ulceration and airway involvement), follow-up intervals, or continuation of guideline-adherent therapies. These risks support the use of conservative safety thresholds, verifiable citations, and escalation of human oversight when model confidence is low. One illustrative example is the claim that "sun exposure exacerbates hemangiomas," which lacks scientific support [20]. Authoritative sources indicate that sun exposure does not directly enlarge or worsen hemangiomas. While moderate sun protection can help safeguard the skin, it does not specifically address pathological changes in hemangiomas [21,22]. In this study, DeepSeek-R1 correctly identified this assertion as a rumor and provided a concise explanation consistent with medical consensus. ChatGPT-4o, in contrast, did not unequivocally refute the claim, instead offering a somewhat reserved answer that did not effectively dispel the misconception. Although both models possess extensive medical knowledge, DeepSeek-R1 displayed a stronger rumor-debunking ability when confronted with evidently incorrect statements, whereas the cautious approach of ChatGPT-40 diluted its capacity to correct misinformation.

As more users turn to AI assistants for medical information, traditional search engines are gradually being supplemented or even replaced by these systems [23,24]. Unlike search engines that merely provide links, AI chatbots often deliver comprehensive, single-point answers whose perceived authority may lead users to over-rely on them instead of consulting additional information sources [25,26]. Consequently, the adverse impact of inaccurate or ambiguous medical information disseminated by AI could be amplified, posing a considerable risk of misleading patients in their health care decisions. Therefore, ensuring higher accuracy in identifying medical rumors is both urgent and critical [27].

Recent research has proposed various methods for leveraging AI to detect medical rumors. For instance, studies comparing GPT-4 with other models trained specifically on health information have shown that specialized models tend to be more accurate in identifying and correcting misinformation [28,29]. These findings underscore that although LLMs have tremendous potential for conveying medical knowledge, they still exhibit shortcomings in fact-checking and real-time verification [30]. Incorporating real-time retrieval mechanisms and referencing authoritative data in responses represents a key direction for improving the accuracy of AI-generated medical information [28]. Notably, conclusions regarding model superiority depend heavily on the task design, dataset scope, and evaluation criteria. These factors help explain the inconsistencies observed in the existing literature and highlight the novelty of our research, which specifically addresses misinformation related to hemangiomas. The methodological workflow applied in this study—consisting of data annotation, multiround generation, BERT similarity assessment, and expert evaluation—not only validates the relative advantages of DeepSeekR1 in our task but also underscores the insufficiency of any single metric for comprehensively assessing model performance. Multidimensional evaluations more effectively reveal nuanced

XSL•FO
RenderX

differences between models in stability, accuracy, and clinical appropriateness, thereby offering valuable lessons and standardized protocols for the deployment and further study of large medical language models.

This study has several limitations. First, our data primarily address hemangiomas and vascular malformations, and the limited number and types of examples may not comprehensively encompass all medical rumors. Second, the labeling of rumors relies on expert judgment, introducing an element of subjectivity, and disagreements may arise when experts evaluate borderline cases. Additionally, discrepancies in the 2 AI models' training data and knowledge cutoff dates could affect their ability to capture the latest medical information. Finally, we did not evaluate aspects such as explanatory depth, response speed, and user-friendliness. For instance, we did not conduct a formal qualitative or user-centered analysis of explanation quality, which remains an important area for future investigation. For clinical decision support, patient-oriented education, or public health surveillance, LLM-generated outputs should be embedded within regulated workflows that include (1) retrieval-augmented validation from curated vascular anomaly sources, (2) human-in-the-loop review of high-risk recommendations, (3) audit trails and disclaimers clearly delineating accountability, (4) transparent rationales with explicit references to guidelines and clearly marked uncertainties, and (5) postdeployment monitoring for data drift and fairness. These safeguards are prerequisites for mitigating liabilities and improving interpretability and usability in practical applications.

In conclusion, this research highlights the performance differences between the 2 LLMs in detecting hemangioma-related medical rumors, stressing the urgency of maintaining accurate medical information as AI gradually supplants traditional search engines. DeepSeek-R1 showed higher accuracy and a more decisive approach to rumor detection, whereas the guarded stance of ChatGPT-4o sometimes led to less definitive answers. Future studies should optimize AI models' fact-checking capabilities, for example, by integrating real-time access to authoritative databases, enhancing domain-specific fine-tuning, and building human-machine collaborative monitoring systems. Continuous improvements in the accuracy and transparency of AI-driven medical communications will better protect patient health and reinforce public trust in evidence-based health care.

Acknowledgments

The authors would like to express their sincere gratitude to the Vascular Anomalies and Vascular Malformations Plastic Surgery Team at the Plastic Surgery Hospital of the Chinese Academy of Medical Sciences for their strong support of this research, the National Clinical Key Specialty Construction Project (23003), and the Plastic Medicine Research Fund of the Chinese Academy of Medical Sciences (2024-ZX-1 - 01). The funders had no role in the design and conduct of the study; collection, management, analysis, and interpretation of the data; preparation, review, or approval of the manuscript; and decision to submit the manuscript for publication.

Data Availability

All deidentified data that support the findings of this study are provided in Multimedia Appendix 1 (vascular anomaly information sources). Additional deidentified data and analysis materials that were generated during the study are available from the corresponding author on reasonable request for noncommercial purposes. Authors are prepared to provide the underlying (anonymized) data to the journal for inspection or verification upon request.

Authors' Contributions

GW wrote the main manuscript and designed the research methodology framework. Y Zhu and WW prepared Figures 1 and 2 and conducted data evaluation. GW, Y Zhang, and HB collected the data. GW and XY designed the study. All authors contributed to the statistical analysis and critically reviewed the manuscript.

Abstract

Background: Recent advances in large language models (LLMs) such as GPT-4o offer a transformative opportunity to extract nuanced linguistic, emotional, and social features from medical crowdfunding campaign texts at scale. These models enable a deeper understanding of the factors influencing campaign success far beyond what structured data alone can reveal. Given these advancements, there is a pressing need for an integrated modeling framework that leverages both LLM-derived features and machine learning algorithms to more accurately predict and explain success in medical crowdfunding.

Objective: This study addressed the gap of failure to capture the deeper psychosocial and clinical nuances that influence campaign success. It leveraged cutting-edge machine learning techniques alongside state-of-the-art LLMs such as GPT-4o to automatically generate and extract nuanced linguistic, social, and clinical features from campaign narratives. By combining these features with ensemble learning approaches, the proposed methodology offers a novel and more comprehensive strategy for understanding and predicting crowdfunding success in the medical domain.

Methods: We used GPT-4o to extract linguistic and social determinants of health features from cancer crowdfunding campaign narratives. A random forest model with permutation importance was applied to rank features based on their contribution to predicting campaign success. Four machine learning algorithms—random forest, gradient boosting, logistic regression, and elastic net—were evaluated using stratified 10-fold cross-validation, with performance measured through accuracy, sensitivity, and specificity.

Results: Gradient boosting consistently outperformed the other algorithms in terms of sensitivity (consistently 0.786 to 0.798), indicating its superior ability to identify successful crowdfunding campaigns using linguistic and social determinants of health features. The permutation importance score revealed that for severe medical conditions, income loss, chemotherapy treatment, clear and effective communication, cognitive understanding, family involvement, empathy, and social behaviors play an important role in the success of campaigns.

Conclusions: This study demonstrates that LLMs such as GPT-4o can effectively extract nuanced linguistic and social features from crowdfunding narratives, offering deeper insights than traditional methods. These features, when combined with machine learning, significantly improve the identification of key predictors of campaign success, such as medical severity, financial hardship, and empathetic communication. Our findings underscore the potential of LLMs to enhance predictive modeling in health-related crowdfunding and support more targeted policy and communication strategies to reduce financial vulnerability among patients with cancer.

Introduction

The cost of cancer care in the United States is increasing rapidly due to various factors, including technological advancements, expensive cutting-edge therapies, and improved access to treatment. Patients with cancer and their families often face substantial financial consequences, such as borrowing money, spending less on food, going into debt, or declaring bankruptcy [1-3]. These issues are exacerbated by a lack of medical insurance or lack of coverage due to health care regulations such as the Affordable Care Act. As a result, patients and caregivers seek help from other sources to raise funds for medical care [2].

Crowdfunding has become a significant tool for raising money through social media and web-based platforms such as Indiegogo, Kickstarter, and GoFundMe, generating US $34.4 billion in 2015 alone [4-7]. Medical crowdfunding constitutes a significant portion of these campaigns in the United States due to gaps in insurance coverage and the prohibitive costs of medical treatments, such as in cancer care, even for those with insurance [8,9]. Success factors for these campaigns include demographic attributes, racial background, campaign images, textual features, and social media characteristics, with campaigns for children attracting more donations than those for adults [6,7,9,10]. In cancer treatment crowdfunding, 65.4% of campaigns involve advanced-stage patients, with detailed information about cancer types, treatments, and costs leading to higher fundraising success [11-15]. In addition, research has characterized the use of crowdfunding to support oncology care needs, examining associations between insurance status and other characteristics related to unmet financial obligations [13].

The field of crowdfunding prediction has primarily relied on traditional statistical methods such as linear and logistic regression in previous studies. These methods assume that the input variables are independent from each other. However, when there are correlations among the input variables, using regression methods can lead to larger prediction errors. To overcome this limitation, researchers have turned to machine learning (ML) techniques. ML algorithms have proven to be effective in analyzing hidden associations within large datasets and identifying complex patterns [16,17]. As a result, researchers have used ML algorithms to predict the success of crowdfunding campaigns [18-20]. This shift in methodology allows for better prediction accuracy and the discovery of more nuanced relationships among the input variables. For instance, ML algorithms such as support vector machine, decision tree, and k-nearest neighbor have been used to predict the success of projects [18,19,21-24]. In addition, algorithms such as extreme gradient boosting, gradient boosting, random forest, and generalized linear models have been used to construct prediction models [25].

Previous crowdfunding research has demonstrated that ML methods can effectively model complex relationships between variables, capture interactions, and yield more accurate and insightful predictions. However, there has been a lack of thorough analysis regarding the selection of predictors and campaign success measures. Furthermore, the application of large language models (LLMs) in the crowdfunding domain remains relatively unexplored. The only study in this domain to date [26] has generated insights on medical financial hardship patterns and unmet social needs by leveraging generative artificial intelligence on GoFundMe cancer crowdfunding campaigns using logistic regression.

In this study, we explored the use of LLMs and ML models to generate and identify predictors of successful campaigns. LLMs are particularly helpful in capturing the semantic meaning of words and phrases in internet-based texts by using word embeddings and contextual embeddings, which were trained on large, diverse texts. GPT-4o [27], developed by OpenAI, is an LLM known for its conversational text generation capabilities. We used GPT-4o and prompted relevant campaign information to extract and analyze linguistic and social determinants of health (SDOH) factors. We also provided a robust feature selection based on the permutation technique for a better understanding of the model.

Our research had three primary objectives: (1) to leverage LLMs, specifically GPT-4o, to automatically generate a wide range of linguistic, social, and clinical features from crowdfunding campaign narratives; (2) to implement a robust feature selection strategy using the random forest algorithm combined with permutation importance to quantify and interpret the relative contribution of each feature to predictive performance without implying causal relationships; and (3) to conduct a comprehensive evaluation of predictive performance across multiple ML algorithms using the key features identified through the random forest–based feature selection approach.

To the best of our knowledge, this study is the first to leverage an LLM for feature extraction and an ML algorithm to establish an effective prediction model for GoFundMe cancer crowdfunding campaigns with a robust feature selection method. By integrating innovative ML algorithms and feature selection strategies into crowdfunding research, we not only advance the academic understanding of this domain but also provide actionable insights that can be directly applied by policymakers and campaign organizers. These advancements are essential for addressing the growing reliance on crowdfunding in the health care sector and ensuring that support reaches those who need it the most.

Methods

Ethical Considerations

All data used in this study were obtained from publicly accessible crowdfunding campaigns on the GoFundMe platform via its public API. The API provides campaign metadata (eg, title, goal amount, amount raised, description text, and campaign category) that are already visible to any online user without registration. No private, donor-level, or personally identifiable information (PII) was accessed, and no authentication was required. The research complied with GoFundMe's published Terms of Service [28] at the time of data collection. Because this study only used publicly accessible data, institutional review was not required, as per local guidelines [29].

XSL•FO
RenderX

Data Collection

The data for this study were collected from the GoFundMe crowdfunding platform, which is the world's largest platform in terms of both the total amount of funding raised and the total number of active campaigns. Founded in 2010, GoFundMe features campaigns for various categories, including medical, memorials, emergencies, and charitable causes. The data for this analysis were extracted using a combination of application programming interface (API) access and web scraping techniques. GoFundMe stores its data in Algolia, a search and analytics engine. We obtained the necessary API key, secret key, and index name by inspecting the network tab on the GoFundMe website. We connected to the Algolia API using a Python (Python Software Foundation) program and retrieved the data. The API provided access to all records stored in the specified index, which we then processed and stored for further analysis. The data consist of 4990 campaigns for patients' oncologic treatment and personal and financial lives that began between January 3, 2023, and December 31, 2023, with funding targets between US $800 and US $100,000.

Campaign Success Measure

We considered a campaign to be successful if it raised a significant percentage of the goal amount. The success ratio was defined as the ratio of funds raised to the campaign goal and was converted to a binary variable at different success thresholds. In this experiment, we selected the success threshold as a ratio of 0.7 based on the observations in exploratory analysis.

Predictors of Campaign Success

Crawled Variables

We collected key campaign data, including launch date, title, description, current raised amount, target goal, number of donors, and campaign duration. These details provide insights into each campaign's progress and engagement.

SDOH and Medical-Related Variables

The selected variables were obtained from the Linguistic Inquiry and Word Count (Pennebaker Conglomerates, Inc) internal dictionary [30] and the Centers for Disease Control and Prevention indicators [31]. In addition, we incorporated several new variables related to medical procedures and treatment factors to enhance the dataset. A full categorization of these variables is provided in Table 1.

Table . Categorization of the extracted features used for crowdfunding campaign analysis.

Category	Factors
Cognitive and psychological	Analytic thinking, cognition, tone, risk, reward, empathy, politeness, and authenticity
Linguistic and communication	Clout, linguistic content, communication, present tense, past tense, and future tense
Medical and health	Cancer site, stage or grade of cancer, type of therapy, treatment status, treatment duration, engagement in health care activities, comorbidities, association with health care organizations and facilities (hospices, hospitals, nursing homes, skilled nursing facilities, and emergency rooms)
Emotional states	Stress, anxiety, mental or behavioral dysfunctions, chronic diseases, cognitive content of communications, expression of social concerns, informal language (swear words and online abbreviations), sentiment (positive, negative, or neutral), and trust in medical care facilities
Employment and education	Employment status, work disruption (for individuals aged ≥18 years), school absenteeism, work absenteeism, and parents' work disruption (for beneficiaries aged <18 years)
Financial and medical support	Lack of sick leave, lack of medical attention, income loss, family income loss, struggles with medical expenses, housing expenses, food expenses, and transportation expenses
Medical procedures and treatments	Laboratory procedures, diagnostic procedures, cancer-specific treatments (chemotherapy and radiotherapy), preventive procedures, alternative physical therapy, occupational therapy, and mental health or substance abuse therapy
Organizations and facilities	Association with health care–related organizations, professional societies, self-help organizations, relief organizations, and receiving care in specific facilities (hospices, hospitals, nursing homes, skilled nursing facilities, emergency rooms, or mental health or substance abuse facilities)
Mental state, sentiment, or trust	Presence of stress, anxiety, mental or behavioral dysfunctions, or chronic diseases; sentiment (positive, negative, or neutral); and level of trust in medical care facilities

Experimental Setup

Feature Extraction and Selection Methodology

The variables were programmatically generated using GPT-4o, a state-of-the-art LLM from OpenAI, through a structured prompting pipeline designed to extract nuanced semantic, emotional, and contextual signals and other factors from campaign narratives. We used a zero-shot prompting strategy tailored to identify all the variables. For example, the following was a representative prompt used: "Analyze the following crowdfunding campaign description and return the sadness (0 -low and 1 -high) score or whether patient struggles with expenses for medical treatments (yes or no),)."

We manually evaluated GPT-4o–based feature outputs for a random sample of 50 crowdfunding campaigns to assess consistency and accuracy. Each campaign was processed using the GPT-4o API with temperature set to 0.5, maximum tokens limited to 256, and top_p (probabilistic decoding parameter) set to 1.0 to ensure stable and contextually appropriate responses. Manual review involved comparing GPT-4o–extracted linguistic and SDOH features against human-annotated references. The observed validation error ranged from 0.06 to 0.08, indicating high reliability and supporting the use of GPT-4o for automated feature generation in this study.

Postprocessing routines were developed to convert the generated responses into structured binary or ordinal variables, which were then added to the campaign-level dataset. These extracted features were then categorized, standardized, and incorporated into downstream statistical and ML models to quantify their relative importance. Importantly, we separately evaluated the contributions of linguistic and SDOH feature sets using permutation-based feature importance within an ensemble random forest classifier, ensuring that observed effects were interpreted as associations within predictive contexts and not causal mechanisms.

We applied minimum-maximum normalization to variables with large value ranges (target amount, raised amount, number of donors, and campaign duration) to minimize their impact on prediction results. GPT-4o was used to standardize measures of linguistics and campaign predictors between 0 and 1. The predictors for social and demographic identity, as well as medical-related predictors, were extracted as a binary (yes or no) and dummy coded.

ML Algorithms

We conducted 2 comparative ML experiments to evaluate the predictive utility of different feature sets in determining the success of cancer-related crowdfunding campaigns. In both experiments, the dataset was divided into training (70%) and testing (30%) subsets, and all models were validated using 10-fold stratified cross-validation on the training data to ensure robustness and minimize overfitting.

In the first experiment, we focused on linguistic and campaign-level features. Linguistic features—such as tone, empathy, clout, and sentiment—were extracted using GPT-4o through structured prompts. These were combined with campaign-level metadata such as fundraising goals, campaign duration, and update frequency. To evaluate the contribution of individual features to prediction performance, we initially trained a random forest classifier using the scikit-learn library (Google Summer of Code project) on the training dataset, with the number of trees set to 100 and the minimum samples required to split an internal node (min_samples_split) set to 2. These parameter values were selected based on a grid search optimization process in which they achieved the highest accuracy (0.72). For feature importance, we used permutation importance, a model-agnostic approach that measures the decline in model performance when each feature is randomly shuffled. This method was applied within the training set to assess the relative contribution of each feature. The features were then ranked by their permutation importance scores. On the basis of these rankings, we constructed a series of feature subsets including the top 3, 6, 9, 12, and 15 features.

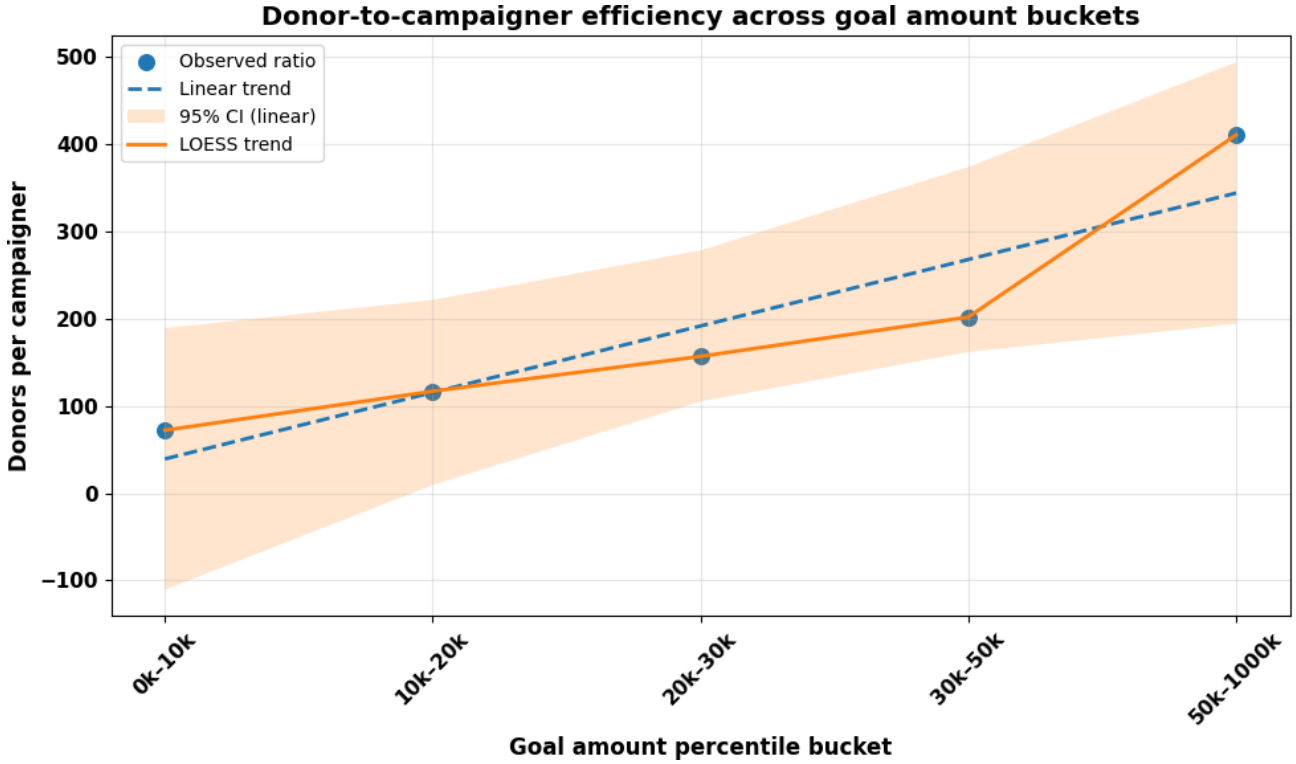
In the second experiment, we applied the same methodology to a different set of features—those reflecting social, demographic, and medical information. These included SDOH (eg, references to employment status, caregiving responsibilities, and financial hardship), demographic attributes (eg, inferred race or ethnicity), and medically relevant content (eg, mentions of chemotherapy, hospice care, or immunotherapy). These features were similarly extracted using GPT-4o with custom prompts designed to infer relevant categories from the narrative descriptions in the campaign text. As with the first experiment, random forest with permutation-based feature importance was used to rank features within the training set, and model performance was assessed at various thresholds of top N features.

For both experiments, we also evaluated the performance of 3 additional ML models: gradient boosting (min_samples_split=2; n_estimators=100), logistic regression, and elastic net (solver="saga"; l1_ratio=0.5) with default parameter settings. We evaluated model performance using subsets of the highest-ranked features, testing configurations with 3, 6, 9, 12, and 15 features to provide a comparative perspective. Model performance was assessed using 3 evaluation metrics: accuracy, sensitivity, and specificity. Sensitivity was defined as the ratio of true positives (successful campaigns) to the sum of true positives and false negatives, specificity was defined as the ratio of true negatives (unsuccessful campaigns) to the sum of true negatives and false positives, and accuracy was defined as the proportion of correct predictions out of all predictions made.

Results

Descriptive Analysis

In our analysis, we used a dataset of crowdfunding campaigns to explore their success in relation to their progress toward the established goal amounts. The descriptive statistics of the raised amounts provided valuable insights into the overall distribution and characteristics of the dataset. Among the 4990 campaigns analyzed, the mean amount raised was US $20,016.67 (SD US $26,456.97), with a median of US $11,819 (IQR US $17,383). Similarly, the mean goal amount among the scraped links was US $40,373.73 (SD US $55,043.88), and the median was US $25,000 (IQR US $38,000). We divided the dataset into 5



XSL•FO
RenderX

distinct groups by categorizing the data into percentile ranges based on the distribution of goal amounts. Each group was of equal size: US $799.99 to US $10,000, US $10,000 to US $20,000, US $20,000 to US $30,000, US $30,000 to US $50,000, and US $50,000 to US $100,000.

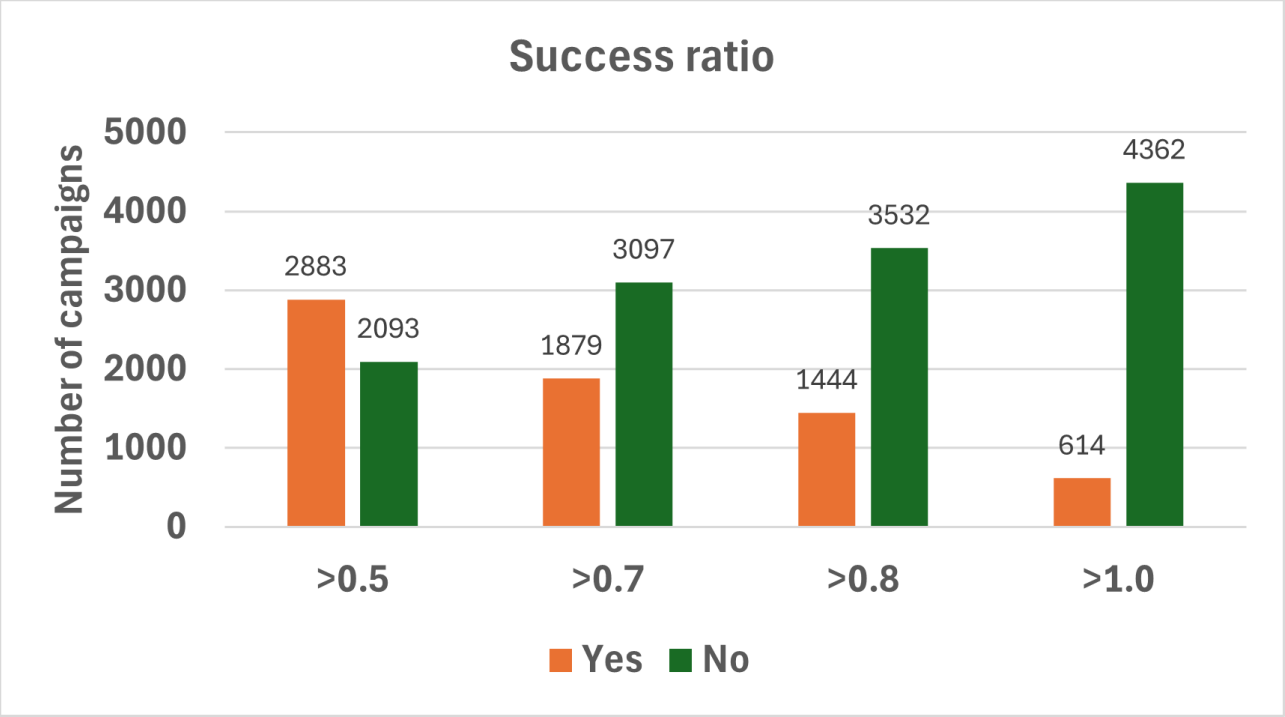
Figure 1 illustrates that the donor-to-campaigner ratio increased steadily across goal-amount percentiles, indicating that campaigns with larger targets typically mobilized more donors on average. The alignment between the linear and locally estimated scatterplot smoothing curves suggests that this relationship is approximately linear, though a mild upward curvature at the upper end (80k-100k) may reflect heightened engagement for high-visibility or urgent medical cases. The broader confidence band among large-goal campaigns implies heterogeneity in donor response, consistent with the notion that some high-goal efforts achieve viral reach while others fail to gain traction. Overall, this pattern supports the hypothesis that higher fundraising targets often signaling greater medical severity or broader social networks are associated with enhanced donor participation efficiency.

Figure 2 shows that as the success ratio threshold increases, the proportion of successful campaigns decreases, whereas the number of unsuccessful campaigns increases. This trend is expected as higher thresholds represent more ambitious funding goals, which are harder to achieve.

Figure 1. Donor-to-campaigner efficiency curve for medical crowdfunding campaigns. Linear trend: slope=304.167; intercept=35.000; R^2=0.966; *P*=.003. LOESS: locally estimated scatterplot smoothing.

XSL•FO
RenderX

Figure 2. Distribution of crowdfunding campaigns based on their success ratio.



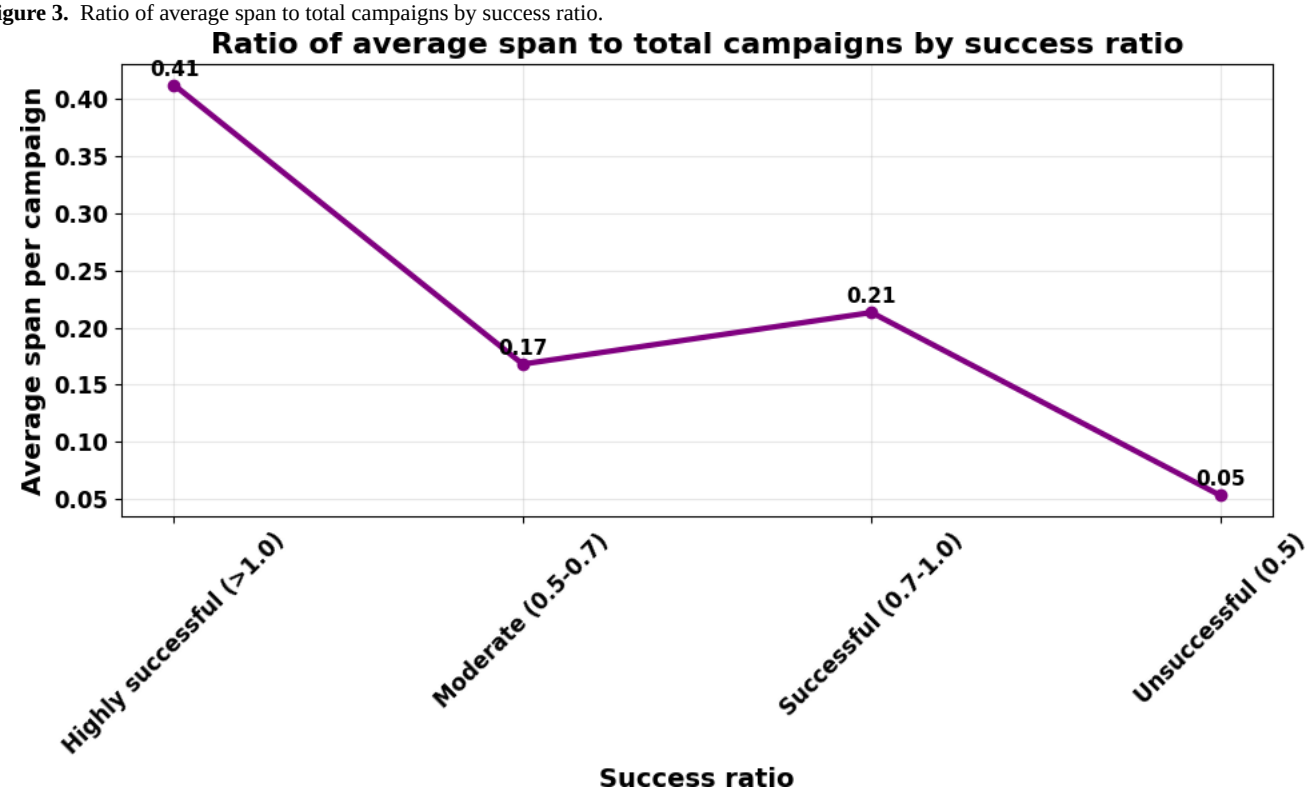


Figure 3 shows the ratio of mean campaign span (days) to total campaigns within each success-ratio category: unsuccessful (<0.5), moderate (0.5-0.7), successful (0.7-1.0), and highly successful (> 1.0). Campaigns achieving higher success ratios exhibited greater relative span durations (approximately 0.41 for highly successful vs approximately 0.05 for unsuccessful campaigns). The upward pattern indicates that prolonged visibility and sustained engagement are associated with improved crowdfunding outcomes, whereas unsuccessful campaigns tend to terminate earlier and attract fewer donors.

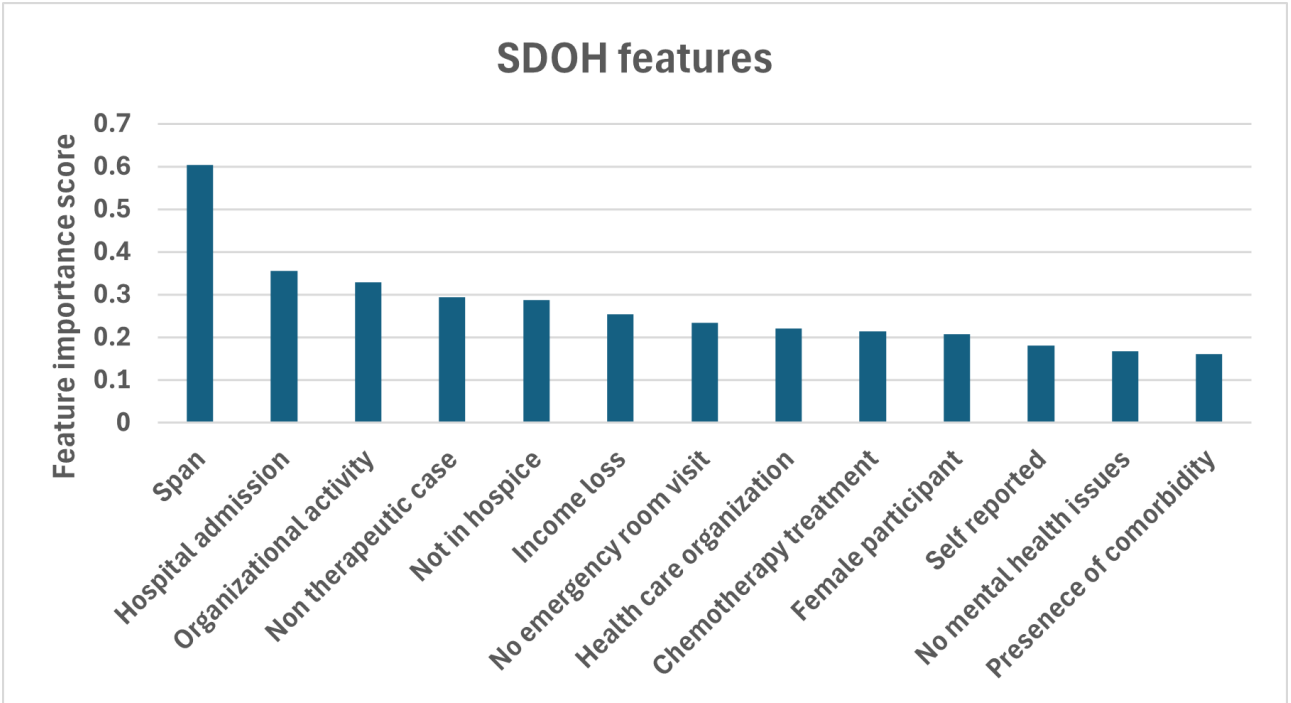
Figure 3. Ratio of average span to total campaigns by success ratio.

XSL•FO
RenderX

Socioeconomic Variables and Their Association With Campaign Success



To assess the role of socioeconomic context in campaign outcomes, we analyzed 5 key variables derived from campaign narratives: work absenteeism, educational activity, friend, struggles with monthly bills, and struggles with food. Work absenteeism captured whether the individual referenced missing work due to illness or treatment, indicating employment disruption and potential income loss. Educational activity included references to school attendance or disruptions to education, suggesting that the campaign involved students or caregivers with educational responsibilities. The friend variable identified campaigns organized by or for a friend, providing insights into the patient's social network and potential campaign reach. Struggles with monthly bills flagged mentions of difficulty affording recurring monthly expenses (eg, rent and utilities), serving as a direct marker of financial strain. Struggling with food indicated food insecurity, reflecting the inability to afford sufficient or nutritious food. Each of these variables was statistically tested for its association with campaign success using chi-square analysis. Although none reached statistical significance at $P<.05$, work absenteeism showed a marginal association ($\chi^2_1=4.7$; $P=.10$), suggesting a potential trend worth further investigation.

Campaign Success Determinants

Figure 4 shows the top 13 important features (SDOH) in predicting success at a 0.7 success ratio for the gradient boosting algorithm. Permutation importance score is a metric that indicates how much a particular feature contributes to the predictive power of an ML model. On the basis of the chart, the fact that being in the hospital or in unspecified hospice care was highly important highlights the severe medical conditions often associated with crowdfunding campaigns. Policymakers could use this information to identify areas in which the medical system is failing to cover critical care, prompting discussions on improving hospital funding or hospice services. The importance of income loss suggests that financial hardship due to illness is a key driver of crowdfunding success. This implies that patients need better income protection policies or insurance solutions to support individuals who face financial difficulties due to medical conditions. The involvement of health care organizations as a feature suggests that campaigns supported by these organizations might have better access to resources than campaigns organized by individuals. The importance of chemotherapy treatment as a feature suggests that crowdfunding campaigns associated with this treatment might attract more attention and support, possibly because donors recognize the high costs and seriousness of cancer treatment. In addition, female patients in general tend to have more successful campaigns.

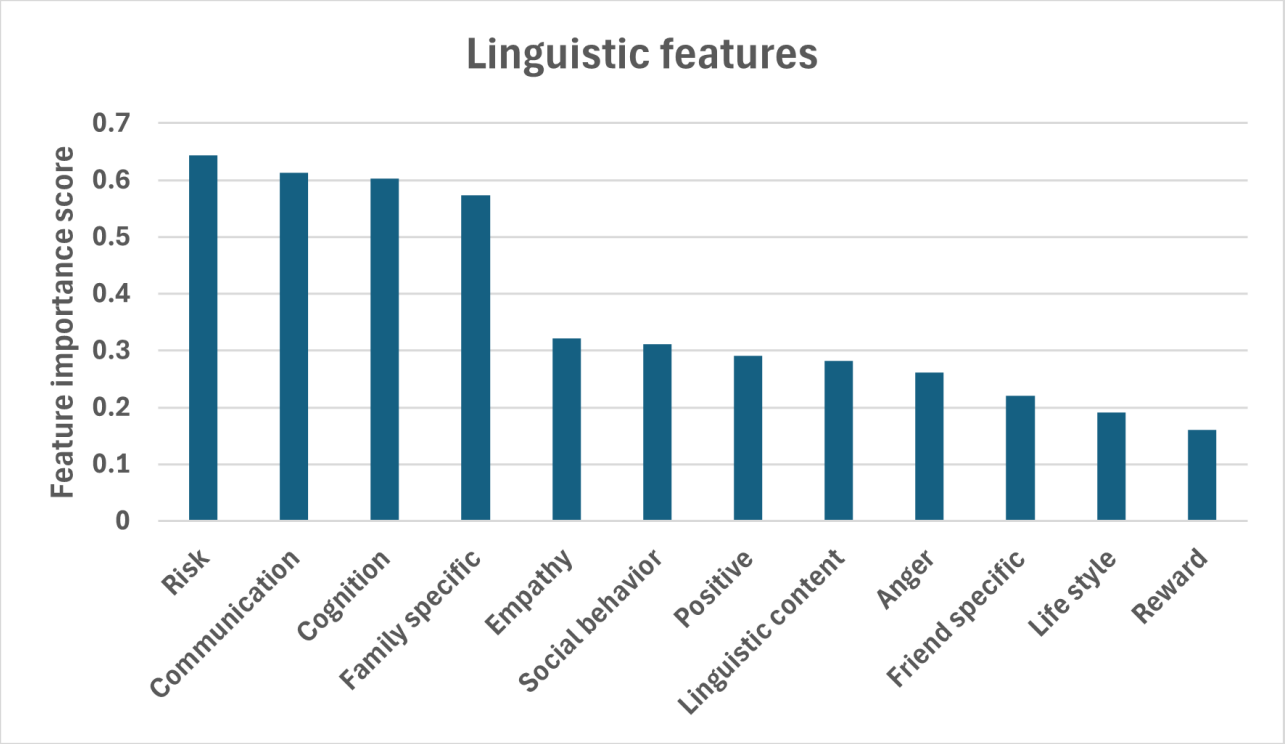


Figure 5 shows the permutation importance scores of various linguistic features related to some aspect of behavior or decision-making, possibly in a medical or social context. The features are ranked by their importance in predicting an outcome, with higher scores indicating a greater influence on the model's performance. The top 4 predictors are risk, clear communication, cognitive style, and family involvement. Empathy and social behaviors are cultivated in professional contexts, and positive messaging should be encouraged across various communication channels. Although less critical, addressing factors such as anger, lifestyle, and reward could further enhance outcomes. These policy recommendations aim to leverage the most influential factors identified by the model to achieve better decision-making and outcomes in the relevant context.

Figure 4. Relative importance of social determinants of health (SDOH) features in predicting crowdfunding campaign success (success ratio threshold=0.7).

Performance Evaluation of ML Models

Table 2 and Table 3 present the performance evaluation of 4 ML algorithms—random forest, gradient boosting, logistic regression, and elastic net—at a 0.7 success ratio threshold for SDOH and linguistic factors. The reported performance metrics are accuracy, sensitivity, and specificity across different subsets of top features (ranging from top 3 to top 15). Gradient boosting consistently outperformed the other algorithms in terms of accuracy (consistently 0.786 to 0.788), indicating its superior ability to identify successful crowdfunding campaigns. Random forest offered a balanced performance with good accuracy (0.767 to 0.769) and specificity (0.831 to 0.863), making it a reliable choice for predicting crowdfunding success while capturing nonlinear relationships and interactions. Logistic regression and elastic net exhibited strong specificity (0.997 to 0.999) but poor sensitivity (0.013 to 0.052), which suggests that they may be overly conservative and are not able to predict successful campaigns correctly.

On the basis of the evaluation, when using gradient boosting, selecting the top 3 to 12 features seems optimal. The top 3 features provide a strong balance of high accuracy and sensitivity with fewer variables, making the model simpler and potentially more generalizable. If one aims to maximize model performance with a bit more complexity, one can consider using up to the top 12 features, which slightly enhances specificity without sacrificing other metrics.

	Specificity	1.00	1.00	1.00	1.00	1.00

[a]Italics indicate the highest accuracy values across the 4 algorithms.

The results indicate that careful feature selection is crucial for optimizing model performance for linguistic features. Gradient boosting and random forest showed that selecting approximately the top 12 features provides a strong balance between sensitivity and specificity, making them well suited for predictive tasks in medical crowdfunding. Logistic regression may require a different approach or fewer features to avoid unnecessary complexity, whereas elastic net's performance suggests that a

XSL•FO
RenderX

moderate feature increase (up to 18-24 features) could be beneficial. Overall, the findings highlight the importance of tailored feature selection strategies to maximize the effectiveness of ML models in this domain.

Discussion

Principal Findings

In this study, we conducted an empirical analysis of medical crowdfunding. The analysis of 4984 crowdfunding campaigns revealed key insights into the relationship among goal amounts, campaign success, and donor engagement. Campaigns with higher goals (US $50,000-$100,000) attracted significantly more donors, indicating that ambitious targets may signal substantial projects, thus drawing greater support. Conversely, lower goal amounts (US $799.99-$10,000) were the most prevalent, suggesting a preference for achievable targets among campaigners. Highly successful campaigns had longer durations, averaging over 250 days. We also focused on deriving features using LLMs and feature selection via the random forest algorithm. We identified donors, goal amount, and span of campaign as critical predictors of success, with emotional and thematic features also contributing to campaign success. Among the ML models evaluated, gradient boosting demonstrated superior performance (range 0.786-0.788) and true positive rate (range 0.693-0.696), outperforming random forest, logistic regression, and elastic net. The analysis highlights the critical role of linguistic and SDOH predictors in the success of crowdfunding campaigns. Linguistic features such as clear and effective communication, particularly regarding risk, along with positive messaging, empathy, and social behaviors, significantly influence campaign outcomes. SDOH predictors, including the severity of medical conditions (eg, hospitalization or unspecified hospice care), income loss, and the involvement of health care organizations, are also key drivers of crowdfunding success. These findings suggest a need for improved hospital funding, better income protection policies, and stronger support from health care organizations. In addition, campaigns associated with high-cost treatments such as chemotherapy tend to attract more attention, underscoring the need for targeted support for patients undergoing such treatments.

Limitations

This study has several limitations. It primarily focused on linguistic, social, demographic, and medical-related features. Other factors, such as donor engagement metrics or campaign visibility on social media platforms, were not evaluated. While cross-validation helps in mitigating overfitting, the generalizability of the model to other types of crowdfunding campaigns beyond the specific dataset used (eg, different medical conditions, geographic regions, or platforms) remains uncertain. The model's performance may vary when applied to other datasets, limiting its broader applicability. This study relied on the available dataset for training and testing. If the dataset is not representative of all cancer crowdfunding campaigns (eg, biased toward certain demographics, treatment types, or socioeconomic groups), the model may not perform well in more diverse or less represented scenarios. Ultimately, the default parameters we chose for random forest feature selection due to a superior performance than that of the grid search method may not be applicable or effective for different datasets.

Comparison With Previous Studies

The findings that communication regarding risk, social behaviors, and empathy play a crucial role in influencing donor behavior have been documented in a previous study [32], where it was found that emotionally compelling narratives significantly improve crowdfunding outcomes. Research highlighting the financial burden [33] of cancer care provides further support for income loss as a significant predictor. The importance of factors such as being in a hospital or receiving chemotherapy treatment is supported by studies showing that campaigns related to severe or high-cost treatments, such as advanced-stage cancers, often receive more attention and donations [34]. Our study also sheds light on new insights on medical crowdfunding. The analysis introduces the importance of specific linguistic features, such as the use of positive language and social behavior indicators, which have not been as thoroughly explored in previous studies. The involvement of health care organizations as a significant predictor suggests that campaigns backed by institutions might have better access to resources and are perceived as more credible.

Conclusions

The reliance on crowdfunding for conditions associated with high-importance features such as hospital stays and income loss highlights potential gaps in health care funding. Policymakers need to assess where these gaps are and consider reforms or additional support mechanisms to reduce the need for crowdfunding in critical areas. The variability in the importance of different features may also point to inequities in access to health care and financial support. Policymakers can better target support to vulnerable populations such as those with comorbidities. A crucial policy objective is ensuring that all individuals, regardless of their medical or financial situation, have equal access to medical care without crowdfunding.

Abstract

Background: Large language models are increasingly applied in health care for documentation, patient education, and clinical decision support. However, their factual reliability can be compromised by hallucinations and a lack of source traceability. Retrieval-augmented generation (RAG) enhances response accuracy by combining generative models with document retrieval mechanisms. While promising in medical contexts, RAG-based systems remain underexplored in orthopedic and trauma surgery patient education, particularly in non-English settings.

Objective: This study aimed to develop and evaluate a RAG-based chatbot that provides German-language, evidence-based information on common orthopedic conditions. We assessed the system's performance in terms of response accuracy, contextual precision, and alignment with retrieved sources. In addition, we examined user satisfaction, usability, and perceived trustworthiness.

Methods: The chatbot integrated OpenAI's GPT language model with a Qdrant vector database for semantic search. Its corpus consisted of 899 curated German-language documents, including national orthopedic guidelines and patient education content from the Orthinform platform of the German Society of Orthopedics and Trauma Surgery. After preprocessing, the data were segmented into 18,197 retrievable chunks. Evaluation occurred in two phases: (1) human validation by 30 participants (orthopedic specialists, medical students, and nonmedical users), who rated 12 standardized chatbot responses using a 5-point Likert scale, and (2) automated evaluation of 100 synthetic queries using the Retrieval-Augmented Generation Assessment Scale, measuring answer relevancy, contextual precision, and faithfulness. A permanent disclaimer indicated that the chatbot provides general information only and is not intended for diagnosis or treatment decisions.

Results: Human ratings indicated high perceived quality for accuracy (mean 4.55, SD 0.45), helpfulness (mean 4.61, SD 0.57), ease of use (mean 4.90, SD 0.30), and clarity (mean 4.77, SD 0.43), while trust scored slightly lower (mean 4.23, SD 0.56). Retrieval-Augmented Generation Assessment Scale evaluation confirmed strong technical performance for answer relevancy (mean 0.864, SD 0.223), contextual precision (mean 0.891, SD 0.201), and faithfulness (mean 0.853, SD 0.171). Performance was highest for knee and back-related topics and lower for hip-related queries (eg, gluteal tendinopathy), which showed elevated error rates in differential diagnosis.

Conclusions: The chatbot demonstrated strong performance in delivering orthopedic patient education through an RAG framework. Its deployment on the national Orthinform platform has led to more than 9500 real-world user interactions, supporting its relevance and acceptance. Future improvements should focus on expanding domain coverage, enhancing retrieval precision, and integrating multimodal content and advanced RAG techniques to improve robustness and safety in patient-facing apps.

(JMIR AI 2025;4:e75262) doi:10.2196/75262

KEYWORDS

retrieval-augmented generation; RAG; orthopedic patient education; medical chatbots; artificial intelligence in healthcare; large language models; LLM; clinical decision support systems; natural language processing; NLP; health information retrieval

Introduction

In recent years, machine learning, particularly through large language models (LLMs), has significantly influenced various industries, with profound implications for health care. These advanced models have transitioned from experimental frameworks to practical tools that enhance patient care and medical research. By analyzing complex, large-scale datasets, LLMs enable health care professionals to extract insights related to patient data, disease trends, and treatment efficacy [1]. Their expanding role includes apps in disease diagnosis, medical

XSL•FO
RenderX

documentation, and patient-provider communication, improving the efficiency and quality of health care services.

A key advancement in LLMs is their ability to process and interpret extensive contextual information, a crucial feature in health care, where context profoundly affects diagnostic and therapeutic decisions. For instance, OpenAI's GPT series has demonstrated improved proficiency in comprehending and generating complex medical dialogs and texts, supporting apps such as automated medical documentation and patient communication [2].

In diagnostics, LLMs assist in extracting and summarizing essential information from unstructured medical data, including clinical notes and imaging reports, facilitating timely and accurate condition assessments [3]. In addition, these models contribute to medical education by providing interactive learning platforms and access to vast medical literature, enhancing the training and preparedness of medical students and professionals [4].

Patient engagement is another critical area where LLMs are used. By delivering clear and informative explanations about medical conditions and treatments, these models enhance patient understanding and adherence to treatment plans [5]. However, their deployment in health care requires caution due to the potential for generating misleading or incorrect information, known as "hallucinations." Such errors can result in misinformed decisions that may compromise patient safety [6].

To mitigate these risks, enhancing the reliability of LLM-generated information is essential. Techniques such as retrieval-augmented generation (RAG), which integrates the generative capabilities of LLMs with data retrieval from trusted sources, have been developed to improve accuracy and verifiability, thereby preserving the integrity of medical advice [7].

Providing patient information on symptoms and conditions in orthopedics and trauma surgery presents unique challenges, as treatment success often depends on patients' understanding of their condition and adherence to therapeutic measures [8]. Traditional methods, including printed materials, online education, and brief personal consultations, have limitations in addressing the comprehensive informational needs of orthopedic patients [9]. Digital solutions are gaining traction for their ability to provide accessible, personalized, and on-demand information, with specialized orthopedic apps demonstrating improved patient outcomes through disease education, tailored rehabilitation programs, and real-time feedback [10].

Despite growing interest in RAG apps in health care, limited empirical research has evaluated such systems specifically within orthopedic settings involving both medical professionals and patients [7,11]. This study seeks to address this gap by developing and evaluating a RAG-enhanced chatbot designed to provide patient-centered information on orthopedic symptoms and conditions.

By integrating multiple evaluation approaches, this study contributes to the emerging literature on specialized RAG apps in health care, with implications for improving patient education in orthopedics and trauma surgery. The primary objective is to develop and evaluate a RAG chatbot that delivers evidence-based information on orthopedic conditions while comprehensively assessing its performance through feedback from both medical professionals and patients, as well as automated metrics.

Methods

Dataset and Preprocessing

Our dataset comprised official guidelines, specialized medical literature, and curated articles licensed from the Berufsverband für Orthopädie und Unfallchirurgie (BVOU-Germany), including texts available on the Orthinform platform [12]. These materials encompassed expert-reviewed medical content and patient education resources, all in German.

To enable contextualized medical information retrieval, we developed an RAG framework using LangChain and OpenAI models. This framework ensures that generated responses are derived from relevant, authoritative sources, supporting an evidence-based and transparent methodology [13,14]. A preprocessing pipeline was implemented to normalize and structure the dataset for efficient retrieval. JSON documents were standardized by extracting and refining metadata, including document names, categories, page numbers, URLs, and timestamps. PDFs were processed using unstructured.partition.pdf, preserving document structure and hierarchical elements. PyMuPDF was used as a fallback when unstructured failed to extract content correctly. To improve text quality, regex-based normalization removed artifacts.

The text was segmented using RecursiveCharacterTextSplitter, with 1000-character chunks and 200-character overlaps. URLs embedded in the text were preserved, and HTML tags were intentionally retained to maintain the structural integrity of web-based content. To enhance traceability, each chunk was assigned a unique identifier generated via MD5 hashing, and the processed data were stored in JSONL format, optimized for retrieval-based workflows.

Vectorization and Document Retrieval

To enable semantic search and efficient retrieval, we implemented Qdrant as a vector database and indexed documents using OpenAI's text-embedding-3-large model. This facilitated high-dimensional vector representations, ensuring precise retrieval of semantically relevant medical texts.

The Qdrant collection was initialized with a 3072-dimensional vector space, using cosine similarity as the distance metric. Processed text chunks were embedded in batches of 50 to optimize performance. The resulting vectors, along with their associated metadata, were stored in Qdrant and efficiently upserted for retrieval [15].

Chatbot Implementation and Query Processing

A Streamlit-based chat interface was developed to enable interactive, real-time retrieval of medical information. The system integrates OpenAI for response generation and Qdrant for document retrieval, supporting a conversational RAG framework. The retrieval mechanism is history-aware, dynamically adapting to previous interactions and retrieving up

XSL•FO
RenderX

to 5 relevant document chunks per query to ensure contextually rich responses.

The retrieval pipeline operates with a predefined search prompt, optimizing precision in medical document retrieval to ensure alignment with evidence-based orthopedic and trauma surgery guidelines. Retrieved documents are then passed to a response generation chain, conditioning GPT-4o to structure answers based on medical system instructions and ongoing conversation context. While the underlying GPT-4o model supports more than 50 languages, the chatbot's responses are primarily grounded in a curated German-language knowledge base (BVOU guidelines, patient education content). Therefore, while multilingual queries are technically possible, factual accuracy is optimized for German.

To ensure that all chatbot responses remain strictly grounded in the retrieved medical context and to prevent hallucinations, we implemented a structured system prompt written in German. This prompt explicitly instructs GPT-4o to generate answers exclusively based on the retrieved documents. If no relevant information is found in the retrieved content, the model is required to return a predefined message stating that sufficient information is not available. The system prompt includes the instruction:

> *Beantworte die folgende Frage basierend ausschließlich auf den Dir vorgelegten Kontext. Wenn du in dem Kontext der Dir vorgelegt wird keine Antwort auf die Frage findest, sag dem User: 'Dazu liegen mir leider keine Informationen vor.' Du darfst keine Empfehlungen geben, keine Diagnosen stellen, keine Inhalte erfinden oder spekulieren. Formuliere sachlich, klar und laienverständlich. Verwende nicht mehr als 250 Wörter, außer der User fordert ausdrücklich mehr. Verwende ausschließlich den folgenden Kontext: {context}*

The English translation of the above instruction is given below for clarity:

> *Answer the following question based strictly on the provided context. If the context does not contain sufficient information to answer the question, respond to the user: 'Unfortunately, I do not have any information on that.' You are not allowed to make recommendations, provide diagnoses, invent content, or speculate. Be objective, clear, and use layperson-friendly language. Do not exceed 250 words unless explicitly requested. Use only the following context: {context}.*

The placeholder {context} is dynamically replaced at runtime with the top-k (k=5) most relevant document chunks retrieved from the Qdrant vector database. These context segments are semantically matched to the user query and serve as the exclusive knowledge base from which the response is generated. This prompt configuration ensures that the model does not rely on its pretrained general knowledge or generate information beyond the curated orthopedic corpus, thereby minimizing the risk of hallucinated or unverifiable content.

To support manual validation and optimization, a debug interface was implemented to inspect retrieved documents, evaluate chunk segmentation, and analyze token consumption. A system prompt was designed to strictly limit response length (250 words, up to 1000 if explicitly requested) and ensure that the chatbot provides only factually grounded answers. The search prompt dynamically reformulates queries based on conversation history to enhance retrieval accuracy.

The chatbot streams artificial intelligence (AI)-generated responses dynamically, maintains a structured session history, and displays extracted URLs from retrieved documents to ensure source transparency and clinical accountability for users.

User Study and Evaluation

To evaluate the chatbot's clinical reliability and user acceptability, we conducted a structured user study via Google Forms, allowing participants to interact with the system and provide qualitative and quantitative feedback. Participants were instructed to input predefined orthopedic queries into the chatbot, covering topics such as herniated discs, hip osteoarthritis, anterior cruciate ligament injuries, and congenital muscular torticollis.

A total of 12 predefined orthopedic questions were developed by 2 independent board-certified orthopedic specialists to represent common clinical inquiries for each topic. The responses were rated using two key metrics on a 5-point Likert scale: (1) response accuracy measures how precisely the chatbot provided medically valid answers, and (2) helpfulness assesses how effectively the chatbot assisted users in understanding medical conditions and treatments.

For each question, mean (SD) values were calculated to quantify the consistency and reliability of ratings. Likert-scale data were treated as interval-level data for descriptive statistical analysis, which we considered acceptable due to the scale's symmetric design and widespread use of mean values in user experience (UX) research.

Beyond response evaluation, the survey included structured sections on empathy, clarity, usability, and response time. Users rated the chatbot's friendliness, ability to recognize intent, trustworthiness, and clarity of medical explanations. In addition, participants assessed navigation, response latency, and overall satisfaction. At the end of the survey, users were given the opportunity to provide open-ended feedback for further improvements. The test group included a mix of medical professionals (students, residents, and specialists) and nonmedical users to reflect diverse perspectives, but no subgroup analysis was conducted.

Automated Evaluation Using Retrieval-Augmented Generation Assessment Scale

To supplement the user-based evaluation, we applied the Retrieval-Augmented Generation Assessment Scale (RAGAS) framework, focusing on three key automated performance metrics [16]: (1) answer relevancy measures how well the chatbot's response aligns with the user query; (2) context precision assesses the quality and medical relevance of retrieved documents; and (3) faithfulness ensures that responses are

XSL•FO
RenderX

grounded solely in retrieved medical contexts, preventing hallucinations.

We generated 100 synthetic test questions using GPT-4o, ensuring each question was grounded in retrieved medical contexts. Corresponding ground truth answers were synthesized and manually reviewed by 2 board-certified orthopedic and trauma surgeons to ensure clinical accuracy and guideline adherence. Any ambiguous or incorrect responses were corrected to align with evidence-based medicine and current best practices. The 100-question test set was processed through the RAG pipeline, retrieving documents via Qdrant and generating responses using GPT-4o. The RAGAS framework then scored each response against ground truth answers using the 3 core evaluation metrics. Evaluation was conducted in batches, and performance metrics were aggregated into a quantitative evaluation report. Heatmaps and statistical summaries were generated to visualize chatbot performance across key medical retrieval tasks. This approach ensured that:

1. Retrieved contexts were clinically relevant (context precision).
2. Responses remained factually grounded in retrieved medical literature (faithfulness).
3. Answers directly addressed the medical queries posed by users (answer relevancy).

By combining user-based evaluations with structured, automated performance assessments, we systematically validated the chatbot's ability to retrieve, interpret, and generate medically accurate orthopedic and trauma surgery information.

Synthetic Query Generation for RAGAS Evaluation

For the automated RAGAS evaluation, 100 synthetic test questions and corresponding ground truth answers were generated using GPT-4o, based exclusively on the curated orthopedic knowledge base. This process ensured that all test questions were clinically relevant, context-grounded, and reproducible Textboxes 1 and 2.

Textbox 1. Prompt for question generation.

Based on this medical context:

[context content]

Generate a specific and challenging patient question on the topic [topic] ([subtopic]) that:

1. Can be answered using the information from this context
2. Tests understanding of medical concepts
3. Requires precise information from the text
4. Could realistically be asked by a patient

The question should sound natural and specific.

Textbox 2. Prompt for ground truth answer generation.

Based on this medical context:

[context content]

Answer this patient question:

[question]

The answer should:

1. Use only information from the provided context
2. Be precise and complete
3. Be formulated in patient-friendly language
4. Be 3 - 5 sentences long

Ethical Considerations

The study was conducted in accordance with the Declaration of Helsinki (World Medical Association; latest version) and applicable national regulations. It used an anonymous, voluntary online questionnaire and did not collect personal identifiers, IP addresses, or contact details. Under the Statutes of the Ethics Committee of the Medical Faculty, Leipzig University (§1(3)), formal review is required when personal data are processed; our protocol analyzed only anonymous responses. Based on this institutional policy and General Data Protection Regulation Recital 26 (anonymous data are not personal data), no formal ethics review was required at our institution. Participation implied consent after reading an online information sheet [17, 18].

Results

Preprocessing and Data Preparation

A total of 899 unique documents were processed, encompassing structured and unstructured medical content from sources such as Orthinform.de, German orthopedic guidelines, and additional

XSL•FO
RenderX

curated literature. The dataset was segmented and preprocessed to enable efficient retrieval and response generation within the RAG framework.

Following the preprocessing pipeline, 18,197 unique text chunks were generated and stored in the Qdrant vector database, optimizing retrieval. These chunks were embedded using OpenAI's text-embedding-3-large model, facilitating high-dimensional semantic search across patient education materials. The dataset contained 5,565,958 tokens, with an average chunk size of 973.27 characters. The largest chunks measured 1000 characters, while the smallest segments were 143 characters, ensuring a structured yet comprehensive representation of the source materials.

Human Validation

The user evaluation included 30 participants: 13 licensed physicians (43.3%), 3 resident physicians (10%), 7 medical students (23.3%), and 10 individuals without a medical background (33.3%). Participants rated chatbot responses to 12 predefined orthopedic queries using a 5-point Likert scale. The queries covered four main orthopedic conditions: a herniated disc, hip osteoarthritis (coxarthrosis), anterior cruciate ligament tear, and congenital muscular torticollis. For each condition, 3 specific subquestions addressed pathophysiology, symptoms, and treatment options. A homogeneous test group was not considered essential for the purposes of this study, as the primary focus was on evaluating UX, transparency, and response plausibility from different user perspectives. Including both medical and nonmedical participants allowed for a more realistic appraisal of trust, clarity, and usability in patient-facing contexts.

Assessment of Disease-Specific Responses

The accuracy ratings of chatbot responses ranged from 4.41 to 4.65 (mean), while helpfulness ratings ranged from 4.48 to 4.74 (mean), Table 1. The highest accuracy rating (mean 4.65, SD 0.61) was recorded for the question on congenital muscular torticollis. The highest helpfulness rating (mean 4.74, SD 0.51) was observed for the question on hip osteoarthritis symptoms. SD values for accuracy ratings ranged from 0.49 to 0.81 and from 0.49 to 0.68 for helpfulness ratings. The highest variance in accuracy (SD 0.81) was measured for responses regarding herniated disc symptoms.

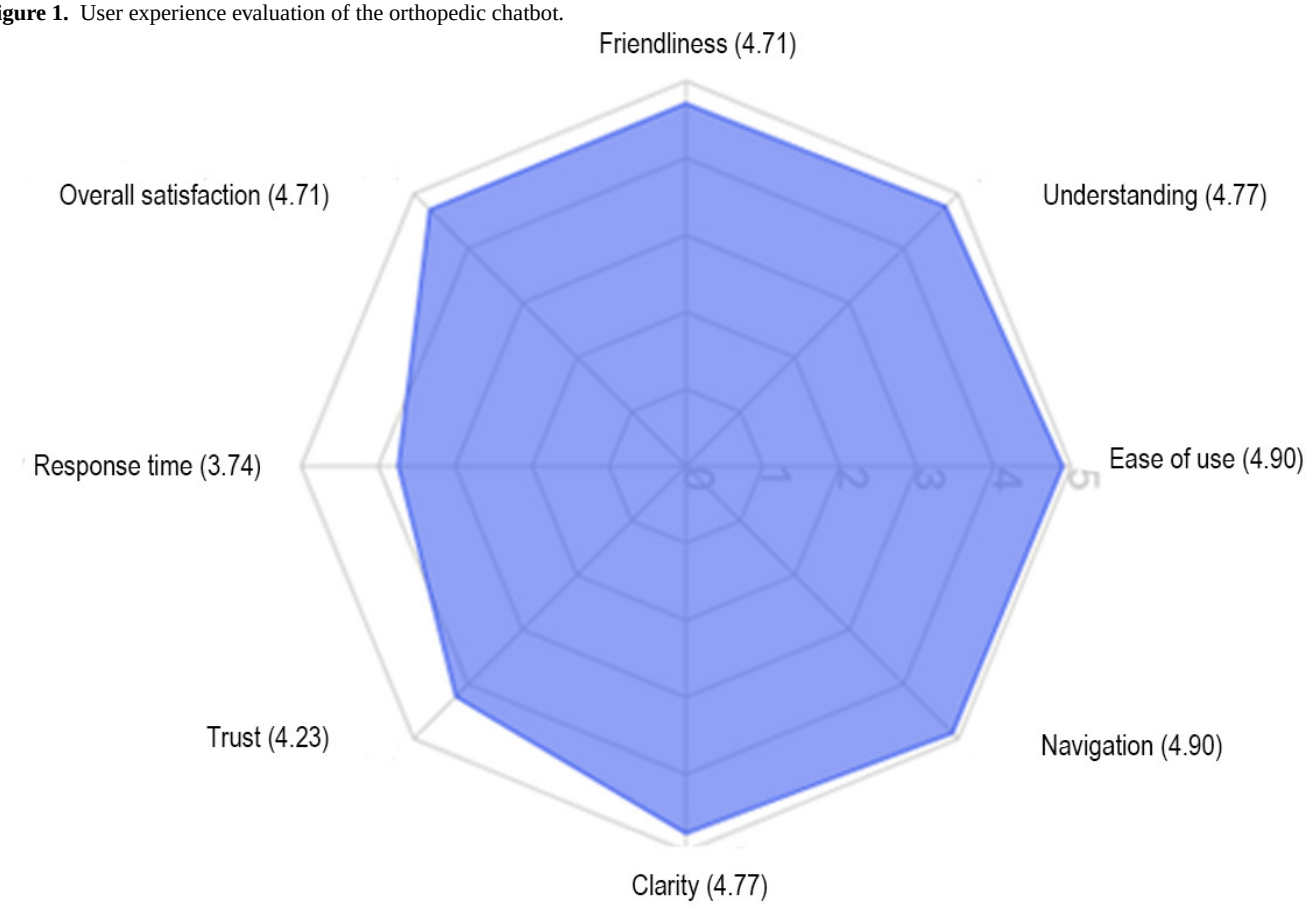
Across all responses, 93.2% received a rating of 4 or higher for accuracy and 95.8% for helpfulness. No systematically lower ratings were observed for treatment-related questions compared to pathophysiological or symptom-related queries.

Table 1 presents data from 30 users, summarizing the average ratings for the accuracy and helpfulness of chatbot responses to specific orthopedic questions. Values are reported as mean (SD). The ratings were collected using a 5-point Likert scale (1=very inaccurate and unhelpful, 5=very accurate and helpful). The data were collected during the evaluation phase in September 2024.

XSL•FO
RenderX

Table . Human validation of disease-specific questions from the chatbot.

Questions	How accurate was the information? mean (SD)	How helpful were the answers? mean (SD)
Herniated disc		
What exactly is a herniated disc?	4.45 (0.72)	4.58 (0.56)
What are the typical symptoms of a herniated disc?	4.41 (0.81)	4.60 (0.49)
What treatment options are available for a herniated disc and how do they differ?	4.52 (0.68)	4.48 (0.68)
Hip osteoarthritis		
What is coxarthrosis and how does this condition develop?	4.55 (0.57)	4.58 (0.56)
What symptoms are typical of hip osteoarthritis?	4.55 (0.62)	4.74 (0.51)
What treatments are available for coxarthrosis?	4.55 (0.67)	4.65 (0.61)
Anterior cruciate ligament tear		
What is an anterior cruciate ligament tear and how can it occur?	4.54 (0.62)	4.61 (0.56)
What symptoms indicate an anterior cruciate ligament tear?	4.61 (0.62)	4.68 (0.65)
What treatment options are available for an anterior cruciate ligament tear?	4.52 (0.68)	4.52 (0.63)
Congenital muscular torticollis		
What does congenital muscular torticollis mean and how can it be recognized in a baby?	4.65 (0.61)	4.61 (0.56)
What are the causes of congenital muscular torticollis?	4.61 (0.56)	4.65 (0.49)
What treatment options are available for babies with congenital muscular torticollis?	4.61 (0.49)	4.61 (0.56)



User Experience

UX metrics were evaluated across 8 dimensions, as visualized in Figure 1. Ease of use and navigation intuitiveness received the highest ratings, both with mean values of 4.90 (SD 0.30). Response clarity (mean 4.77, SD 0.43) and understanding of user concerns (mean 4.77, SD 0.43) were also rated positively. Trust in the provided information was rated moderately lower (mean 4.23, SD 0.56). System response time received the lowest rating (mean 3.74, SD 0.73) and exhibited the highest variance. This may partly reflect limitations of the test environment: during the user evaluation, the chatbot was accessed via a local Streamlit app, which lacked the server-side performance optimization of the final production system. In contrast, the deployed version on the Orthinform platform demonstrates faster and more stable response times in real-world use. Overall satisfaction with the chatbot was high (mean 4.71, SD 0.53).

UX evaluation of the orthopedic chatbot during the user study (September 2024). The radar chart summarizes ratings across 8 dimensions (ease of use, navigation, response clarity, understanding of user concerns, trust, empathy, system response time, and overall satisfaction). Data were collected from 30 participants (licensed physicians, medical students, and nonmedical users) using a 5-point Likert scale (1=very poor and 5=excellent).

XSL•FO
RenderX

Figure 1. User experience evaluation of the orthopedic chatbot.

Automated Evaluation Using RAGAS

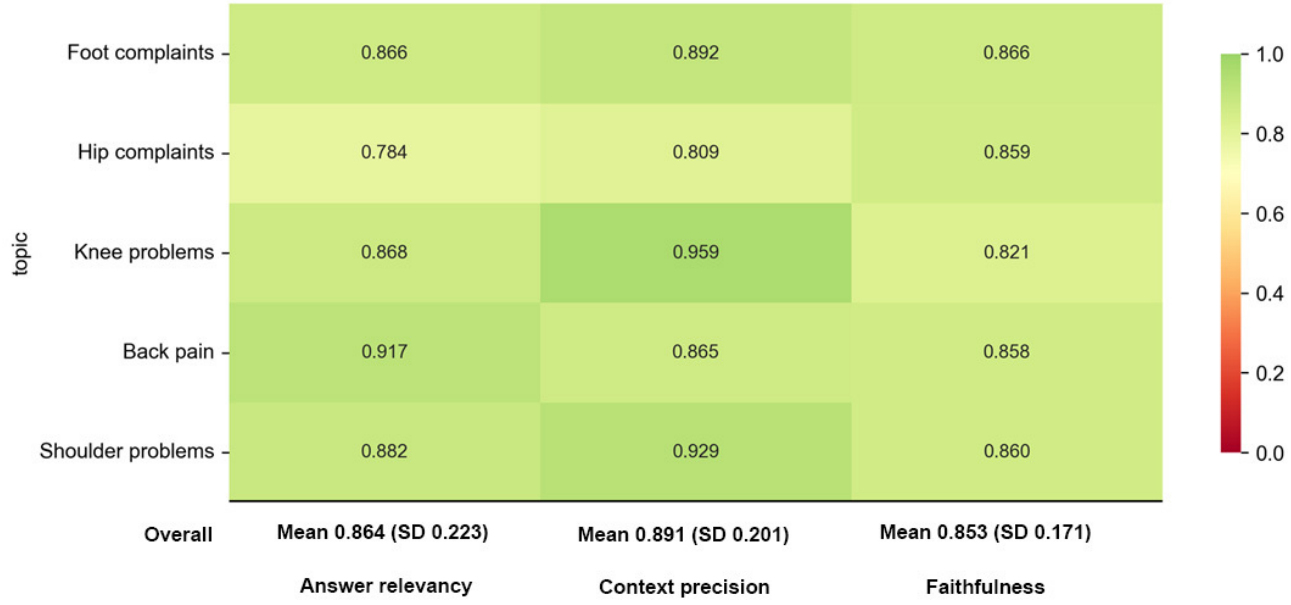
The 100-question synthetic test set was processed through the chatbot's retrieval pipeline, retrieving up to 5 (k=5) document chunks per query and generating responses using GPT-4o. RAGAS evaluation was conducted on 3 core metrics, with results reported as mean (SD) scores to quantify both performance and variability across the test set.

Answer Relevancy

The chatbot's ability to generate responses directly aligned with user queries achieved a mean score of 0.864 (SD 0.223). Queries related to back pain and shoulder problems scored the highest, with means of 0.917 and 0.882, respectively, while hip-related topics exhibited slightly lower performance, with a mean of 0.784 (SD 0.338).

Context Precision

The retrieval mechanism returned highly relevant documents per query, achieving a mean precision score of 0.891 (SD 0.201). The highest precision was observed for knee-related queries, with a mean of 0.959 (SD 0.078), while hip-related topics showed lower retrieval performance, with a mean of 0.809 (SD 0.362).



Faithfulness

Responses remained strongly grounded in retrieved documents, with a mean faithfulness score of 0.853 (SD 0.171). A total of 71% of responses were fully based on the retrieved context (scoring above 0.8), while 19% displayed minor inconsistencies or additional inferred information (scoring between 0.6 and 0.8).

As shown in Figure 2, the chatbot demonstrates strong performance across all orthopedic domains, with most metrics scoring above 0.8. Notable performance variations were observed across different orthopedic topics. Knee-related queries showed the highest overall context precision score (0.959), indicating exceptionally accurate retrieval of relevant information. Back pain queries achieved the highest answer relevance (0.917), suggesting the system excels at generating targeted responses for this common musculoskeletal complaint.

XSL•FO
RenderX

Figure 2. Retrieval-Augmented Generation Assessment Scale evaluation metrics across major orthopedic domains.

Hip-related queries, while still performing adequately, showed comparatively lower scores across all 3 dimensions, particularly in answer relevancy (0.784). This indicates an area for potential improvement in the knowledge base or response generation for hip-related orthopedic conditions.

RAGAS evaluation metrics across major orthopedic domains (automated evaluation, October 2024). The chart visualizes answer relevancy, context precision, and faithfulness for 5 major orthopedic domains (back pain, hip, knee, shoulder, and foot problems) based on a synthetic test set of 100 GPT-generated queries. Values range from 0 to 1, with a color gradient from red (poor performance) to dark green (excellent performance). Overall mean (SD) values for each metric are displayed at the bottom of the chart.

Performance Analysis and Observations

The subanalysis of the RAGAS evaluation of 100 synthetic test questions across 31 subcategories of major orthopedic conditions reevaluated the chatbot's performance using 3 key metrics: answer relevancy, context precision, and faithfulness. A comprehensive analysis demonstrates that 86% of all queries attained values above 0.8 in both answer relevancy and context precision, while 92% of responses exhibited answer relevancy values above 0.8. Among the 6% of queries with answer relevancy values below 0.1, 60% pertained to the hip domain (primarily tendinitis), 25% to foot complaints, and the remaining 15% to various other conditions.

Figure 3 illustrates performance metrics across all 31 orthopedic conditions examined. Several subtopics reached the maximum score (1) in individual metrics. In context precision, this applied to toe arthritis, hip dysplasia, knee instability, shoulder bursitis, and shoulder impingement syndrome. Knee osteoarthritis achieved the maximum value of 1 in faithfulness, combined with high answer relevancy (0.936) and maximum context precision (1). In contrast, hip tendinitis exhibited the lowest answer relevancy value of 0.298 in the entire dataset.

RAGAS performance metrics across 31 orthopedic subtopics (automated evaluation, October 2024). The chart visualizes answer relevancy, context precision, and faithfulness across 31 specific orthopedic subcategories, grouped by their main domains. Values range from 0 to 1 and are displayed using a color gradient from red (poor performance) to dark green (excellent performance). Overall, mean (SD) values for each metric are provided at the bottom of the chart.

A detailed analysis of individual questions accounts for the performance deficits in hip tendinitis, as illustrated in Figure 2. Out of the 3 queries on this topic, 2 (Q19: differential diagnosis of tendinitis; Q20: clinical distinguishing features) received answer relevancy values of 0, while the third query (Q18: therapeutic options) achieved 0.893. This uneven distribution resulted in a low average value of 0.298.

Overall, 3% of the 100 test questions exhibited total context retrieval failures (score=0). Hip-related topics were disproportionately affected, with complete failures in 15% of answer relevancy assessments and 20% of context precision assessments. These failures primarily occurred in complex differentiation tasks, notably Q19 (hip tendinopathy) and Q6 (hip impingement syndrome).

Figure 3. Retrieval-Augmented Generation Assessment Scale performance metrics across 31 orthopedic subtopics.

Qualitative Output Analysis and Sample Responses

To illustrate the output quality of our system, we selected representative user queries along with the corresponding retrieved passages, generated answers, and associated evaluation metrics (answer relevancy, context precision, and faithfulness). These examples reflect typical dialog scenarios and demonstrate both the content quality and the traceability of source references. The selected samples cover a range of anatomical regions (eg, lumbar spine, knee joint, and shoulder) and include questions on diagnostics, conservative management, and surgical decision-making.

Table 2 presents 2 representative examples of user queries, retrieved context excerpts, and corresponding RAGAS evaluation scores from the automated test set. The user queries and 2 sample answers have been translated from German into English, while other context excerpts remain in the original language to ensure fidelity. All examples are based on the synthetic evaluation conducted since October 2024. A complete list of all original queries, answers, and evaluation metrics is provided in Multimedia Appendices 1 and 2.

Table . Representative examples of user queries, retrieved context excerpts, and Retrieval-Augmented Generation Assessment Scale evaluation scores.

User query	Retrieved context (excerpt)	Answer relevancy	Context precision	Faithfulness
What conservative treatments are typically used for a lumbar disc herniation, and under what circumstances is surgery unavoidable?	Conservative treatments include physiotherapy, medication, targeted spinal injections, weight reduction, and avoiding prolonged sitting. Surgery is considered if symptoms persist for more than 6 months despite therapy or in cases of neurological deficits or loss of bladder/bowel control.	0.974	1	1
What is the most common location for cartilage damage in the knee joint detected in MRI[a] examinations with a field strength of 3.5 Tesla, and how do the results of these examinations, together with pain localization and intensity, influence the selection of therapy?	In MRI examinations of the knee joint with a field strength of 3.5 Tesla, the most common location for detecting cartilage damage is the medial femoral condyle, followed by the posterior surface of the patella, although the latter is much less common. The results of these MRI examinations, in conjunction with the patient's clinical examination which includes pain localization and intensity, play a crucial role in influencing the selection of a therapy. While clinical tests rarely provide direct evidence of cartilage damage, the information gathered from them, alongside MRI and X-ray diagnostics, helps determine the appropriate treatment method. The key factors for selecting the therapy are the depth and extent of the cartilage defect that needs to be treated.	0.9702	0.833	1

[a]MRI: magnetic resonance imaging.

Discussion

Principal Results

The evaluation of our RAG chatbot for orthopedic and trauma surgery patient education demonstrated strong performance metrics. Human assessments yielded accuracy ratings averaging 4.55 (out of 5) and helpfulness ratings of 4.61 (out of 5) across orthopedic conditions. UX metrics showed high scores for ease of use (4.90) and response clarity (4.77).

Comparison With Prior Works

Compared to previous studies on health care chatbots, our system demonstrates significantly higher performance in terms of accuracy, helpfulness, and user satisfaction. For instance, Nadarzynski et al [19] reported acceptance rates of 67% and trust scores averaging 3.4 out of 5 in a general population sample, reflecting persistent concerns about reliability and factual correctness. Similarly, Milne-Ives et al [20] observed usability scores typically ranging between 3.5 and 4.2 in various chatbot apps, with considerable heterogeneity depending on system design and target audience. In contrast, our chatbot achieved mean scores of 4.55 for perceived accuracy and 4.61 for helpfulness, supported by strong ratings for usability and clarity. These differences may partly be explained by the academic background of our user cohort, but they also reflect domain-specific design choices and system robustness.

A notable strength of our study lies in the integration of human and automated evaluation strategies. Beyond structured user feedback, we applied the Retrieval-Augmented Generation Assessment Score (RAGAS) framework to evaluate the chatbot's contextual precision, answer relevancy, and grounding fidelity. The chatbot achieved strong mean scores across all 3 dimensions (eg, answer relevancy: mean 0.864, SD 0.223), indicating effective retrieval and factual consistency. The relatively high SD values reflect expected variability across subdomains, consistent with known topic-specific limitations in medical LLM performance.

XSL•FO
RenderX

In direct comparison to baseline LLMs without retrieval mechanisms, the advantages of RAG become evident. For example, Deng et al [21] showed that ChatGPT-4 provided accurate responses to only 17% of treatment-related orthopedic questions, while 75% were deemed merely comprehensive without being verifiably correct. In contrast, our system achieved 92% of responses above 0.8 in answer relevancy, demonstrating substantial improvements in factual alignment and contextual precision. These results align with findings by Jabal et al [22], who observed that retrieval-enhanced LLMs outperformed traditional models in structured data extraction tasks in clinical settings.

Beyond performance metrics, our system introduces several architectural and contextual innovations that distinguish it from existing chatbot solutions.

This domain-specific adaptation approach is comparable to methodologies applied in other specialized RAG contexts, such as religious text retrieval [23].

Recent studies further support this pattern: a 2-layer RAG architecture improved grounding and answer quality in medical Q&A, and RAG variants outperformed GPT-4 in clinical fact-checking, underscoring the value of retrieval for verifiable, source-linked outputs [24,25].

Unlike general-purpose medical chatbots that often rely solely on pretrained LLMs, our framework combines semantic retrieval with domain-specific grounding. All responses are generated based on verified German-language materials, including guideline-compliant content licensed from the BVOU. This ensures high clinical relevance and alignment with local standards of care.

Furthermore, the system is explicitly tailored to German-speaking users and reflects orthopedics-specific terminology, diagnostic reasoning, and patient communication norms. Unlike many tools focused on English-speaking audiences, our chatbot addresses the information needs of a specific linguistic and clinical population. The RAG architecture also promotes transparency by displaying the source URLs and retrieved text segments for each response, enabling traceability and user trust. Finally, our validation approach integrates structured Likert-based user ratings with RAGAS metrics and expert-reviewed reference answers, providing a robust multiperspective evaluation framework.

In summary, the combination of retrieval-based grounding, language and domain specificity, and transparent validation distinguishes our chatbot from conventional medical AI tools and supports its use in clinically relevant patient education scenarios.

Real-World Implementation

Following the evaluation phase, the chatbot was integrated into the public patient education platform of the German Society of Orthopedics and Trauma Surgery (BVOU) and has been accessible via Orthinform.de since October 2024. This real-world deployment enables patients across Germany to access AI-guided orthopedic information around the clock. The system is clearly labeled as an informational tool, not intended for diagnosis, treatment decisions, or appointment scheduling. It does not support direct communication with clinics.

As of June 2025, the chatbot has processed a total of 9514 user interactions. The most frequent topics, in descending order of frequency, included back pain, hip joint degeneration, meniscus tear, knee pain, spinal stenosis, shoulder impingement, and disc herniation. These usage statistics underscore the chatbot's practical relevance and indicate a high level of user acceptance for AI-assisted patient education in orthopedics.

Limitations

Despite the overall strong performance, several limitations must be noted. First, hip-related queries showed disproportionately high failure rates, with 15% resulting in complete answer relevancy failures (score=0) and 20% exhibiting context precision failures. Questions involving complex differential diagnoses, such as distinguishing gluteal tendinopathy from trochanteric bursitis, proved particularly challenging for the retrieval system. This pattern of domain-specific performance variance, reflected in elevated SD values across metrics, suggests uneven coverage in the knowledge base or suboptimal document chunking in specialized orthopedic subdomains. These findings are consistent with observations by Johnson et al [26], who reported similar retrieval limitations in RAG-based diagnostic systems due to gaps in knowledge coverage.

Second, while the system performed reliably on standard diagnostic and treatment questions, more nuanced or comparative queries, such as those related to treatment efficacy or surgical decision-making, exhibited greater variability in faithfulness scores. The observed mean value of 0.853 (SD 0.171) in faithfulness suggests inconsistent grounding across different query types. Genovese et al [27] similarly reported that RAG model accuracy in patient education depends heavily on the depth and quality of the underlying dataset.

Third, there is a persistent risk of hallucinations. Although the retrieval architecture significantly reduces the likelihood of fabricated responses compared to standard LLMs, it cannot eliminate them entirely. The quality of generated outputs is directly tied to the relevance and completeness of the underlying documents. Underrepresented orthopedic subdomains may thus produce lower fidelity outputs. This aligns with concerns raised by Altofer et al [28], who described generative AI as a "double-edged sword" in medicine—capable of exceeding expert performance in some domains, yet also prone to generating misleading content.

Fourth, the current implementation omits several advanced RAG features that may enhance response quality. These include hybrid retrieval methods (combining sparse and dense search), contrastive answer generation, knowledge graph integration, and multimodal capabilities (eg, linking imaging findings with textual explanations). Future work should explore these approaches to strengthen context matching, improve factual precision, and reduce hallucination risks in complex query types.

Finally, a deliberately implemented safeguard in the form of a persistent disclaimer emphasizes that the chatbot serves solely for general informational purposes and is not intended for self-diagnosis or clinical decision-making. This ethical design

XSL•FO
RenderX

feature underlines the system's patient-centered focus and risk awareness. Future versions may benefit from the integration of an autonomous detection mechanism to recognize when a query exceeds the system's informational boundaries and to proactively prompt users to consult a qualified health care professional.

Another promising enhancement is domain-specific knowledge organization. The observed regional performance variations, with knee-related queries outperforming hip-related ones, suggest that tailored knowledge representation strategies may be needed for different orthopedic subdomains. Introducing hierarchical retrieval mechanisms that model anatomical and pathological relationships could improve response accuracy for conditions requiring cross-document integration.

Future Work

To address these limitations, advanced RAG mechanisms could further enhance the system's capabilities. Implementing agentic RAGs, which dynamically reformulate queries based on conversational context, could improve performance on complex differential diagnostic questions. Unlike static top-k retrieval, this approach enables iterative, context-aware information gathering, particularly benefiting challenging hip-related queries identified in our evaluation.

In future work, domain-specific knowledge organization should also be explored. The observed regional performance variations, with knee-related queries outperforming hip-related ones, suggest that tailored knowledge representation strategies may be needed for different orthopedic subdomains. Introducing hierarchical retrieval mechanisms that model anatomical and pathological relationships could improve response accuracy for conditions requiring cross-document integration.

Conclusions

Our RAG-based chatbot demonstrates strong potential for improving patient access to orthopedic information, with solid evaluation scores and reliable performance. While it already provides valuable support for patient education, continuous adaptation is essential to keep pace with rapid AI advancements and ensure optimal accuracy. Our data show strong overall performance with identifiable outliers where the RAG pipeline is less robust. To ensure consistent quality in patient education and broader medical use cases, performance should be validated across additional datasets and settings with clear, reproducible quality control. The impact of RAG will hinge on high-quality, well-managed corpora and reliable retrieval that keeps answers traceable to sources.

Acknowledgments

This project was developed in collaboration with the Professional Association for Orthopaedics and Trauma Surgery (Berufsverband für Orthopädie und Unfallchirurgie e.V. - BVOU). We acknowledge their financial support and valuable contributions in shaping the research, providing domain expertise, and facilitating the evaluation process. While BVOU provided financial support and domain expertise, they had no role in the study design, data collection, analysis, or decision to publish. This study was supported by the Open Access Publishing Fund of Leipzig University.

Data Availability

The detailed performance metrics of the retrieval-augmented generation system are provided in the Multimedia Appendix 1. The datasets generated or analyzed during this study are available from the corresponding author on reasonable request.

Abstract

Background: Despite public health efforts, tobacco use remains the leading cause of preventable death in the United States and continues to disproportionately affect underrepresented populations. Public policies are needed to improve health equity in tobacco-related health outcomes. One strategy for promoting public support for these policies is through health messaging. Improvements in artificial intelligence (AI) technology offer new opportunities to create tailored policy messages quickly; however, there is limited research on how the public might perceive the use of AI for public health messages.

Objective: This study aimed to examine how knowledge of AI use impacts perceptions of a tobacco control policy video.

Methods: A national sample of US adults (N=500) was shown the same AI-generated video that focused on a tobacco control policy. Participants were then randomly assigned to 1 of 4 conditions where they were (1) told the narrator of the video was AI, (2) told the narrator of the video was human, (3) told it was unknown whether the narrator was AI or human, or (4) not provided any information about the narrator.

Results: Perceived video rating, effectiveness, and credibility did not significantly differ among the conditions. However, the mean speaker rating was significantly higher (P=.001) when participants were told the narrator of the health message was human (mean 3.65, SD 0.91) compared to the other conditions. Notably, positive attitudes toward AI were highest among those not provided information about the narrator; however, this difference was not statistically significant (mean 3.04, SD 0.90).

Conclusions: Results suggest that AI may impact perceptions of the speaker of a video; however, more research is needed to understand if these impacts would occur over time and after multiple exposures to content. Further qualitative research may help explain why potential differences may have occurred in speaker ratings. Public health professionals and researchers should further consider the ethics and cost-effectiveness of using AI for health messaging.

KEYWORDS

artificial intelligence; tobacco control; health communication; generative artificial intelligence; health policies

Introduction

Despite some progress in tobacco control and prevention, tobacco remains the leading cause of preventable death in the United States [1], with persistent inequities in health outcomes among youth, rural residents, people with mental health illnesses, communities of color, and the Lesbian, Gay, Bisexual, Transgender, Queer or Questioning, Intersex, Asexual + community [2,3]. Secondhand smoke exposure disproportionately impacts Black people compared to any other racial group, putting them at higher risk for asthma and long-term lung disease [2,4]. Public policies are essential for addressing health inequities associated with tobacco use and exposure [2].

While there is evidence that policies can decrease smoking behaviors [5], there is a need to implement more comprehensive policies to promote and achieve health equity in the United States. Given this need, more countries and US jurisdictions are moving toward “Endgame” policies [6]. Endgame policies focus on strategies that address existing health inequities and target commercial sales of tobacco products rather than individual use. Existing research in New Zealand indicates some support for Endgame policies [7-9]. For example, flavored tobacco products have been specifically targeted to communities

XSL•FO
RenderX

of color and youth, which in turn has led to higher tobacco-related disease and death among these communities [10-13]. One potential Endgame strategy to reduce these inequities is a policy banning the sale of tobacco products.

While research has examined the overall effectiveness of some tobacco control policies, there is limited research on how to best promote support for these types of policies. Developing and testing messaging for promoting tobacco Endgame policies is essential for promoting local, state, and national efforts in the United States to address tobacco-related inequities. However, developing and testing high-quality content, particularly video content, can be expensive and time-consuming, given that it can require a significant investment of resources [14].

With limited resources, public health organizations such as local tobacco control coalitions often lack the time, funding, or expertise to design high-quality content. Generative artificial intelligence (AI) offers tools to address these challenges by enabling the rapid creation of targeted messages, supporting simple analyses of communication features (eg, pause counts), and producing high-quality videos [15-18]. Platforms such as ChatGPT (OpenAI) can generate scripts or social media text within seconds, while other programs can create videos featuring digital avatars that deliver messages with customizable voices and appearances. These capabilities can reduce costs, shorten production time, and allow messages to be tailored to specific audiences. For example, one study found that AI-generated health messages were rated higher in quality and clarity than human-generated messages from Twitter (xAI; [19]), although the findings were limited to a sample of college and young adult women.

With this in mind, AI messages can help tailor messages to a specific population. In addition, the use of AI, such as ChatGPT, can be used to decrease language barriers in health care and simplify medical jargon to make it more accessible [20]. Incorporating AI in health messaging has been associated with several positive outcomes, including increased clarity, improved message tailoring, and reduced language barriers in health communication [19,20]. Within tobacco control, AI is already being used to personalize quitting interventions (eg, chatbots for cessation support) and to monitor tobacco-related trends (eg, social media surveillance) [21].

Overall, AI has the potential to revolutionize health communication and allow public health organizations to create quality content more quickly and cost-effectively. However, understanding how the public perceives the use of AI for health messaging is important. Research highlights several barriers to accepting messages involving AI, including concerns that such messages may be perceived as less trustworthy or relatable, and discomfort associated with AI entities mimicking human characteristics (commonly referred to as the “uncanny valley”) [22]. For example, though traditionally applied to visual AI, the “uncanny valley” may also occur with synthetic voices that mimic human voices but may lack natural emotion or fluctuation, potentially eliciting audience discomfort [22]. These factors can diminish the perceived effectiveness and credibility of public health messages.

Existing theoretical frameworks can help explain how audiences perceive AI in health messaging. The elaboration likelihood model (ELM) describes 2 routes of information processing: the central and peripheral [23]. When individuals have little interest in or connection to a topic, they are less likely to critically think about the information presented [23] and instead rely on heuristics such as source credibility to make decisions [23]. For example, the source or speaker in a message and their perceived credibility could influence individuals’ decisions to follow or not follow the message. In the case of AI-delivered messages, positive perceptions of AI may increase acceptance of the message, whereas negative perceptions of AI may lead audiences to discount or ignore it.

The computers as social actors (CASA) paradigm further shows that people apply social expectations such as trust and empathy to digital agents [24]. Recent work has extended CASA to health communication contexts, demonstrating that perceived characteristics of AI sources can shape message credibility and audience engagement [25]. In health messages, when trust and credibility are vital to the processing of a message, audiences may evaluate AI speakers as more or less credible than human ones, even when delivering identical content. These frameworks highlight key factors shaping how audiences interpret and respond to AI-delivered health information.

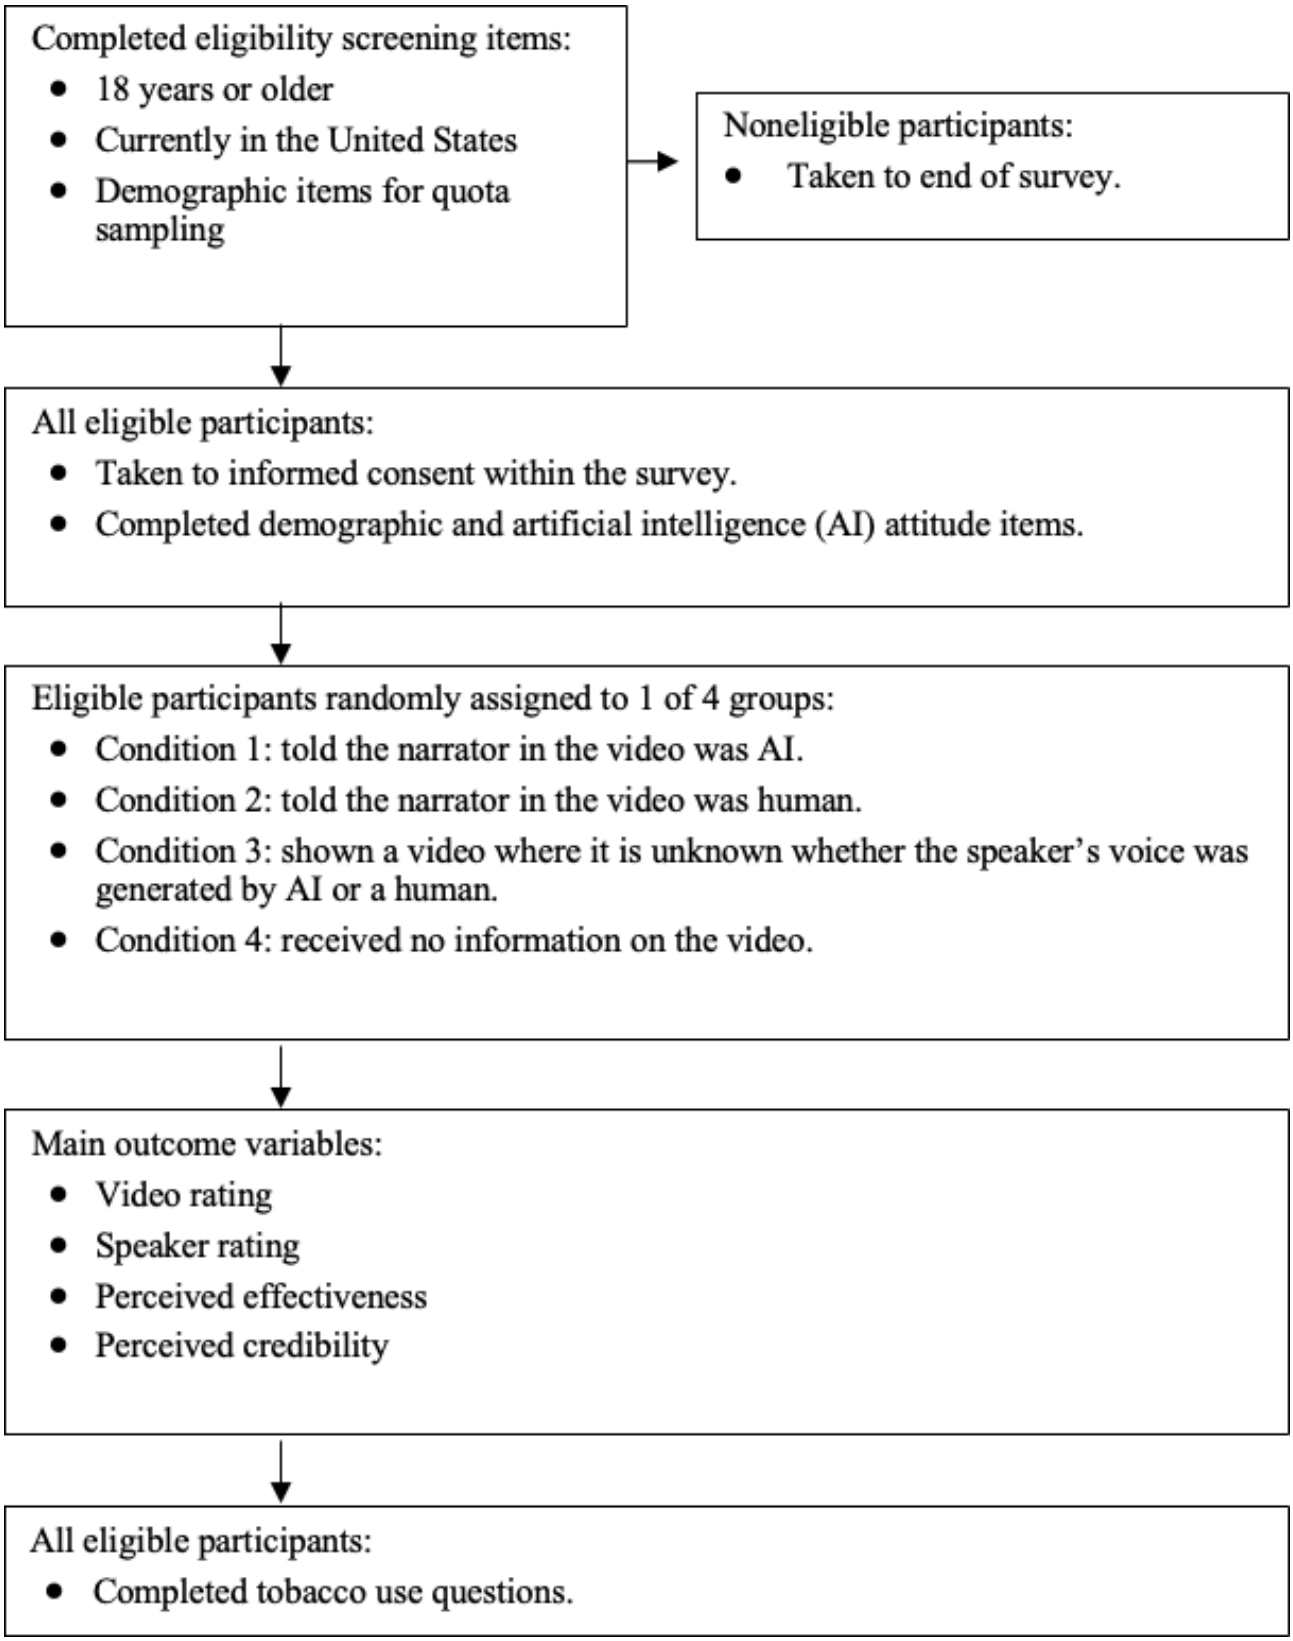
To the authors’ knowledge, no existing research has specifically investigated how perceptions of an AI-generated speaker may impact message outcomes in an experimental design using both qualitative and quantitative data. Therefore, the purpose of this study was to explore whether awareness that a speaker is AI-generated influences the message outcomes of a tobacco policy video. We hypothesized that participants who were informed that the narrator was AI-generated would rate the video lower in overall quality, perceived effectiveness, credibility, and speaker evaluations compared with those who were told that the narrator was human, unknown, or not informed.

Methods

Recruitment and Data Collection

Data were collected between January 25 and February 1, 2024. US adults (N=500) were recruited through the Qualtrics Survey Panel for an electronic survey. Quota sampling was used to approximate the US adult population distribution for age, sex, race, and ethnicity based on the American Community Survey from the US Census Bureau [26]. A priori power analysis using G*Power (Erdfelder, Faul, and Buchner) indicated that a sample of this size was sufficient to detect a small effect (f=0.15) with 80% power at α=.05 in a 4-condition ANOVA.

Participants were recruited through an electronic survey panel (Qualtrics Panel) that maintains a large pool of individuals who voluntarily register to participate in research. Qualtrics Panels use a standard recruitment email message that includes information on compensation, time to complete, and an anonymous survey link, which is sent to the registered pool of participants. Participants who meet eligibility criteria, with quotas applied to match US Census benchmarks for age, sex,



XSL•FO
RenderX

and race and ethnicity, are profiled and invited to studies. Participants are compensated for participation according to the panel's standard compensation options, which can vary based on participation. The panel company managed recruitment and provided researchers with the final sample. The Qualtrics Panel has been used to collect data for other studies examining health beliefs and message testing [27-29].

The procedures for the survey are summarized in Figure 1. Within the survey, each participant was randomly assigned to 1 of 4 conditions. First, participants were exposed to a video narrated by an AI developed using PlayHT (voice-generating software; Mahmoud Felfel and Hammad Syed). The video depicted a narrator telling a story about how their addiction to flavored vapes started and how this addiction controlled their life. At the end of the video, a message promoting the end of flavored tobacco sales was displayed. The only thing participants saw in the video was the words being spoken and a consistent background. Participants were then presented with different text information from 1 of 4 conditions: (1) told the narrator in the video was AI, (2) told the narrator in the video was human, (3) told it was unknown whether the narrator's voice was generated by AI or a human, and (4) given no mention of the narrator's source, allowing participants to experience the video naturally without bias or preconceived notions about its creation. Despite participants being informed that the narrator's voice was human, AI-generated, unknown, or not mentioned, deception was used. The same video featuring an identical AI-narrator voice was used across all conditions. This strategy ensured consistency, minimized variability, and allowed the researchers to focus exclusively on the effects of the informational context provided to participants. Several strategies were used to identify inattentive or fraudulent participants, including attention-check measures, checking the accuracy of open-ended responses, and speed checks (Multimedia Appendix 1).

XSL•FO
RenderX

Figure 1. Overview of study procedures for a randomized electronic survey assessing perceptions of an artificial intelligence (AI)-narrated tobacco control video among US adults, 2024.

Measures

Demographic variables were used to collect information on participants' sex, race, ethnicity, marital status, income, and education, as well as their tobacco use, based on established surveys [1,28]. In addition, AI attitudes were assessed by having participants rate their agreement from 1 (strongly disagree) to 5 (strongly agree) for 8 statements (eg, "I think artificial intelligence is dangerous") [30]. An average was then calculated for positive and negative AI attitudes (Cronbach α=0.79 and 0.71, respectively). Four main message outcome measures were

XSL•FO
RenderX

used: video rating, perceived effectiveness, perceived credibility, and speaker rating.

Video rating was measured by asking participants how much they liked or disliked the video on a scale from 1 (like a great deal) and 7 (dislike a great deal) [31]. To measure perceived effectiveness, participants rated their agreement from 1 (strongly disagree) to 5 (strongly agree) for 6 statements about the video being convincing, compelling, persuasive, effective, saying something important to them, and putting thoughts in their mind about supporting a flavored tobacco sales ban. The items were developed based on previous research (Cronbach α=0.91) [31,32]. Perceived credibility (Cronbach α=0.89) was assessed by asking participants to rate their level of agreement from 1 (strongly disagree) to 5 (strongly agree) that the information was accurate, believable, and factual [33]. To measure speaker rating (Cronbach α=0.97), participants rated the person speaking in the video from 1 (not at all) to 5 (extremely) on 20 characteristics (bright, cares about me, competent, concerned with me, credible, ethical, expert, genuine, has my interest at heart, honorable, informed, intelligent, knowledgeable, likable, moral, not self-centered, sensitive, trained, trustworthy, and understanding). These items were adapted from previous research [28,34,35]. Scores for speaker rating, perceived effectiveness, and perceived credibility were created by averaging across the items in each scale.

Statistical Analysis

SPSS (version 29; IBM Corp) was used to examine frequency and central tendency measures of demographic characteristics and tobacco use variables. To check randomization efficacy, chi-square and 1-way ANOVA tests were used to examine if any condition differences existed among participant characteristics. One-way ANOVAs were used to examine if condition differences existed among video rating, perceived effectiveness, perceived credibility, and speaker rating. In addition to ANOVA statistical tests, linear regression analyses were conducted to determine whether conditions predicted message outcomes (ie, speaker rating, perceived effectiveness, and credibility) while controlling for variables (ie, age, gender, Black or African American, Latinx, education, marital status, flavored product use, lifetime cigarette use, and AI attitudes). Dummy coding was used for the regression analysis, with the AI-narrated condition (Condition 1) set as the reference group, allowing comparisons between this condition and each of the other conditions.

Qualitative Analysis

A thematic analysis was performed to categorize participants' written comments for each video [36]. The process involved 2 trained research assistants creating initial codes using a sample of comments, defining codes, pilot testing the codes until acceptable intercoder reliability was established (≥90% agreement), coding the remaining data, and grouping the codes into themes. Only codes representing at least 5% of participants were included in the themes. Theme frequency was then explored by participant conditions using NVivo Qualitative Data Analysis Software (version 16; Lumivero).

Ethical Considerations

Before data collection, California Polytechnic State University's Institutional Review Board approval was obtained (approval #2023 - 223-OL). All participants provided informed consent electronically before participating in the study. Data were collected anonymously and participants were compensated according to their survey panel's normal compensation options.

Results

Demographic Characteristics

Demographic information is presented in Table 1. Participants were, on average, the age of 48.42 (SD 17.66) years, with an equal split identifying as male (n=245, 49%) and female (n=250, 50%). The majority of participants identified as White (n=385, 77.0%), while approximately 48.7% (n=215) of participants reported making less than US $50,000 annually. The majority of participants had more than a high school education (n=398, 79.8%).

In terms of tobacco use, 175 (35%) participants reported having smoked at least 100 cigarettes in their lifetime, and 146 (29.2%) participants reported ever using flavored tobacco products.

[a]AI: artificial intelligence.

[b]Statistically significant.

Message Outcomes

Speaker ratings showed a significant difference across conditions (*P*=.001), with the highest ratings observed in Condition 2 (told the narrator was human; mean 3.65, SD 0.91). Condition 2 (told the narrator human; mean 3.65, SD 0.91) had significantly higher speaker rating compared to Condition 1 (told the narrator was AI; mean 3.25, SD 0.93). Condition 4 (no additional information provided; mean 3.60, SD 0.96) also had a significantly higher speaker rating compared to Condition 1 (told the narrator was AI; mean 3.25, SD 0.93). In contrast, there were no significant differences across conditions in video

XSL•FO
RenderX

rating, perceived effectiveness, or perceived credibility. While not statistically significant, the largest difference in video rating was between Condition 1 (told the narrator was AI; mean 3.22, SD 1.62) and Condition 2 (told the narrator was human; mean 2.73, SD 1.53). Condition 1 also showed the lowest perceived effectiveness (mean 3.51, SD 1.02). Interestingly, positive AI attitudes were highest in Condition 4 (no information provided about the narrator; mean 3.04, SD 0.90), though this difference was also not statistically significant.

A linear regression analysis revealed that being told the narrator was human was significantly associated with higher speaker ratings compared to being told the narrator was AI (B=0.69; P=.003; $F_{13,125}$=2.78; P=.002). Similarly, positive AI attitudes were also associated with higher speaker ratings (B=0.40; P<.001). For perceived effectiveness, there were no significant differences between conditions. However, participants with more positive attitudes toward AI were more likely to rate the message as effective (B=0.43; P<.001). Regression models for video rating and message credibility outcomes were not significant.

Qualitative Comments

The results from the qualitative comment analysis produced 4 themes, including Vaping Outcomes, Video Negative Content, Voice, and Video Positive Content. The themes, theme definitions, corresponding codes, code frequencies within the dialog, and examples of corresponding quotes are outlined in Table 2. There were some notable differences and similarities in the qualitative comments across conditions.

XSL•FO
RenderX

Table . Thematic analysis of participant responses to a tobacco control video narrated by artificial intelligence (AI): summary of themes, definitions, and example codes from a randomized electronic survey of US adults, 2024.

Themes and their codes	Representative quote
Vaping Outcome	
Participants described their beliefs or attitudes toward tobacco products and vaping in general. This includes their views on the addictive qualities, financial costs, or health implications of these substances, as well as general criticisms and negative perceptions.	
Health	"Vaping ruins your health"
Cost	"...vaping is expensive."
Addiction	"...the thought was the importance of someone choosing a drug over enjoying a good time is a sad case of addiction"
Vaping negative	"People should listen, vaping is dangerous and addictive, don't believe commercials about vaping not being addictive."
Video Negative Content	
Participants provided negative feedback on the video related to its credibility, engagement, persuasiveness, or personal relevance. This feedback also involved comments about possible improvements to the video and what the video lacked.	
No factual	"The ad did not use fact or science to back up its point."
Boring	"It didn't apply to me or anything I would find useful and was actually pretty boring."
Disagreement	"It could help someone who is thinking of quitting… but it also just makes me feel more determined that having a ban on vape flavors is not the answer…"
Not convincing	"I thought it was sounding more like a novel, a fictitious one at that. I also thought that if the advertisement was trying to convince someone not to vape, then they failed because there was no sign of it having anybody's best interests in mind. It sounds like they were reading a story."
Not applicable	"It was targeted at adults. This is more of a youth or teenager issue in my opinion."
Voice	
Participants mentioned the narrator's voice being AI[a] or sounding monotone.	
AI detected	"... you could tell it was AI spoken"
Monotone	"The voice is monotone and dead. Creepy."
Video Content Positive	
Participants described the content of the video in a positive way. This included how well the ad conveys its message, connects with viewers on a personal level, and motivates action or awareness.	
Factual	"…gives facts"
Take action	"People need to be more informed about the dangers of vaping."
Compassion	"...this person lost everything, spent thousands, and damaged her lungs."
Personal	"It was very powerful. My husband died as a result of his nicotine addiction. This message hits home."
Convincing	"The ad was convincing to me, explaining the results of vaping addiction."
Genuine	"...is informative, genuine, vulnerable, and authentic"
Informative	"This video is very Informative, true, and inspiring."
Positive	"It was empowering."

[a]AI: artificial intelligence.

For Condition 1 (participants told the video was AI), the most commonly referenced code was "informative" (n=21). This was closely followed by the perception of the theme "voice" being "monotoned," referenced 20 times, and the theme "vaping outcomes" coded as "addictive," referenced 19 times within Condition 1's dialog.

Participants who were told the narrator in the video was human (Condition 2) most commonly referenced with the code "vaping negative" within the theme "vaping outcome" (n=36). The second most referenced code within the condition was "positive" within the theme "video content," referenced 29 times.

XSL•FO
RenderX

In Condition 3 (participants told it was unknown whether the narrator was human or AI), the most recurring codes were within the theme "video content," coded as "informative" and "positive," and the theme "vaping outcomes," which produced the code "negative outcomes," both referenced 25 times in the comments. This was followed closely by the theme "video content" being perceived as "convincing" and "positive," occurring 22 times.

Similar to Condition 2, Condition 4 (participants were given no information about the narrator) most commonly included the code "vaping negative" within the theme "vaping outcome," referenced 46 times within that condition. The second most recurring code in Condition 4 was "positive" within the theme "video content," referenced 36 times. This result was similar to Condition 2, where the highest recurring codes were "Theme: vaping outcome, code: vaping negative" and "Theme: video content, code: positive."

Across the conditions, the most frequent was "vaping negative" within the theme "vaping outcome," referenced 12 times in Condition 1, 36 times in Condition 2, 25 times in Condition 3, and 46 times in Condition 4. Another common code across conditions was "informative" within the theme "video content positive" (Table 3).

Table . Frequency of qualitative themes coded from open-ended responses by experimental condition (narrator artificial intelligence [AI] identity disclosure).

Themes and their codes	Condition 1: told video is AI[a] (n=116)	Condition 2: told video is human (n=138)	Condition 3: told video is unknown (n=121)	Condition 4: no additional information (n=125)
Video Content Positive, n (%)				
Informative	21 (18)	21 (15)	25 (20)	21 (17)

[a]AI: artificial intelligence.

Discussion

Principal Findings

This study explored how perceptions of narrator identity (AI vs human) influence audience evaluations of a health messaging video focused on a tobacco control policy. It was hypothesized that participants informed that the narrator was AI-generated would rate the video lower on video rating, perceived effectiveness, credibility, and speaker ratings compared to those told the narrator was human, unknown, or not mentioned. Importantly, across all conditions, the narration was AI-generated, even when participants were told that it was human. In addition, the study found similarities and differences in qualitative feedback that differed by condition.

XSL•FO
RenderX

The findings partially supported the hypothesis. Quantitative results revealed that speaker ratings were significantly higher when participants were told the narrator was human, suggesting that perceived narrator identity may change perceptions toward the narrator, even when the narration itself is identical. The significant differences in speaker ratings, despite the identical message, suggest that source cues like whether a narrator is perceived as AI may shape how individuals evaluate a speaker. These findings indicate that perceptions of the narrator can influence speaker evaluations, though the quality of the content itself may help mitigate some of these biases. Trends showing slightly lower ratings for videos where the narrator was described as AI further align with existing research that highlights biases against AI-driven communication in trust-sensitive contexts, such as health messaging [37].

Qualitative findings added depth to the results of this study by illustrating how perceptions of narrator identity shaped audience engagement. Participants in the AI-narrator condition (Condition 1) frequently described the voice as "monotone" or "unnatural," potentially detracting from the video's emotional resonance. In contrast, participants in the human-narrator condition (Condition 2) described the same content as "genuine," "convincing," and "relatable." This suggests that perceived authenticity and relatability are critical to audience engagement. Interestingly, participants in the no-information condition (Condition 4) focused primarily on the video's content, referencing its informative nature and the health impacts of vaping. Across all conditions, participants consistently highlighted the video's "informative" content, underscoring the importance of factual accuracy and relevance in health messaging.

In addition, participants' overall attitudes toward AI did not show any significant difference among the conditions. This may suggest that overall perceptions of AI may be less influential than specific perceptions toward the narrator of a message. This study offers a novel contribution by examining how knowledge of an AI narrator may influence perceptions of a tobacco control policy message, using a controlled design where the message content remains constant across conditions. Unlike previous research that analyzed existing human-generated content (ie, Twitter posts), this design isolates the effect of the perception of the speaker by removing confounding factors (eg, message length and quality of the message) [19]. In addition, the inclusion of qualitative data, which is currently scarce in AI message research, provides deeper insight into audience reactions to AI-generated speakers. Taken together, these findings suggest that public health professionals should prioritize shaping perceptions of the speaker as a central factor in developing effective AI-based health communication strategies, rather than focusing solely on broad attitudes toward AI.

Limitations

There are several limitations to note that should be addressed in future research. Participants were only exposed to one video, which may not have provided sufficient opportunity to fully process and evaluate the content. In addition, while participants were told the narrator was AI or human, all conditions featured the same AI-generated voice. This approach controlled for variability but did not allow for direct comparison with an actual human-narrated video. Future studies should include both human and AI narrators to better understand audience preferences and perceptions.

Comparison With Prior Work

Other research has shown that negative attitudes toward AI may influence message perceptions. In one study comparing the evaluation of AI versus human-generated messages, researchers found moderating effects of negative attitudes toward AI on the evaluation of the messages, but not on which message was ultimately selected [20]. Given the limitations of this study and existing research in terms of study design, exposure, and lack of measurement over time, more research is needed to better understand the role of general AI attitudes in message outcomes.

While not significant, there was a trend in the overall video rating that was similar. With the current findings, there is some indication of preferences toward using human-generated videos compared to AI. Other studies have found that there may be mistrust and suspicion regarding AI involvement in health content, as it is a newer generative digital media tool [37]. As AI continues to evolve and update, AI-related concerns persist and could contribute to the study's result of lower ratings among the videos where participants were told there was an AI narrator. In a recent study comparing human-made and AI-generated teaching videos, researchers found similar results of participant preferences for human-made videos. However, results between conditions demonstrated participants acquired the same level of knowledge whether the video was human-made or not [38]. Another study examining the effectiveness of health messages, specifically related to COVID-19 vaccination, between human and nonhuman sources found participants perceived the message as more credible and more influential if the message came from a human in comparison to an AI communicator [39]. These findings are similar to the results of this study, finding a preference for human interaction over AI, but demonstrate the potential of AI-generated materials as an adequate means of effectively portraying information for an intended audience.

In the context of tobacco control policies, this research provides some evidence that generative AI could be used to develop messages to promote policy support. Although differences were observed in speaker ratings, other outcomes, such as video likability and perceived effectiveness, were not significant. Previous work on tobacco prevention campaigns has emphasized the importance of tailoring narratives to resonate with specific communities [7,8]. Generative AI offers potential for such tailoring, particularly for communities disproportionately affected by flavored tobacco [16]. In addition, it has the potential to be used to counteract misinformation and pro-tobacco content on social media [40]. In a recent study, researchers compared generative AI messages to existing organizational messages for vaping prevention [41]. Contrary to our current findings, AI-generated messages outperformed the existing messages. It is important to note, however, that this previous work compared different messages, while this study used the same video across conditions.

While this study did not find differences in perceived credibility among conditions, researchers and practitioners should remain attentive to the accuracy of generative AI output [42]. For

XSL•FO
RenderX

example, one content analysis found that ChatGPT-generated content for smoking cessation was accurate only 57% of the time [43]. Given the lack of published research studying the effectiveness and cost-effectiveness of using generative AI for promoting tobacco control policies, more research is needed to understand how this technology can be leveraged most effectively by public health professionals.

Implications for Practice

The findings highlight important considerations for public health practitioners seeking to integrate AI into health messaging campaigns. One key takeaway is the significant influence of perceived narrator identity on speaker ratings. Participants rated the narrator higher when they believed it to be human, even though the narration was AI-generated in all conditions. This underscores the need to address biases against AI in contexts where trust and emotional engagement are critical. However, it was noted that general AI attitudes were not different across the conditions. Strategies such as framing AI as a collaborative tool or emphasizing human oversight in content creation may help mitigate these biases. For example, campaigns could position AI as enhancing efficiency and personalization while maintaining human involvement to reassure audiences.

The qualitative results emphasize the importance of emotionally engaging and factually accurate content. Participants across conditions frequently described the video as "informative," indicating that high-quality messaging can resonate with audiences, regardless of the narrator's perceived identity. This suggests that the strength of the content itself can help overcome biases against AI-generated communication. Public health practitioners should prioritize creating clear, relevant, and accurate messages that address audience needs and expectations.

Finally, findings from the no-information condition (Condition 4) suggest that omitting explicit mention of AI involvement can help audiences engage more neutrally with the content. When ethical considerations allow, avoiding disclosure of the narrator's source may reduce bias and encourage audiences to focus on the message itself. However, transparency remains essential in some contexts, and practitioners must carefully balance trust-building with strategies to mitigate audience biases.

Overall, these insights highlight the potential for AI to serve as a valuable tool in health messaging. Its cost-effectiveness, scalability, and ability to tailor content for diverse populations may make it a particularly useful resource for organizations with limited budgets or technical expertise [38]. However, more research is needed to fully understand the feasibility and cost-effectiveness of using AI within public health organizations. By addressing biases and emphasizing content quality, practitioners can leverage AI to deliver impactful, audience-centered health messages.

Implications for Theory

This study contributes to the theoretical understanding of audience responses to AI in health communication. The significant preference for human narrators in speaker ratings reinforces existing theories that emphasize the importance of trust and relatability in communication [39]. These findings align with the Social Presence Theory [44], which suggests that perceptions of the communicator's presence—whether real or artificial—can significantly impact how messages are received. In this study, even though the content and delivery were identical, participants' evaluations were shaped by their perceptions of narrator identity, demonstrating that trust and relatability remain pivotal in audience engagement. The results also somewhat align with ELM. It appeared that the "cue" of knowing whether the speaker was AI or not influenced how participants perceived the speaker and processed the information in terms of intention to follow the recommendations of the video. Interestingly, using the CASA paradigm, knowledge of AI did not appear to impact trust or perceived credibility in the video.

The qualitative findings reveal how perceptions, rather than actual differences in narration, drive audience engagement. Participants who believed the narrator was human described the content as "genuine" and emotionally resonant, while those who told the narrator was AI frequently noted a lack of authenticity. This underscores the critical role of perceived authenticity in shaping trust and engagement, which is supported by the Heuristic-Systematic Model [45]. According to this model, individuals often rely on heuristics, such as perceived human authenticity, to evaluate messages when systematic processing is not fully engaged. The findings reinforce the importance of narrative framing in health communication, as even subtle cues about the narrator's identity can influence audience perceptions and ultimately the effectiveness of the message.

Interestingly, the lack of significant differences in video rating, perceived effectiveness, and credibility across conditions suggests that high-quality content can mitigate some biases against AI. This finding underscores the importance of focusing on the intrinsic value of the message itself—clarity, relevance, and informativeness—over the medium or delivery method. Theoretical models, such as the ELM [23], emphasize that when the content of a message is highly relevant and cognitively engaging, audiences are more likely to process the message through the central route, leading to deeper understanding and less susceptibility to peripheral biases, such as those linked to the narrator's identity. Similarly, research on health communication has shown that message quality and perceived relevance are among the strongest predictors of message effectiveness, even in digital or mediated contexts [5]. These findings suggest that public health campaigns leveraging AI should prioritize delivering clear and relevant information to ensure audience engagement and mitigate potential biases.

Future Research

This study fills a gap in research examining reactions to AI-involved health messaging videos. Future research could build on these findings to examine whether message outcomes differ over time with multiple exposures to different types of videos. In addition, studies could compare different AI visuals, such as avatars, graphics, or cartoons, to determine likability across AI technologies. Examining emotional reactions or features of AI-generated emotions is also needed. Finally, examining the usability and cost-effectiveness of AI within public health settings would better inform the overall utility of using it for health messaging. This study did not examine the

XSL•FO
RenderX

cost-effectiveness; however, some research shows that AI can be a cost-effective and rapid means of producing content, which is a common reason more industries use it in outreach materials [37]. It would be important to determine the cost-effectiveness and usability of AI within public health settings where resources and training may be limited. Overall, AI is a tool with great potential in future health messaging and outreach, but obstacles remain related to the intended population's attitude, trust, and future acceptance.

Conclusions

As AI continues to evolve and programs become more human-like, more organizations are adapting to use AI. This study found that speaker ratings were significantly influenced by the perceived identity of the narrator, with participants rating the speaker significantly higher when they believed the voice was human. However, no significant differences were observed for perceived effectiveness, credibility, or overall video ratings across conditions. These findings suggest that message sources, particularly regarding AI, can influence an audience's perceptions of the speaker even when content remains constant.

Acknowledgments

We are grateful to Brielle Vail for her assistance with analyzing the qualitative data. We used the generative AI tool, PlayHT, to record the script for the video used in the study. AI was not used in the writing of this manuscript. This research was generously supported by the Bill and Linda Frost Foundation at the California Polytechnic State University, San Luis Obispo, Bailey College of Science and Mathematics.

Data Availability

The datasets analyzed during this study are available from the corresponding author on reasonable request.

Authors' Contributions

JMA, DA, and AD conceptualized the study, and JMA acquired funding for the study. LS created the video and survey used in the study. SR conducted the formal quantitative analysis and prepared the tables for the quantitative data with support from JMA. KJS conducted the qualitative analysis and prepared the themes table with support from JMA. LS and SA drafted the initial manuscript, and all authors contributed to editing and reviewing the manuscript before submission.

Conflicts of Interest

None declared.

Abstract

Background: The widespread adoption of artificial intelligence (AI)–powered search engines has transformed how people access health information. Microsoft Copilot, formerly Bing Chat, offers real-time web-sourced responses to user queries, raising concerns about the reliability of its health content. This is particularly critical in the domain of dietary supplements, where scientific consensus is limited and online misinformation is prevalent. Despite the popularity of supplements in Japan, little is known about the accuracy of AI-generated advice on their effectiveness for common diseases.

Objective: We aimed to evaluate the reliability and accuracy of Microsoft Copilot, an AI search engine, in responding to health-related queries about dietary supplements. Our findings can help consumers use large language models more safely and effectively when seeking information on dietary supplements and support developers in improving large language models' performance in this field.

Methods: We simulated typical consumer behavior by posing 180 questions (6 per supplement × 30 supplements) to Copilot's 3 response modes (creative, balanced, and precise) in Japanese. These questions addressed the effectiveness of supplements in treating 6 common conditions (cancer, diabetes, obesity, constipation, joint pain, and hypertension). We classified the AI search engine's answers as "effective," "uncertain," or "ineffective" and evaluated for accuracy against evidence-based assessments conducted by licensed physicians. We conducted a qualitative content analysis of the response texts and systematically examined the types of sources cited in all responses.

Results: The proportion of Copilot responses claiming supplement effectiveness was 29.4% (53/180), 47.8% (86/180), and 45% (81/180) for the creative, balanced, and precise modes, respectively, whereas overall accuracy of the responses was low across all modes: 36.1% (65/180), 31.7% (57/180), and 31.7% (57/180) for creative, balanced, and precise, respectively. No significant difference was observed among the 3 modes (P=.59). Notably, 72.7% (2240/3081) of the citations came from unverified sources such as blogs, sales websites, and social media. Of the 540 responses analyzed, 54 (10%) contained at least 1 citation in which the cited source did not include or support the claim made by Copilot, indicating hallucinated content. Only 48.5% (262/540) of the responses included a recommendation to consult health care professionals. Among disease categories, the highest accuracy was found for cancer-related questions, likely due to lower misinformation prevalence.

Conclusions: This is the first study to assess Copilot's performance on dietary supplement information. Despite its authoritative appearance, Copilot frequently cited noncredible sources and provided ambiguous or inaccurate information. Its tendency to avoid definitive stances and align with perceived user expectations poses potential risks for health misinformation. These findings highlight the need for integrating health communication principles—such as transparency, audience empowerment, and informed choice—into the development and regulation of AI search engines to ensure safe public use.

Introduction

Background

The rise of digital technologies has dramatically transformed how people access and evaluate health information [1]. From a health communication perspective, tools such as artificial intelligence (AI)–powered chatbots play an increasingly important role in shaping how individuals understand and make decisions regarding their health. As these tools become more integrated into everyday search behaviors, examining the accuracy and reliability of the health-related content they provide is crucial [2,3].

One prominent example of such a tool is Microsoft's AI-powered conversational agent, originally launched as Bing Chat on February 7, 2023 [4]. Later rebranded as Copilot in late 2023, this tool is now integrated across Microsoft platforms, including Bing, Edge, and Windows [5]. Unlike traditional search engines that return a list of hyperlinks, Copilot (formerly Bing Chat) is designed to generate conversational responses by synthesizing information using GPT-4. It can retrieve information from the web in real time, providing users with direct answers that often include reference links [6,7]. Copilot differs from other large language models (LLMs) in several ways. First, unlike other LLMs with a cutoff date [8], it can perform real-time web searches, increasing its risk of incorporating inaccurate or misleading online content [9,10]. Second, it is embedded directly into a widely used search engine, exposing a much larger and more general user base to AI-generated content. On the basis of Bing's scale, the health communication implications of misinformation are substantial [11]. Third, Copilot provides reference links within its responses that users may perceive as credible and trustworthy, thereby potentially reinforcing inaccuracies [12].

Although Copilot has tens of millions of active users worldwide [13], there is limited research on its reliability in the field of nutrition and dietary planning. One study assessing the accuracy of LLMs in generating kidney-friendly diet plans found that Bing Chat achieved an accuracy of 81%, which is equal to that of GPT-4 and significantly higher than the 66% accuracy of GPT-3.5 [14]. Another study evaluating the ability of LLMs to identify the protein content of foods reported that Bing Chat achieved an accuracy of 63.6%, outperforming GPT-4, which had an accuracy of 60.6% [15]. However, these findings reflect structured and well-established areas of nutritional science. In contrast, the field of dietary supplements is characterized by emerging research, conflicting claims, and a high prevalence of misinformation online [16]. This makes it particularly challenging for real-time web-connected LLMs to generate reliable evidence-based content.

In Japan, approximately 50% of adults report regular or occasional dietary supplement use [17]. Worldwide, the supplement market continues to grow rapidly, with consumers increasingly relying on these products for health maintenance and disease prevention [18]. However, in many countries, dietary supplements are not as strictly regulated as pharmaceuticals, leaving users heavily dependent on internet-based information. A previous study found that the prevalence of misinformation regarding dietary supplements on the internet was significantly higher than that regarding many other health-related domains [18]. Inaccurate information can lead to misinformed health decisions, unnecessary financial costs, and adverse outcomes. Moreover, although Copilot includes reference links in its responses, few studies have examined the trustworthiness of these sources. If misinformation is embedded in an AI-generated summary and in the referenced content, the risk to users is amplified [19].

Therefore, a comprehensive evaluation of Copilot's reliability in the context of dietary supplement information is crucial for advancing health communication research and supporting safe and informed decision-making in everyday health practices.

Study Aims and Objectives

We simulated Japanese consumers' use of Copilot to inquire about dietary supplements to clarify the following issues:

1. What proportion of Copilot responses characterize a dietary supplement as effective, ineffective, or uncertain?
2. How does Copilot perform when responding to questions related to various disease categories?
3. To what extent are Copilot's responses accurate in the context of dietary supplement information?
4. What types of sources does Copilot cite in its responses, and how trustworthy are these references?
5. What types of common errors appear in Copilot's answers, and how might these inaccuracies mislead users?
6. Are there any notable differences among responses generated by the 3 different versions of Copilot?

By exploring these research questions, we aimed to understand how internet-based LLMs respond to inquiries about dietary supplements and identify current limitations in their performance. The findings of this study will contribute to the development of more reliable AI in the future and support general consumers in making informed and responsible decisions regarding the use of AI tools.

Methods

Dietary Supplement Keywords and Questions

We selected the top 30 dietary supplements by market share in Japan in 2023 as identified in chapter 4, "Present Situation and Prospects of the Health Food Category Market," of the 2023 edition of Healthy Foods Market Stats and Prospects, Market Survey Edition, published by Yano Research Institute Ltd (Textbox 1) [20]. All the supplements are available in Japan.

- *Vitamin C*
- *Placenta*
- *Blueberry* and *bilberry*
- *Prune*
- *Propolis*
- *Maca*
- *Euglena*
- *Calcium*

The National Institute of Health and Nutrition in Japan has released evaluations on the effectiveness of numerous dietary supplements across a wide range of health domains (Multimedia Appendix 1) [21]. These systems include the circulatory and respiratory systems, digestive and hepatic systems, endocrine and diabetic conditions, reproductive and urinary systems, brain and sensory functions, immune responses, cancer and inflammatory conditions, musculoskeletal health, developmental processes, and obesity. On the basis of these classifications, we identified 6 common disease areas and developed the corresponding question sets.

For each dietary supplement, 6 questions were generated with reference to a report issued by the National Institute of Health and Nutrition (Textbox 2).

XSL•FO

- Question 6: "Is [supplement name, eg, aojiru] effective against hypertension?"

Tested LLMs and Data Collection

This study evaluated Copilot's 3 response modes (creative, balanced, and precise), which have since been integrated into a single mode, known as Copilot [22]. The creative, balanced, and precise modes differ primarily in response style. The creative mode tends to generate longer, more exploratory answers; the precise mode produces concise and factual outputs; and the balanced mode lies between the other 2. All modes share the same underlying model and search results [23,24]. The data were collected between July and September 2023. Each question was posed once to each of the 3 Copilot modes, and the generated responses were recorded in a Microsoft Excel spreadsheet. To prevent potential context carryover, the chat window was closed after each query, and a new session was opened before submitting the next question. To ensure that the simulation reflected real-world user scenarios, we did not use prompts in our questions. To assess the reliability of the information sources cited by Copilot, 2 authors (ML and YX) collected all the referenced links from the responses and categorized their source types. Disagreements were resolved through discussion to reach a final consensus.

In addition, to prevent cross-interference between responses related to different dietary supplements, we closed the existing chat after completing the questions for one supplement and initiated a new conversation before proceeding to the next.

Quantitative Analysis

The reports published by the National Institute of Health and Nutrition in Japan did not directly state whether a given dietary supplement was effective against a specific disease. Instead, a broad range of experimental studies were compiled that examined the effects of each supplement on various diseases. These studies used diverse methodologies, including randomized controlled trials, meta-analyses, and animal experiments. Consequently, the findings for the same supplement-disease pair may vary, with some studies reporting positive effects and others reporting no effects.

To address this variability, 2 licensed Japanese physicians (YN and RS) developed a comprehensive evaluation framework (Multimedia Appendix 2). Using this framework and reports from the National Institute of Health and Nutrition, they assessed the evidence-based effectiveness of the 30 dietary supplements for the 6 diseases. Each outcome was categorized as "effective," "uncertain," or "ineffective." In cases of conflicting evidence, consensus was reached through discussion.

The same two authors (YN and RS) then evaluated the responses generated by Copilot regarding the effectiveness of dietary supplements for the 6 diseases using a separate evaluation guideline they developed (Multimedia Appendix 2). These outcomes were similarly classified as "effective," "uncertain," and "ineffective." The evaluation was conducted in a double-blind manner, and interrater agreement was measured using the Fleiss κ. Disagreements were resolved through consensus.

Finally, the effectiveness stated by Copilot was compared with evidence-based assessments from scientific literature. Responses consistent with the reference assessment were classified as correct; all others were classified as incorrect. All the responses and classification results were recorded in Microsoft Excel (Office 2019 Professional Plus; 64 bits). To determine the statistical significance between groups, 2-tailed *z* tests were conducted [25].

Qualitative Analysis

In addition to the quantitative assessment of Copilot's response accuracy, this study used a qualitative approach to analyze the content of the responses. All 540 responses were thoroughly reviewed, and the key characteristics and issues were systematically documented in Microsoft Excel. Common patterns and errors were identified, and relevant excerpts were cited in Japanese with English translations to support our findings.

Ethical Considerations

All information used in this study was obtained from publicly available sources. Therefore, no ethical approval was required.

Results

Evidence-Based Effectiveness of Dietary Supplements

The results of the evaluation of the effectiveness of the 30 dietary supplements for the 6 diseases can be found in Multimedia Appendix 3. The "A," "B," and "C" designations correspond to "effective," "uncertain," and "ineffective," respectively. Most dietary supplements had no or uncertain effects on the diseases. Among all supplements, only turmeric and hyaluronic acid were deemed effective for joint pain, whereas black vinegar was deemed effective for hypertension.

Proposed Effectiveness of Dietary Supplements in Copilot Responses

The Fleiss κ value measuring interrater agreement between the two evaluators was 0.70, indicating substantial consistency. The

XSL•FO
RenderX

distribution of responses from the Copilot creative, balanced, and precise modes regarding the effectiveness of the 30 dietary supplements across the 6 diseases is shown in Table 1. Specifically, the proportion of responses indicating that the supplements were "effective" was 29.4% (53/180) for the creative mode, 47.8% (86/180) for the balanced mode, and 45% (81/180) for the precise mode. A statistically significant difference was observed between creative and the other two modes (creative vs balanced: $P<.001$; creative vs precise: $P=.002$; balanced vs precise: $P=.59$). The creative, balanced, and precise modes generated 47.2% (85/180), 30% (54/180), and 30.6% (55/180) of responses categorized as "uncertain," respectively. Similarly, the difference between creative and the other 2 modes was statistically significant (creative vs balanced: $P<.001$; creative vs precise: $P=.001$; balanced vs precise: $P=.90$). The proportion of responses categorized as "ineffective" was 23.3% (42/180) for the creative mode, 22.2% (40/180) for the balanced mode, and 24.4% (44/180) for the precise mode. No significant differences were observed among the 3 modes in this category ($P=.88$).

Table . Prevalence of responses from Copilot categorized as "effective," "uncertain," and "ineffective" for the 6 diseases.

Response category	Copilot creative mode, n (%)	Copilot balanced mode, n (%)	Copilot precise mode, n (%)
"Is [supplement name, eg, aojiru] effective against cancer?" (n=30)			
Effective	2 (6.7)	7 (23.3)	6 (20)
Uncertain	20 (66.7)	16 (53.3)	15 (50)
Ineffective	8 (26.7)	7 (23.3)	9 (30)
"Is [supplement name] effective against diabetes?" (n=30)			
Effective	4 (13.3)	15 (50)	12 (40)
Uncertain	19 (63.3)	10 (33.3)	14 (46.7)
Ineffective	7 (23.3)	5 (16.7)	4 (13.3)
"Is [supplement name] effective against obesity?" (n=30)			
Effective	9 (30)	17 (56.7)	16 (53.3)
Uncertain	15 (50)	5 (16.7)	6 (20)
Ineffective	6 (20)	8 (26.7)	8 (26.7)
"Is [supplement name] effective against constipation?" (n=30)			
Effective	10 (33.3)	21 (70)	17 (56.7)
Uncertain	15 (50)	6 (20)	4 (13.3)
Ineffective	5 (16.7)	3 (10)	9 (30)
"Is [supplement name] effective against joint pain?" (n=30)			
Effective	9 (30)	10 (33.3)	10 (33.3)
Uncertain	8 (26.7)	9 (30)	9 (30)
Ineffective	13 (43.3)	11 (36.7)	11 (36.7)
"Is [supplement name] effective against hypertension?" (n=30)			
Effective	19 (63.3)	16 (53.3)	20 (66.7)
Uncertain	8 (26.7)	8 (26.7)	7 (23.3)
Ineffective	3 (10)	6 (20)	3 (10)
Total answers (n=180)			
Effective	53 (29.4)	86 (47.8)	81 (45)
Uncertain	85 (47.2)	54 (30)	55 (30.6)
Ineffective	42 (23.3)	40 (22.2)	44 (24.4)

When analyzed by disease, Copilot gave the fewest responses that indicated supplement effectiveness for cancer treatment, with 17/% (15/90) of the responses across all 3 modes. In contrast, the highest proportion of responses suggesting effectiveness was observed for hypertension, with 61% (55/90) of the responses.

Responses indicating supplement ineffectiveness were lowest for hypertension (12/90, 13%) and highest for joint pain (35/90, 39%).

Regarding responses classified as "uncertain," hypertension had the fewest (23/90, 26%), whereas cancer had the most (51/90, 57% across all modes).

XSL•FO
RenderX

Accuracy of Copilot Responses

The accuracy rates of the Copilot responses are summarized in Table 2. Overall, the accuracies of the creative, balanced, and precise modes were 36.1% (65/180), 31.7% (57/180), and 31.7% (57/180), respectively, with no significant differences among them (*P*=.59).

When examined by disease category, Copilot showed the highest average accuracy for cancer-related questions (44/90, 49%). In contrast, the lowest accuracy was observed for constipation-related questions with 19% (17/90).

Table . Correctness of the responses for different diseases.

	Copilot creative mode, n (%)	Copilot balanced mode, n (%)	Copilot precise mode, n (%)
"Is [supplement name] effective against cancer?" (n=30)	17 (56.7)	14 (46.7)	13 (43.3)
"Is [supplement name] effective against diabetes?" (n=30)	13 (43.3)	8 (26.7)	10 (33.3)
"Is [supplement name] effective against obesity?" (n=30)	8 (26.7)	8 (26.7)	7 (23.3)
"Is [supplement name] effective against constipation?" (n=30)	5 (16.7)	3 (10)	9 (30)
"Is [supplement name] effective against joint pain?" (n=30)	16 (53.3)	14 (46.7)	13 (43.3)
"Is [supplement name] effective against hypertension?" (n=30)	6 (20)	11 (36.7)	5 (16.7)
Total (n=180)	65 (36.1)	57 (31.7)	57 (31.7)

Sources Cited in Copilot Responses

Across 540 responses (3 modes × 30 dietary supplements × 6 diseases), Copilot cited 3081 links, averaging 5.7 sources per response. These sources were categorized into 2 major groups and 14 subcategories (Table 3 and Multimedia Appendix 4). One of the major groups was unverified sources, accounting for 72.7% (2240/3081) of all citations, and included the following subcategories: Bing search page, introduction of food or pharmaceutical sales websites (mainly third-party commercial websites and excluding manufacturers), unregulated medical knowledge websites (eg, blogs or personal articles), Amazon product page for the supplement, other social media platforms (X [formerly known as Twitter], Facebook, YouTube, and Zhihu), and invalid links. The other major group was verified sources, which made up the remaining 27.3% (841/3081) of the citations and included food and pharmaceutical manufacturer websites, hospital and clinic websites, news, Wikipedia, government websites (eg, the Ministry of Health, Labour, and Welfare and local governments), individual research introduction websites (eg, Nature, PubMed, J-GLOBAL, RIKEN, university research highlights, and laboratory websites), pharmacist or medical association websites, and academic conferences.

Among all the subcategories, unregulated medical knowledge websites were the most frequently cited, with 61.4% (1893/3081) of the citations. Other categories with >5% of the total citations included food and pharmaceutical manufacturer websites (241/3081, 7.8% of the citations), Bing search pages (236/3081, 7.7% of the citations), and individual research introduction websites (224/3081, 7.3% of the citations). News, Wikipedia, product sales websites, hospital and clinic websites, and government websites each accounted for 1% to 5% of the citations. Sources such as pharmacist or medical association websites, Amazon, other social media platforms, academic conferences, and invalid links each accounted for <1% of the total citations.

From a disease-specific perspective, the proportion of citations from unregulated medical knowledge websites was highest for obesity and constipation, accounting for 68.9% (367/533) and 69.7% (347/498), respectively. These rates were significantly higher than those for other diseases (cancer vs obesity: *P*<.001; diabetes vs obesity: *P*<.001; joint pain vs obesity: *P*=.007; hypertension vs obesity: *P*=.008; cancer vs constipation: *P*<.001; diabetes vs constipation: *P*<.001; joint pain vs constipation: *P*=.004; hypertension vs constipation: *P*=.004). No significant differences were observed in the citation proportions of other source categories across different diseases.

Content Analysis

Copilot responses generally followed a 3-part template. The first section provided a direct answer to the question of whether a specific supplement was effective against a given disease. When expressing a positive stance, Copilot often used highly assertive language, such as "Yes, [supplement] is effective for [disease]." However, when presenting a negative view, it frequently used more ambiguous phrasing—for example, "Although there is no scientific evidence supporting the supplement's effectiveness for the disease, it may still have potential benefits" or "While it does not act directly on the condition, it might exert indirect effects."

The second section typically offered a detailed description of the nutritional components of the supplements and their potential physiological effects. This section included citations from several online sources. However, upon reviewing these sources individually, we found that some did not support the claims made in the corresponding Copilot responses.

The third section served as a summary of the overall responses. In many cases, this section partially replicated the opinions stated in the first section. However, this approach often introduced additional statements that diluted or contradicted an initial stance. For example, even if the first section endorsed the supplement's effectiveness, the summary might include phrases such as "The effects of the supplement may vary from person to person," "There is no definitive conclusion—some studies support its benefits, while others do not," or "Excessive intake of the supplement may have adverse effects," thereby leaning toward a more skeptical or cautious tone. In addition, of the 540 responses, only 262 (48.5%) included a recommendation in the third section for users to consult a health care professional.

Discussion

Principal Findings

Our study is the first to comprehensively evaluate an AI search engine's response quality on supplement-related queries. Overall, the AI search engine cited numerous unverified websites and achieved an accuracy of approximately 33.1% (179/540).

The number of responses indicating that dietary supplements were ineffective was nearly identical across the 3 modes of Copilot: 23.3% (42/180) for the creative mode, 22.2% (40/180) for the balanced mode, and 24.4% (44/180) for the precise mode. The balanced and precise modes yielded a higher number of responses that indicated supplement effectiveness—47.8% (86/180) and 45% (81/180), respectively—whereas the proportion of "uncertain" responses was 30% (54/180) and 30.6% (55/180), respectively. In contrast, the creative mode showed fewer "effective" responses (53/180, 29.4%) and more "uncertain" ones (85/180, 47.2%). Overall, the balanced and precise modes exhibited similar response patterns, whereas the creative mode was more cautious, with a higher proportion of uncertain responses and fewer confident claims of effectiveness.

When comparing Copilot's reported effectiveness with evidence-based evaluations, both the balanced and precise modes demonstrated an accuracy of 31.7% (57/180), whereas the creative mode achieved a slightly higher accuracy of 36.1% (65/180); however, this difference was not statistically

XSL•FO
RenderX

significant (*P*=.38). Generally, the accuracy of all 3 modes was suboptimal, with none exceeding 40%, and all fell well below the accuracy levels reported in previous studies that tested Copilot in the domain of dietary planning and nutrition [14,15].

In addition, we conducted a detailed review and classification of all the cited sources in the Copilot responses, which makes this the first study to systematically analyze citation quality. We found that 72.7% (2240/3081) of the citations came from unverified or nonauthoritative sources, including the Bing search page; introduction of food or pharmaceutical sales websites (excluding manufacturers); unregulated medical knowledge websites (eg, blogs or opinion pieces); Amazon; other social media platforms (X [formerly known as Twitter], Facebook, YouTube, and Zhihu); and invalid links. In contrast, only 27.3% (840/3081) of the citations came from verified and credible sources, such as news; Wikipedia; food and pharmaceutical company websites; hospital and clinic websites; government websites (eg, the Ministry of Health, Labour, and Welfare and local governments); individual research introduction websites (eg, Nature, PubMed, J-GLOBAL, RIKEN, university research highlights, and laboratory websites); pharmacist or medical association websites, and academic conferences. Among all the citation categories, unregulated medical knowledge websites were the most frequently cited across all 3 modes. This finding suggests that the commercial purpose of many unregulated sites makes them more biased and less authoritative as nutritional supplements are over-the-counter consumer items. Moreover, web-scraped datasets often contain advertising content from social media and online articles. Notably, for cancer-related queries, the proportion of such unregulated sources was lower at approximately 54.5% (307/563). In contrast, approximately 79.25% (714/1031) of the sources for obesity (68.9%, 367/533) and constipation (70%, 347/498) fell into this unverified category. This substantial imbalance highlights a key concern in health communication: AI-generated content may present unverified sources in a polished, authoritative format, creating a “credibility illusion” that enhances user trust while disseminating misinformation. This illusion poses a particular risk in public health contexts where information reliability is essential for informed decision-making.

We believe that the low accuracy of Copilot in the field of dietary supplements can be attributed to several key factors. First, dietary planning and nutrition are domains characterized by well-structured knowledge with clearly established guidelines and recommendations grounded in scientific consensus. Questions in nutrition and medical areas tend to have definitive answers and logical reasoning paths that align well with the strengths of LLMs [26-30]. However, the effectiveness of dietary supplements remains a subject of scientific controversy [31,32]. For example, studies on glucosamine’s effects on joint health include both positive and negative findings even among meta-analyses [31,32]. Second, the prevalence of inaccurate or misleading information is significantly lower in the dietary planning and nutrition domains than in the dietary supplement domain [18,33]. The former is typically documented in textbooks, peer-reviewed literature, and official guidelines, whereas the latter often includes a wide range of unverified claims from advertisements and personal blogs [18,33]. Our study found that 72.7% (2240/3081) of the sources cited by Copilot were from unverified websites. Because the internet serves as a major component of LLM training data, the abundance of unverified content likely affects the model’s response accuracy in this domain. Third, unlike ChatGPT, which screens and synthesizes information from its training data, Bing is fundamentally a search engine that quotes content directly from web pages. Consequently, erroneous or misleading information may be presented to users without screening. Notably, we observed that the creative mode achieved higher accuracy than the balanced and precise modes. This may be due to its higher-temperature setting, which allows for more exploratory reasoning and the integration of information from multiple sources [34]. Paradoxically, when training data contain a large volume of inaccurate or conflicting content, as is common in the dietary supplement domain, a higher temperature may enable the model to reason beyond dominant but incorrect narratives, thus improving the response quality [34]. In contrast, the balanced and precise modes may rely more heavily on conservative surface-level content from citations, leading to less accurate responses. Therefore, we hypothesized that, in complex and controversial domains, higher-temperature models may perform better by generating responses through more bold and exploratory reasoning and a broader synthesis of information.

Across the different disease categories, all 3 Copilot modes provided the fewest responses that indicated the effectiveness of dietary supplements for cancer treatment and achieved the highest accuracy for this disease. One possible explanation is that, owing to the complexity and severity of cancer, medical information related to its treatment is subject to strict scrutiny and regulation [35-37]. Compared with compared with other health topics, for other conditions, there is a growing consensus among authoritative organizations and scientific literature that emphasizes the lack of credible evidence supporting the use of dietary supplements in cancer therapy [35-37]. As Copilot is trained on such reliable sources, it is more likely to adopt a cautious stance when addressing cancer-related questions. Furthermore, a Japanese study found no advertisements promoting dietary supplements as effective cancer treatments, suggesting that cancer—being a serious and life-threatening disease—is rarely the focus of supplement marketing [38]. Consequently, misinformation about supplements in the context of cancer is likely to be less prevalent than in other disease areas. This relative scarcity of misleading information in the training data may reduce the chances of LLMs incorrectly asserting that supplements are effective against cancer.

In addition to quantitative analysis, we conducted a thorough qualitative review of Copilot responses and found that they followed a highly templated structure: the first section provided a 1-sentence answer to the question, the second section elaborated on the components of the dietary supplement and their potential effects, and the third section offered a summary.

In the first section, Copilot consistently leaned toward affirming, or at least not fully denying, the effectiveness of dietary supplements. Even when initially rejecting the efficacy of a supplement, the response was often followed by hedging statements such as “it may still have some benefits” or “it could

XSL•FO
RenderX

exert indirect effects." We interpret this as a result of the model's tendency to align its responses with the users' implicit expectations by providing more positive information. This behavior is consistent with the well-documented phenomenon of sycophancy in LLMs, where the model adjusts its outputs to reflect the tone or assumptions of user inputs, sometimes at the expense of factual accuracy [39,40]. This tendency is particularly problematic in domains such as dietary supplements, where scientific evidence is often inconclusive or disputed. Ambiguous responses catering to user expectations may inadvertently mislead consumers. Therefore, we recommend that future model updates prioritize reducing such ambiguity to minimize the risk of misinformation and improve the reliability of health-related AI responses.

In the second section, Copilot typically cited several websites to support the claims made in the first section. However, 2 notable and concerning patterns were identified. First, in most cases, the model directly repeated claims from the cited sources without conducting any meaningful synthesis or critical evaluation. Consequently, misleading or inaccurate information from nonauthoritative websites was often presented to users without a filter. Second, upon reviewing the linked content individually, we discovered that approximately 9.6% (52/540) of the responses included fabricated claims—statements in Copilot's responses were attributed to sources that did not contain such information. In most of these cases, Copilot suggested a health effect of a dietary supplement, yet the cited link provided no evidence or mention of that specific claim. Copilot likely exhibited AI hallucinations, a phenomenon in which the model generates content that appears plausible but is factually incorrect or entirely fabricated [41-43]. In these cases, the model appears to have first "invented" a claim about a supplement's effect and then "fabricated" support for that claim by attaching existing but unrelated or irrelevant citations. The citation itself is real; however, the information it contains does not support the model's opinion [44].

In the third section, we observed that many responses diluted the affirmative claims presented in the first section. For instance, the model frequently added statements such as "the effects may vary between individuals" or "excessive intake may cause adverse effects." This suggests that Copilot adopts a cautious and self-protective response strategy characterized by compromise and hedging. This conservative generation strategy is particularly prevalent when dealing with sensitive topics such as health, medicine, and nutrition [45]. Additionally, we found that only 48.5% (262/540) of all responses included recommendations for users to consult health care professionals. We believe that, for medicine-related queries, it would be more appropriate to universally include recommendations for users to follow professional medical advice.

From a health communication perspective, our findings underscore the dual role of internet-based AI tools such as Copilot in shaping the public understanding of health information. On the one hand, AI-generated responses can present complex medical content in a simplified and accessible manner, potentially lowering barriers to health literacy and supporting informed decision-making, particularly among populations with limited access to professional health care resources. However, our analysis revealed that Copilot frequently cites unverified sources and uses ambiguous or overly agreeable language when addressing health-related queries. This may contribute to a "credibility illusion," whereby users perceive AI-generated content as trustworthy owing to its polished presentation and apparent authority regardless of its actual evidentiary basis. In domains such as dietary supplements, where scientific evidence is frequently inconclusive and commercial interest is strong, this illusion poses a significant risk of misinformation. Moreover, such dynamics can exacerbate existing health information asymmetries by disproportionately affecting users who cannot critically assess online content quality. These findings highlight the urgent need to embed the core principles of health communication, such as informed choice, audience empowerment, and transparency, into the design and governance of AI systems. Only through such efforts can these technologies fulfill their promise as facilitators of public health rather than inadvertent amplifiers of health misinformation.

Limitations

This study evaluated Copilot's creative, balanced, and precise modes, which were later merged into a single default mode. Reports suggest that the 3 modes mainly differed in style parameters (eg, verbosity and creativity) rather than underlying model architecture. Although explicit mode switches have been removed, the unified mode likely preserves a blended style; therefore, our accuracy and citation results remain informative [23,24].

Second, this study focused on evaluating Copilot's performance in a Japanese-language context and did not assess its accuracy in other languages or cultural settings. As a multilingual tool, the performance of Copilot may vary depending on linguistic and cultural factors, as well as on the distribution of its training data. Given that English is likely to be overrepresented in the training corpus, responses in non-English languages such as Japanese may be less accurate because of limited high-quality data.

Conclusions

This study is the first to evaluate the performance of an AI search engine in the dietary supplement domain. Overall, the results were suboptimal. Copilot affirmed the effectiveness of dietary supplements in approximately 40.7% (220/540) of the responses, yet the overall accuracy was only approximately 33.1% (179/540). The creative mode performed slightly better than the others, achieving an accuracy of 36.1% (65/180), suggesting that higher-temperature LLMs may perform better in complex domains. The primary challenge for Copilot seems to arise from the controversial and inconclusive nature of scientific evidence regarding dietary supplements. Notably, 72.7% (2240/3081) of the sources cited, such as personal blogs and sales websites, were unverified. Copilot frequently quoted information from these sources without proper screening and, in some cases, even attributed claims to sources that did not support them. In terms of response style, Copilot tended to adopt a conservative and hedging tone, often avoiding a clear affirmation or denial of supplement effectiveness. This reflects a tendency toward sycophancy, in which responses align with

XSL•FO
RenderX

perceived user expectations. Finally, only half (262/540, 48.5%) of the responses included recommendations to consult medical professionals. We believe that all health-related answers should include such guidance to ensure user safety and responsibility.

Abstract

Background: Australians can face significant challenges in navigating the health care system, especially in rural and regional areas. Generative search tools, powered by large language models (LLMs), show promise in improving health information retrieval by generating direct answers. However, concerns remain regarding their accuracy and reliability when compared to traditional search engines in a health care context.

Objective: This study aimed to compare the effectiveness of a generative artificial intelligence (AI) search (ie, Microsoft Copilot) versus a conventional search engine (Google Web Search) for navigating health care information.

Methods: A total of 97 adults in Queensland, Australia, participated in a web-based survey, answering scenario-based health care navigation questions using either Microsoft Copilot or Google Web Search. Accuracy was assessed using binary correct or incorrect ratings, graded correctness (incorrect, partially correct, or correct), and numerical scores (0 - 2 for service identification and 0 - 6 for criteria). Participants also completed a Technology Rating Questionnaire (TRQ) to evaluate their experience with their assigned tool.

Results: Participants assigned to Microsoft Copilot outperformed the Google Web Search group on 2 health care navigation tasks (identifying aged care application services and listing mobility allowance eligibility criteria), with no clear evidence of a difference in the remaining 6 tasks. On the TRQ, participants rated Google Web Search higher in willingness to adopt and perceived impact on quality of life, and lower in effort needed to learn. Both tools received similar ratings in perceived value, confidence, help required to use, and concerns about privacy.

Conclusions: Generative AI tools can achieve comparable accuracy to traditional search engines for health care navigation tasks, though this did not translate into an improved user experience. Further evaluation is needed as AI technology improves and users become more familiar with its use.

KEYWORDS

artificial intelligence; large language models; search engines; Australia; health services accessibility; questionnaires

Introduction

Health care in Australia is recognized as both comprehensive and highly complex, making it challenging for many individuals to navigate [1,2]. Although the majority of Australians—around 86%—report navigating the system with relative ease, 14% find it difficult [1]. The challenge is particularly pronounced for health services in regional, rural, and remote contexts, where lack of awareness and the complexity of accessing care are cited as major barriers [3]. Moreover, rural Australians, who comprise roughly 28% of the population, experience higher rates of illness and lower per capita funding compared to their urban counterparts [4,5]. These disparities underscore the importance of effective tools and strategies that can simplify health care navigation, with implications for rural and regional populations.

To ensure that studies aimed at developing effective tools and strategies for simplifying health care navigation truly address the needs of communities, it is essential to involve health consumers directly in setting research priorities [6,7]. The research priority for this study was informed via a consumer engagement session held in Dalby, Queensland, a rural town approximately 200 kilometers west of Brisbane, on February 14, 2024. The roundtable brought together community members, regional health service providers, and researchers to discuss health care challenges specific to rural and remote populations.

XSL•FO
RenderX

Participants highlighted significant barriers to accessing health care, particularly the difficulty of understanding what services are available and determining if they are eligible for them. Many described feeling uncertain about where to seek help, encountering confusing bureaucratic processes, and struggling to navigate both in-person and online health resources. Guided by this input, the present study focuses on health navigation challenges involving rural and remote health services in Queensland, Australia.

In recent decades, the internet has emerged as a primary source of health information for Australians of all ages, with a search engine being the most common starting point [8-11]. However, individuals searching for health information online often do not engage in thorough source comparison, instead extracting information from the search results page or a single website rather than critically assessing multiple authoritative sources [12]. This can lead to suboptimal decisions and increased barriers to timely, appropriate care, particularly in complex health care systems like that of Australia.

One technological innovation that may help address these challenges is the deployment of generative artificial intelligence (AI) in health information searches. Research indicates that users in Australia are already testing the waters with AI-based tools; for instance, nearly one in 10 Australians reported using ChatGPT to ask health questions in the first half of 2024 [13]. Large language model (LLM)–based systems can simplify health information so that it is more readable [14], potentially improving health information seeking. Emerging research suggests that clinicians generally prefer LLM-generated responses to common patient health queries, rating them as more accurate and comprehensive than the results provided by traditional search engines [15-19]. In addition, LLMs can be interfaced with search engines to create generative AI search tools (also known as conversational search), which promise to streamline information retrieval by automating the process of selecting search terms, filtering content, and providing a readable summary of information from multiple sources [20,21]. However, there are significant concerns about the reliability of LLMs. For instance, LLMs often "hallucinate," generating information that appears plausible but is inaccurate [22,23]. In a health care context, where evidence-based information is critical, the consequences of these inaccuracies can be serious. Although early adopters may find these tools appealing, it is not clear whether generative AI search tools are as accurate as conventional search engines in helping Australians navigate the health care system.

The primary aim of the present study is to compare the accuracy of Australian users' answers to health care navigation scenarios when using a generative AI search (Microsoft Copilot) versus using a conventional search engine (Google Web Search). The secondary aim is to compare the user experience of these 2 tools, in terms of factors such as perceived value, concerns about privacy, perceived effort to use, and willingness to adopt.

Methods

Participant Recruitment

We recruited participants using the web-based platform Prolific, who were then linked to Qualtrics to complete the survey. All Prolific users are required to be over 18 years of age. We only recruited those located in Australia and whose profile indicated they could speak English. To ensure all participants would have similar familiarity with state-based health policies and services, we screened out participants who resided in Australian states other than Queensland or had past or present employment in a health profession.

Participants were recruited between November 3, 2024, and January 8, 2025.

Baseline Measures

Initial demographics were also collected, including age, gender (man, woman, nonbinary, or prefer not to disclose), and language proficiency. Additional data about participants' eHealth literacy and computer skills and knowledge were collected using the eHealth Literacy Scale (eHEALS) [24]. The eHEALS includes 8 questions rated on a 5-point Likert scale, ranging from 1 (strongly disagree) to 5 (strongly agree), with a total possible score between 8 and 40.

In addition, a 4-item computer skills and knowledge questionnaire was used for the purpose of assessing use of computers, knowledge, skills with programs, and skills with computer applications [25]. Each item was rated on a 9-point rating scale, ranging from 1 (very low skill or knowledge) to 9 (very high skill or knowledge).

Procedure

Participants were randomized to use either the generative AI search tool or Google Web Search. They were given simple instructions on how to access the site and interact with it; however, no guidance was provided on how best to formulate a prompt or search strategy.

Participants were tasked to complete 5 task-based scenarios, each presenting a brief vignette of a person, their location in rural or regional Queensland, their health condition, and the health service or health payment, subsidy, or scheme about which they were seeking information. Each scenario had 1 or 2 tasks respondents were asked to complete using their assigned tool (Table 1), for a total of 8 tasks. An example of a scenario (Scenario 3) and the 2 associated tasks is provided in Textbox 1 (all scenarios and tasks available in Multimedia Appendix 1). Although they were instructed to spend no more than five minutes per scenario, no time limits were enforced. Seven participants who did not provide a response to any of the 5 scenarios were removed from the sample.

XSL•FO
RenderX

Table . Task-based scenarios with corresponding outcome (and associated scoring criteria).

Scenario	Task	Outcome	Scoring
1	Locating telehealth physiotherapy clinics	Number of correctly identified services	0 - 2
2	Locating nearby aged care providers	Number of correctly identified providers	0 - 2
2	Naming aged care application service	Whether a service named is correct	Incorrect, correct
3	Listing mobility allowance eligibility criteria	Number of correctly identified criteria	0 - 6
3	Providing mobility allowance helpline number	Whether a phone number provided is correct	Incorrect, correct
4	Locating nearby mental health center	Correctness of identified facility(name AND address)	Incorrect, partially correct, correct
5	Assessing patient travel subsidy eligibility	Correctness of subsidy identified	Incorrect, partially correct, correct
5	Providing travel subsidy agency contact details	Whether any contact details provided are correct	Incorrect, correct

Textbox 1. An example of a scenario (Scenario 3) provided to participants, with the 2 tasks associated with this scenario.

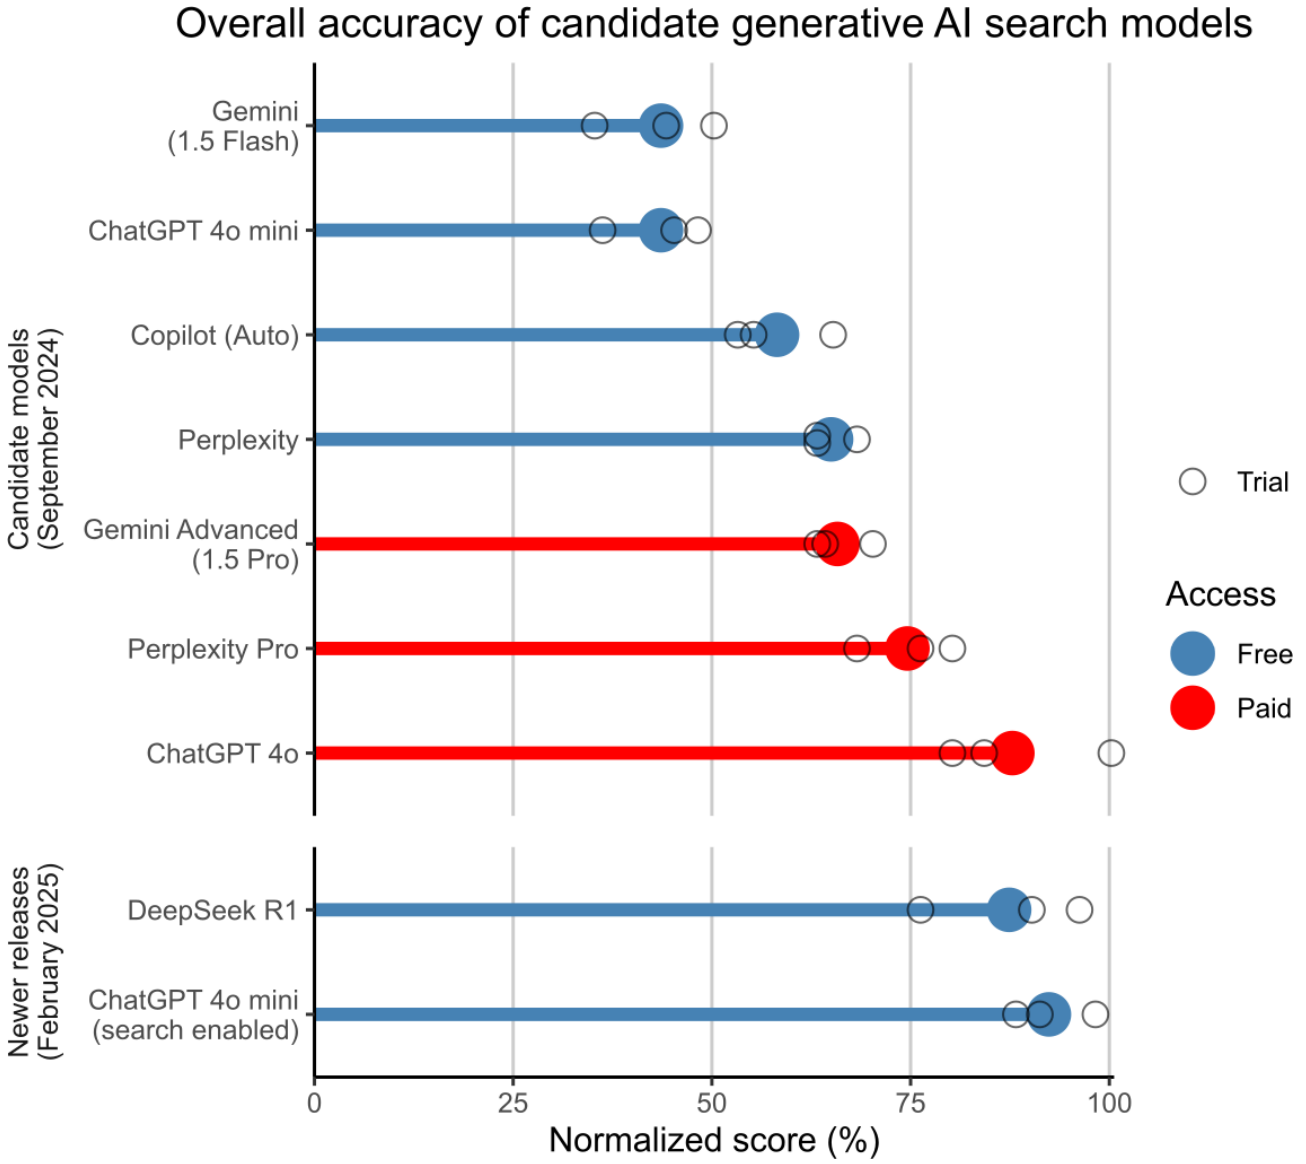
Scenario 3

Hamid sustained a spinal injury in a motor vehicle collision 9 months ago. He now uses a wheelchair permanently for mobility. He recently moved to live with family in Charters Towers and is looking for employment opportunities. However, he finds it difficult to pay for the cost of travel to look for work as he cannot drive and there is no public transport in the area. He has a membership for the Queensland Government's Taxi Subsidy Scheme (TSS), but this only pays half of his taxi fares. He recently learned of a funding program called Mobility Allowance.

Task 1:

What information about Hamid would you need to know to determine if he is eligible for this program?

Task 2:



Hamid wants to talk to somebody over the telephone about getting mobility allowance, but struggles with speaking English. What phone number(s) should he call?

Model Selection

To determine which generative AI search tool would be more appropriate for the current study, the accuracy of various free-access and subscription-only generative AI search tools was assessed. In September 2024, using the same prompts as detailed above, each answer engine was prompted 3 times. Each trial was conducted in an independent session (ie, a new chat was started each time), with any 'memory' features across chats disabled where applicable. The responses were scored by one author (JS), using the same scoring metric as the primary outcome measure, and scores were discussed with the research team. An equal-weighted total average score for each model was calculated by assigning numeric scores to all binary or ordinal scores (eg, Incorrect=0, Partially correct=0.5, Correct=1), weighting each of the 5 scenarios equally. By this metric, all subscription-only generative AI search tools available at the time were substantially more accurate than the free-access versions available at the time (Figure 1). However, it was not feasible to supply all survey participants with access to a paid subscription. Of the free-access tools available at the time, Microsoft Copilot (formally Bing Chat) was chosen due to not requiring user accounts to be created for access, which streamlined the survey process and decreased the burden on participants. For additional context, newer free models released after the study began were tested in February 2025 and are also shown in Figure 1.

XSL•FO
RenderX

Figure 1. Chart of mean accuracy of the candidate free-access and subscription-only generative AI search tools across 3 trials. Results for each trial indicated by empty circles.

Outcome Measures

Primary Outcome Measure

The primary outcome variable was the accuracy of the response, based on whether correct information was retrieved. One author (JS) developed a scheme to score each response, which was reviewed and refined based on feedback from a second author (MHR). Two authors (JS, MHR), both registered physiotherapists in Queensland, scored each response based on these criteria and resolved any disagreements through discussion. Scoring was blinded to the search tool used to generate the answers. Points were awarded based on the presence of correct information (eg, services or payments that would address the client's needs, correctly identified eligibility criteria, or correct contact details). Scores were not deducted for the presence of incorrect information in the responses, nor was the score deducted for providing more information than asked (eg, if asked for 2 potential services and giving 3).

Secondary Outcome Measure

Responses to a Technology Rating Questionnaire (TRQ) [25] were collected as secondary outcomes. Participants were asked to respond to 7 items on a 1-9 numerical rating scale (anchored by 1 as none or not at all and 9 as a lot or extremely) about the technology, including their:

- Willingness to adopt
- Confidence in learning
- Help needed to learn
- Perceived effort to learn
- Perceived value
- Privacy concerns
- Quality of life impact

Data Analysis

Data were analyzed using R software (version 4.4.1; R Core Team). To compare the 2 groups (Microsoft Copilot and Google Web Search) for the primary outcome of how well responses matched the pre-set criteria, appropriate statistical methods were selected for each question. For questions assessed on a

XSL•FO
RenderX

continuous or interval scale (eg, number of correct answers), the mean difference between scores was presented alongside boot-strapped 95% CIs generated with the "boot" package, using the bias-corrected and accelerated (BCa) method with 5000 iterations. For questions with binary answers (ie, marked as either correct or incorrect), the difference in proportions of correct responses between groups was presented alongside the 95% CIs calculated with the "DescTools" package using the Agresti-Coull method. For questions with ordinal answers (eg, marked as Incorrect, Partially Correct, or Correct), ordinal regression was performed using cumulative link models with the "ordinal" package, with a logit link function. The proportional odds assumption was verified using Brant tests with the package "brant." The secondary outcome on the technology rating questionnaire was analyzed using the same bootstrapping method as the interval scale data for the primary outcome.

Ethical Considerations

This study was approved by The University of Queensland Faculty of Health and Behavioural Sciences Low and Negligible Risk Panel (2024/HE001343). Participants provided electronic informed consent after reviewing a participant information sheet. Recruitment occurred via a research panel (Prolific), and—given the anonymous design—data provided before withdrawal could not be removed. Participants were compensated for their time through Prolific, receiving an average of £5.50 (approximately US$6.90). We maintained participants' privacy and confidentiality by collecting only nonidentifiable data, which were stored on The University of Queensland Research Data Management System.

Results

Sample Characteristics

After receiving 672 submissions from Prolific, the final sample consisted of 97 participants. Most participants were from metropolitan areas (72/97, 74%). Mean age was 36 (SD 14) years with an age range from 18 to 83 years. Gender distribution included 49% (48/97) identifying as men, 42% (41/97) as women, and 3% (3/97) as nonbinary. Only 6% (6/97) of the sample reported being of Aboriginal or Torres Strait origin. See Table 2 for full details.

The mean self-reported eHEALS of participants (mean sum score) was 27 (SD 4; min 12, max 35) out of 40, indicating most participants were confident using the internet for health information. The average rating for computer and internet skills and knowledge was around 7.5-8 (of a range of 1-9), indicating participants were very confident with the use of computers and the internet.

Primary Outcome

Participants in the present study using Microsoft Copilot achieved an overall accuracy averaging 68.2% (equally weighted across all tasks), while those using Google Web Search averaged 65.9%. Median length of participants' written responses across all tasks in the Microsoft Copilot was 158 characters (IQR 37-373; Min=7, Max=1558), whereas in the Google Web Search group median response length was 65 characters (IQR 16-104; Min=3, Max=1492), a median difference of 93 characters (95% CI 53-138).

In the Scenario 1 task (locating telehealth physiotherapy clinics), respondents randomly assigned to Microsoft Copilot correctly located an average of 1.47 telehealth services, just 0.07 (95% CI −0.22 to 0.34) more than the 1.40 services found by those assigned Google Web Search (Figure 2).

In the first Scenario 2 task (locating nearby aged care providers), respondents assigned to Microsoft Copilot identified an average of 1.20 services, only 0.08 (95% CI −0.27 to 0.42) services more than the 1.12 services identified by those assigned to Google Web Search. In the second Scenario 2 task (naming aged care application service), 84% (38/45) of respondents in the Microsoft Copilot group identified the correct government service compared with 58% (29/50) who did so in the Google Web Search group. This indicates Microsoft Copilot increased the proportion of correct responses for this question by 0.26 (95% CI 0.08-0.42) over Google Web Search (Figure 2).

In the first Scenario 3 task (listing mobility allowance eligibility criteria), Microsoft Copilot respondents correctly identified an average of 4.67 eligibility criteria compared to 3.43 criteria in the Google Web Search group (Figure 2). This represents a clear advantage in favor of Microsoft Copilot, with a mean difference of 1.24 (95%CI 0.49-1.91). In the second Scenario 3 task (providing mobility allowance helpline number), just 28 of the 44 Microsoft Copilot group listed a correct phone number for the translation service, which was a lower proportion than the 38 of 48 respondents assigned Google Web Search (Figure 2). This is a mean difference in proportions of −0.16 (95% CI −0.33 to 0.03).

For the Scenario 4 task (locating a nearby mental health center), 53% (24/45) of respondents in the Microsoft Copilot group were completely correct and 3 of the 45 were partially correct. In contrast, 69% (34/49 respondents) in the Google Web Search group were completely correct and 3 of 49 were partially correct (Figure 2). Estimated odds ratio from the ordinal logistic regression analysis of 0.5 (95% CI 0.2-1.1) suggests that assignment to Microsoft Copilot may substantially reduce the odds of achieving a higher score relative to Google Web Search. However, the wide confidence interval indicates imprecision, with possible effects ranging from a large reduction through no difference to even a modest increase.

In the first Scenario 5 task (assessing patient travel subsidy eligibility), 86% (38/44 respondents) in the Microsoft Copilot group answered completely correctly, with an additional 3 (of the 44) providing partially correct answers (Figure 2). For the same question, 80% (39/49 respondents) in the Google Web Search group were completely correct, and 5 (of the 49) offered partially correct responses. Based on ordinal logistic regression,

XSL•FO
RenderX

participants assigned to Microsoft Copilot had approximately 1.6 times the odds of achieving a more accurate answer compared to those in the Google Web Search group (odds ratio [OR] 1.6, 95% CI 0.5-5.2). However, the wide confidence interval ranges from a reduction in odds to a substantial increase. In the second Scenario 5 task (providing travel subsidy agency contact details), just 40% (18/45) of respondents in the Microsoft Copilot group listed correct contact details for the government agency, whereas exactly half of those in the Google Web Search group (24 of 48) did so (Figure 2). This is a difference in proportions of −0.1 (95% CI −0.29 to 0.10).

XSL•FO
RenderX

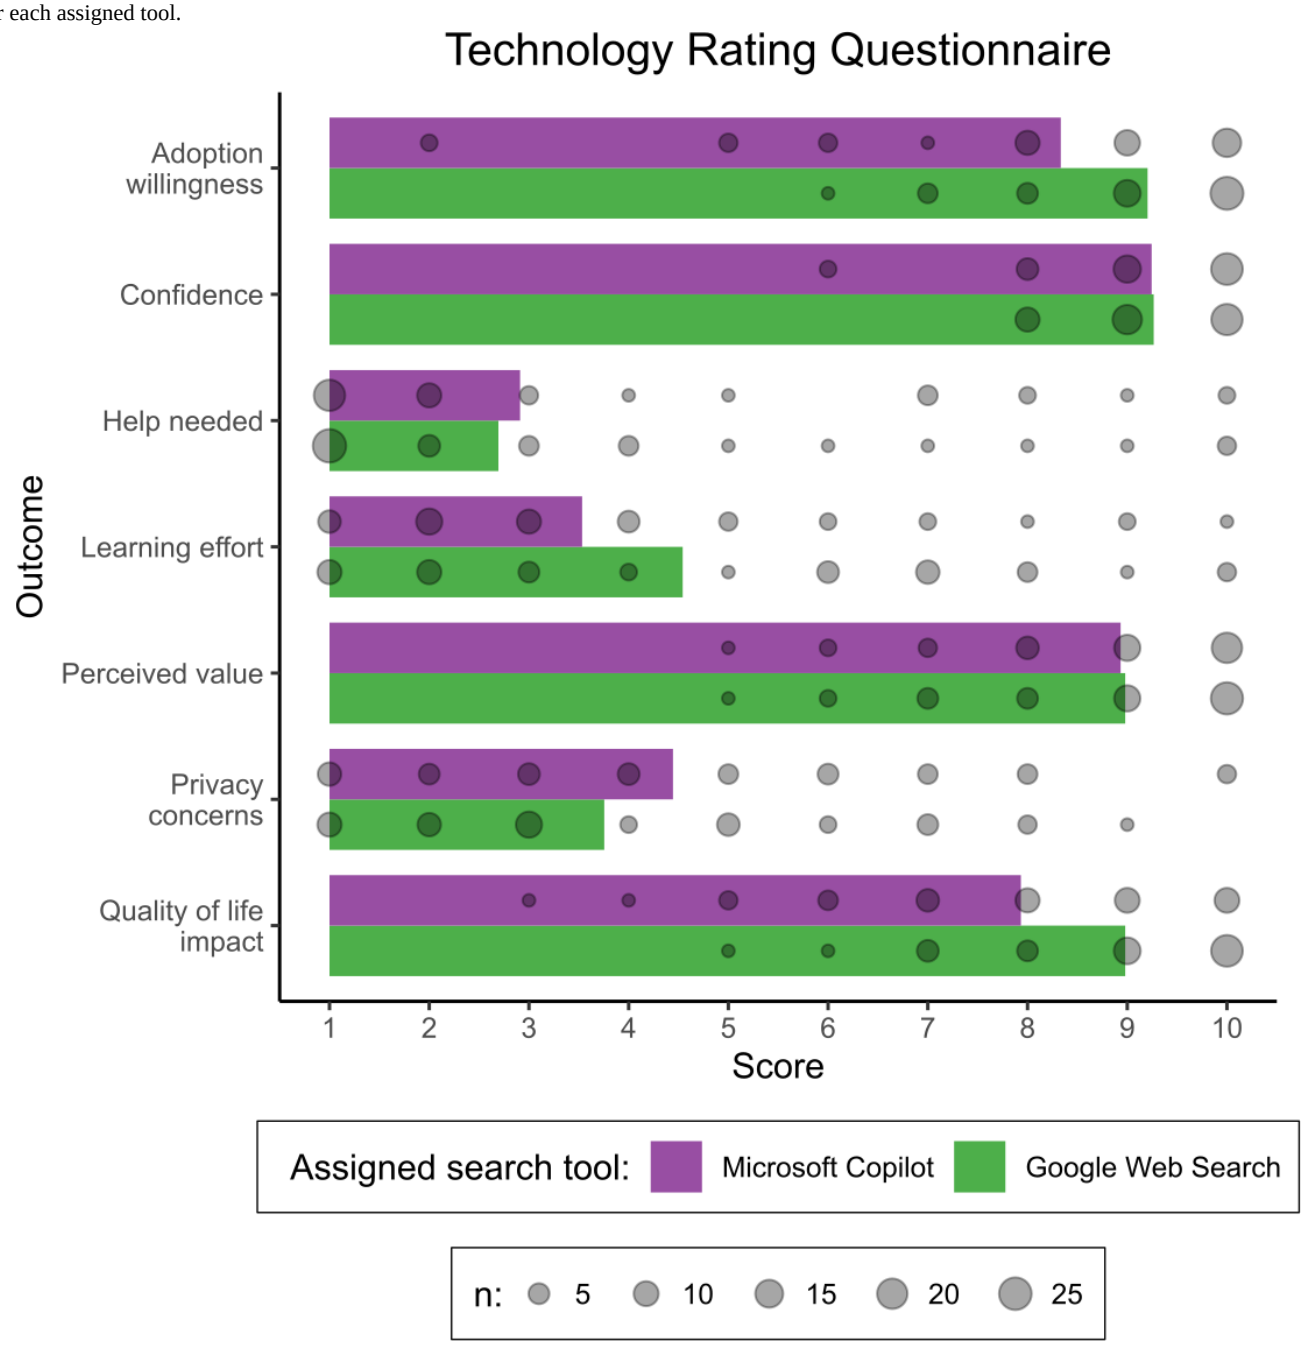
Secondary Outcome (Technology Rating Questionnaire)



On the 0 - 10 TRQ subquestions (Figure 3), participants on average rated Microsoft Copilot as 0.87 points lower for willingness to adopt (95% CI −1.65 to −0.28) and 1.05 points lower for impact on quality of life (95% CI −1.69,−0.42). These 95% CIs are compatible with meaningful differences favoring Google Web Search, though the precise effect sizes remain uncertain.

For perceived value (mean difference −0.05, 95% CI −0.57 to 0.49), help needed (mean difference 0.22, 95% CI −0.89 to 1.33), and confidence (mean difference −0.02, 95% CI −0.43 to 0.32), the confidence intervals are all compatible with small effects in either direction or essentially no difference between the 2 tools.

Privacy concerns were 0.69 points higher for Microsoft Copilot (95% CI −0.32 to 1.67), though the confidence interval includes the possibility of no difference or even slightly greater concerns about Google Web Search.

Finally, participants reported that Google Web Search required 1.01 points less effort to learn than Microsoft Copilot (95% CI −1.69 to −0.42), consistent with Google Web Search being perceived as somewhat easier to learn than Microsoft Copilot.

Discussion

Summary of Findings

The present study compares the occurrence of correct information in responses to health navigation queries from users assigned to use either a generative AI search tool (powered by an LLM augmented with the retrieval of live web data) or a traditional search engine. Our primary results found those assigned to Microsoft Copilot outperformed the Google Web Search group for 2 tasks: naming the service to apply for an aged care assessment and assessing mobility allowance eligibility. There was no clear evidence of differences between the tools for the remaining 6 tasks. This suggests that while this generative AI search tool might be superior to a search engine in some specific instances, its overall advantage in terms of accuracy in health navigation tasks is not guaranteed.

We acknowledge that our selection of Microsoft Copilot as the generative AI search tool may limit generalizability to other current and future generative AI search tools. Microsoft Copilot was selected because it offered free access without the need for participants to create an account. However, the field of AI is evolving rapidly, with many newer and more advanced search-enabled models being released by OpenAI, DeepSeek, Anthropic, and others. Indeed, our initial testing of various models (Figure 1) indicates that many other generative AI search tools were substantially more accurate than Microsoft Copilot on the health navigation tasks used in the present study. Therefore, if participants had been assigned a more advanced generative AI search tool, it is possible they would have achieved higher accuracy compared to Google Web Search.

The growing integration of generative AI into conventional web search has blurred the lines between traditional search engines and AI-based search tools, potentially influencing the outcomes of the present study. In October 2024, just one month before recruitment commenced for the present study, Google rolled out AI Overviews across Australia, a generative AI feature that provides users with concise, AI-generated summaries within search results [26]. However, these summaries would (at the time) only appear when users were logged in using their Google account and participants assigned to Google Web Search were instructed to open a private (or incognito) window to ensure they were not logged in. Despite this, participants who did not follow these instructions could potentially have encountered these AI-generated summaries. Participants were responding to a web-based survey, and therefore, it was not possible to track or record their exact search queries or which websites were visited. As generative AI becomes more embedded in everyday search experiences, traditional web searches could potentially become less common. This may make studying search engines in isolation less practically relevant and increase the need for ongoing research into the accuracy and reliability of generative AI search.

It is noteworthy that the Microsoft Copilot group achieved an overall accuracy of 68.2%, compared with 58.2% observed during preliminary testing conducted 2 months earlier, where scenarios were simply copy-pasted into Copilot 3 times. The higher accuracy observed might suggest that participants visited source websites to verify the information in the AI-generated summaries. It could also result from participants using more effective prompting strategies (than using the question verbatim), asking follow-up questions, or retrying prompts when initial responses were clearly incorrect. However, this is an incidental observation rather than a study objective. We cannot exclude sampling bias, given our preliminary estimate was based on just 3 attempts. In addition, improvements in Copilot's underlying AI model or updates to the accuracy of content available on the web between preliminary testing and study commencement could also have contributed to this difference.

Participants in our study skewed toward higher formal education and were generally quite confident in their ability to find health information on the internet. This may limit generalizability, as individuals with lower educational levels have lower self-rated ability to evaluate online health information and report lower overall trust in such information, compared to their more educated counterparts [27]. Furthermore, some evidence suggests that generative AI tools tend to offer greater benefits for nonexperts [28], though other evidence suggests no advantage in favor of ChatGPT (without web search capability) among lower-education users with lower proficiency using Google Web Search [29]. It is possible that most participants in our study were able to effectively complete the task using either tool, potentially decreasing any between-tool differences. We did not design or power the study to test differences by education or eHealth literacy, so any differential effects remain a question for future work.

Health care navigation is a multifaceted process, depending not only on access to accurate information, but also consideration of the affordability of the health service, flexibility of service options, inclusivity of the clinical environment, and alignment with consumers' personal beliefs and knowledge [30]. Given this complexity, the scenario-based tasks used in this study likely do not fully capture the nuances of real-world health care navigation. Participants were presented with contrived scenarios in which they had no personal or emotional investment, only a single attempt to find the correct answer within a brief 5-minute window, with no opportunity to reassess or refine their responses, and scored on an artificial scoring metric. The scenarios were also deliberately designed to be challenging yet solvable, specifically to enable a meaningful comparison between the 2 tools, rather than to represent the most common real-world health navigation scenarios. Therefore, performance on these scenarios cannot be used to draw definitive conclusions about real-world health navigation ability. Future research exploring generative AI in authentic health care contexts should better account for these nuances and thus more accurately represent how individuals engage in health decision-making.

Secondary outcome results indicate that the willingness to adopt Google Web Search was higher than Microsoft Copilot. This contrasts with a previous study, which found that despite greater trust in an LLM (OpenAI's ChatGPT) for health information, participants rated intention to use the LLM similarly to Google Web Search [31]. This difference may be due to familiarity with the specific LLM, as ChatGPT is more widely used than Copilot for health-related queries [32], potentially leading to greater willingness to use. More broadly, users' trust in health

XSL•FO
RenderX

information and chatbots is shaped by factors such as usability, perceived risk, and credibility [33,34], all of which could differ between ChatGPT and Copilot. Furthermore, the difference in tasks between seeking health information and navigating health care services might influence users' trust and adoption decisions, especially if there is a perception that LLM-based systems can struggle with more context-dependent or location-specific queries.

The present study found no clear evidence of a difference in perceived effort to use or help required between the generative AI search and conventional search, in concordance with existing research comparing ease of use of LLMs and search engines for health queries [32]. Contrasting our findings, a recent study [35] reported lower cognitive load among students researching socio-scientific issues about sunscreen with ChatGPT compared to Google. Participants may have greater concerns about the reliability and accuracy of AI-generated health information than other types of information, potentially limiting the advantages of AI-driven tools in a health context. In addition, it has been reported that users tend to prefer traditional search engines for fact-based information retrieval, turning to LLMs primarily when they need more personalized or lay-language explanations [36]. Because the health navigation tasks in this study were relatively fact-based, the strengths of a generative AI search tool may not have been prominent.

Strengths and Limitations

A key strength of this study is that it closely observed how real users interact with 2 distinct search tools, rather than merely comparing the static accuracy of the output of each tool. By allowing participants to formulate queries and responses freely, a more realistic picture of AI-assisted health care navigation was obtained. In addition, focusing on generative AI search—rather than an LLM without the capability to augment responses with information from a web search—better reflects the tools now emerging in consumer products. Our relatively large sample size of approximately 100 participants also provides a solid basis for analyzing differences between the 2 groups.

Despite these strengths, an important methodological limitation lies in our scoring approach, which looked only at the presence of correct information in responses and did not account for the presence of incorrect information. Not penalizing incorrect information means our scores may overestimate the accuracy of responses, since in real-world health navigation contexts, misinformation can delay care or impose additional burden on users. Although when compared to other health contexts (such as clinical advice), such risks may be somewhat less impactful for health navigation, as users may receive assistance when contacting incorrect government services, these risks may still be important for urgent health navigation tasks. Consequently, longer responses with multiple possible answers may have received inflated accuracy scores due to an increased chance of including correct items. This may have favored the Microsoft Copilot group, perhaps because they could easily copy the generated AI response, responded with much longer answers to the scenarios than the Google Web Search group. Similarly, our scoring metric may not have been able to capture the practical value of receiving partially helpful information, such as being directed to call a general help line (marked as incorrect in the scoring metric) that could have referred callers to the more appropriate service (which the metric marked as correct). We therefore highlight that our metric should be interpreted as measuring whether users can obtain correct information with these search tools, rather than whether they do so without adding incorrect information.

In addition to the scoring issues, several other methodological limitations stem from participant characteristics and study context. Participants in our sample were predominantly living in metropolitan areas and may have had limited direct experience with rural health care services, which may have affected how they interpreted the navigation tasks of the present study. Furthermore, we did not explore the extent to which participants were familiar with their assigned tool, and familiarity (or lack thereof) could have affected both the accuracy of the responses and how participants rated the technology. Overall, these methodological constraints mean that our findings should be interpreted cautiously, especially when extending them beyond the specific population, tasks, or tools studied here.

Future research should explore these findings further by conducting a follow-up study focused exclusively on rural participants to determine whether the observed patterns persist in different geographic contexts. In addition, future studies should prioritize methods that can more precisely capture user behavior, such as incorporating screen-tracking software or controlled environments, to yield more definitive insights. Another critical avenue for investigation is how users engage with lengthy LLM-generated responses, particularly how they prioritize or dismiss certain portions when seeking health-related information. Understanding this selection process could inform strategies to improve AI-generated content for critical decision-making. Finally, longitudinal research could help clarify whether repeated exposure to AI-generated content enhances users' ability to critically assess multiple answers or, conversely, reinforces reliance on AI as an authoritative source.

Conclusions

Although Microsoft Copilot demonstrated improved accuracy over Google Web Search on 2 of the tested scenarios, for all others, the accuracy estimates were compatible with no difference between the 2 tools. Participants also reported lower willingness to adopt Copilot, as well as higher concerns around privacy and ease of learning. The results of this study underscore how generative AI tools still face hurdles in accuracy and user acceptance. Future work should investigate whether newer and more capable generative AI tools can consistently outperform conventional search engines across a broader range of real-world health navigation tasks.

Abstract

Background: Early diagnosis of diabetes is essential for early interventions to slow the progression of dysglycemia and its comorbidities. However, among individuals with diabetes, about 23% were unaware of their condition.

Objective: This study aims to investigate the potential use of automated machine learning (AutoML) models and self-reported data in detecting undiagnosed diabetes among US adults.

Methods: Individual-level data, including biochemical tests for diabetes, demographic characteristics, family history of diabetes, anthropometric measures, dietary intakes, health behaviors, and chronic conditions, were retrieved from the National Health and Nutrition Examination Survey, 1999 - 2020. Undiagnosed diabetes was defined as having no prior self-reported diagnosis but meeting diagnostic criteria for elevated hemoglobin A_{1c}, fasting plasma glucose, or 2-hour plasma glucose. The H2O AutoML framework, which allows for automated hyperparameter tuning, model selection, and ensemble learning, was used to automate the machine learning workflow. For comparative analysis, 4 traditional machine learning models—logistic regression, support vector machines, random forest, and extreme gradient boosting—were implemented. Model performance was evaluated using the area under the receiver operating characteristic curve.

Results: The study included 11,815 participants aged 20 years and older, comprising 2256 patients with undiagnosed diabetes and 9559 without diabetes. The average age was 59.76 (SD 15.0) years for participants with undiagnosed diabetes and 46.78 (SD 17.2) years for those without diabetes. The AutoML model demonstrated superior performance compared with the 4 traditional machine learning models. The trained AutoML model achieved an area under the receiver operating characteristic curve of 0.909 (95% CI 0.897-0.921) in the test set. The model demonstrated a sensitivity of 70.26%, specificity of 90.46%, positive predictive value of 64.10%, and negative predictive value of 92.61% for identifying undiagnosed diabetes from nondiabetes.

Conclusions: To our knowledge, this study is the first to utilize the AutoML model for detecting undiagnosed diabetes in US adults. The model's strong performance and applicability to the broader US population make it a promising tool for large-scale diabetes screening efforts.

KEYWORDS

machine learning; AutoML; self-report; screening; undiagnosed diabetes

Introduction

Diabetes mellitus is the eighth leading cause of death in the United States and contributes to substantial health care costs [1]. In 2021, an estimated 38.4 million Americans of all ages had diabetes, representing 11.6% of the US population [2,3]. Of those with diabetes, 22.8% were unaware of or did not report having diabetes [2,3]. When diabetes is undiagnosed, and consequently hyperglycemia remains unmanaged, severe and irreversible microvascular and macrovascular complications can develop, including diabetic neuropathy, nephropathy, retinopathy, and cardiovascular disease [4-7].

Screening asymptomatic individuals for undiagnosed diabetes enables earlier diagnosis and treatment, ultimately reducing the risk of complications and premature death [8-10]. The latest American Diabetes Association (ADA) and US Preventive

XSL•FO
RenderX

Services Task Force guidelines recommend beginning diabetes screenings at the age of 35 years [11,12]. However, diabetes screening guidelines that rely on blood testing are not widely followed. Only 50% - 60% of US adults who met the criteria for screening reported receiving glucose testing within the past 3 years [13,14]. The testing rate was alarmingly low among high-risk groups, including those with low education, low household income, and limited health care access [13,14].

Risk assessment tools for diabetes detection using easily accessible and self-reported data have been proposed, but they have shown low overall accuracy and validity in the general population [15-21]. In recent years, various machine learning algorithms have been used to predict diabetes and have yielded better performance than traditional statistics-based models [22-28]. Few studies have developed machine learning models to detect undiagnosed diabetes in the US population [29,30]. Although 2 studies reported a good overall accuracy of 80%, the quality of a positive prediction by models (ie, precision) was notably low, which could lead to a high number of false positives and unnecessary follow-up testing [29,30].

More recently, there has been growing interest within the health care community in automated machine learning (AutoML), which automates machine learning models' selection, composition, and parameterization to optimize performance [31-33]. AutoML uses voting and stacking ensemble techniques to combine multiple learning models, often improving classification accuracy more effectively than a single machine learning algorithm. Its automation also reduces human error and bias by impartially exploring a wide range of machine learning models [33]. However, despite its potential, no prior studies have investigated the feasibility and performance of AutoML in screening for undiagnosed diabetes.

This study aimed to investigate the potential use of AutoML and self-reported data in detecting undiagnosed diabetes among US adults in a nationally representative survey. The trained model could aid in detecting undiagnosed diabetes in the general US population, particularly in underserved populations with limited access to blood glucose tests. This study could also promote the adoption of AutoML in diabetes research.

Methods

Data Source

Individual-level data were retrieved from the National Health and Nutrition Examination Survey (NHANES), 1999 - 2020. NHANES is a nationally representative, repeated cross-sectional study conducted by the National Center for Health Statistics. NHANES adopts a complex, multistage probability sampling design to ensure that the collected data are representative of the noninstitutionalized civilian population in the United States. NHANES includes clinical examinations, selected medical and laboratory tests, and self-reported data. NHANES interviews people in their homes and conducts health examinations in a mobile examination center, including laboratory analysis of blood, urine, and other tissue samples. The detailed study design and methodology of NHANES have been described elsewhere [34,35]. This study followed the CREMLS (Consolidated Reporting Guidelines for Prognostic and Diagnostic Machine Learning Models) [36,37].

Biochemical Tests for Undiagnosed Diabetes

Following the ADA guidelines [38], diabetes was diagnosed based on elevated levels of hemoglobin A_{1c} (≥6.5%), fasting plasma glucose (≥126 mg/dL), or 2-hour plasma glucose (≥200 mg/dL) during a 75-g oral glucose tolerance test. In this analysis, undiagnosed diabetes was defined as having no prior self-reported diagnosis but meeting any of the diagnosis criteria for elevated hemoglobin A_{1c}, fasting plasma glucose level, or oral glucose tolerance test level. The details of the diagnostic method used to define diabetes in this study are provided in Table 1.

XSL•FO

Table . Diagnostic method used to define diabetes in this study.

	Diagnostic method
Diabetic	
Diagnosed diabetes	Answer "Yes" to "Other than during pregnancy, have you ever been told by a doctor or health professional that you have diabetes or sugar diabetes?"
Undiagnosed diabetes	Answer "No" to "Other than during pregnancy, have you ever been told by a doctor or health professional that you have diabetes or sugar diabetes?" AND Any of the following tests meet criteria: • HbA_{1c}[a]≥6.5% (≥48 mmol/mol). • FPG[b]≥126 mg/dL (≥7.0 mmol/L). • 2-h PG[c]≥200 mg/dL (≥11.1 mmol/L) during OGTT[d].
Nondiabetic	
Prediabetes	Does not meet criteria for diabetes diagnosis AND Any of the following tests meet criteria: • HbA_{1c} 5.7% - 6.4% (39 - 47 mmol/mol) • FPG 100 - 125 mg/dL (5.6 - 6.9 mmol/L) • 2-h PG 140 - 199 mg/dL (7.8 - 11.0 mmol/L)
Normoglycemia	All the following tests meet criteria: • HbA_{1c}<5.7% (<39 mmol) • FPG<100 mg/dL (<5.6 mmol/) • 2-h PG<140 mg/dL (<7.8 mmol/L)

[a]HbA_{1c}: hemoglobin A_{1c}.

[b]FPG: fasting plasma glucose.

[c]PG: plasma glucose.

[d]OGTT: oral glucose tolerance test.

Participant Selection

The study utilized data from NHANES 1999 - 2020, comprising an initial cohort of 112,502 participants. Participants with self-reported diabetes (n=8657) and those with missing data on self-reported diabetes status (n=9672) were excluded. Individuals aged <20 years (n=43,879) and pregnant females (n=1540) were removed from the cohort. Participants with missing laboratory results for diabetes were further excluded (n=36,939). For inclusion in the nondiabetic group, participants had to meet all 3 test criteria to confirm the absence of diabetes. For the diabetes group, participants were included if at least one test met the diagnostic criteria, even if the other two test results were missing. In total, the study cohort included 11,815 participants and was categorized into 2 groups: 9559 without diabetes and 2256 with undiagnosed diabetes.

Features

Demographic Characteristics

Demographic features included age at the survey, gender (male/female), race/ethnicity (non-Hispanic White, non-Hispanic Black, Mexican American, and other races), educational attainment (lower than 9th-grade education, 9th- to 11th-grade education, high school, some college or associate degree, college or higher), marital status (married, widowed, divorced, separated, never married, living with a partner), and income-to-poverty ratio (ratio of monthly family income to the poverty guidelines).

Family history of diabetes was ascertained from the Medical Conditions Questionnaire: "Including living and deceased, were any of your biological, that is, blood relatives including grandparents, parents, brothers, sisters ever told by a health professional that they had diabetes?"

Anthropometric Measures

Participants were weighed in mobile examination centers, wearing only underclothing and an examination gown. Weight was recorded on a digital scale in kilograms. Standing height was measured using a stadiometer with a fixed vertical backboard and an adjustable headpiece. BMI was calculated as measured weight in kilograms divided by height in meters squared. Waist circumference was measured just above the iliac crest using a steel measuring tape.

Diet Intake and Behaviors

In NHANES, 24-hour dietary recalls were administered to obtain detailed nutritional intake information from participants. Daily dietary intake (the average of 2 d) of energy (kcal), total fat (g), cholesterol (mg), and total sugars (g) was calculated. The frequency of eating out per week was obtained from the question: "On average, how many times per week do you eat meals prepared in a restaurant?"

XSL•FO
RenderX

Health Behaviors

The NHANES physical activity questionnaire included questions about daily and leisure-time activities. The average hours spent in each activity were multiplied by the suggested metabolic equivalent (MET) scores to estimate MET hours per week [39]. Indicators (yes/no) for smoking and drinking were obtained from answers to questions: "In any one year, have you had at least 12 drinks of any type of alcoholic beverage?" and "Have you smoked at least 100 cigarettes in your entire life?"

Chronic Conditions

Comorbid conditions were obtained from self-reports to the Medical Conditions Questionnaire, "Have you ever been told by a doctor that you had (medical problem)?" which includes hypertension, rheumatoid arthritis, myocardial infarction, congestive heart failure, coronary heart disease, stroke, liver disease, weak/failing kidneys, and cancer/malignancy of any kind.

AutoML and Custom Machine Learning Models

The H2O AutoML framework was used in this study to automate the machine learning workflow. The H2O AutoML trains several models, cross-validated by default, by using the following available algorithms: extreme gradient boosting (XGBoost), gradient boosting machine, generalized linear model, distributed random forest, extremely randomized trees, and fully connected deep neural network. H2O AutoML introduces two essential advancements to optimize model performance. First, it fine-tunes base models using a fast random search approach, where hyperparameters are selected from a range of values identified as most impactful. Second, H2O AutoML leverages a sophisticated stacking technique to create two powerful ensemble models: "All models ensemble," which combines all the base models trained, and "Best of the Family ensemble," which contains the best-performing models. The stacked ensemble models are designed to leverage the diverse strengths of various algorithms, resulting in a final model that is accurate and generalizable across different datasets. H2O AutoML has built-in functionality for class balancing and handling of missing values. Detailed documentation, as well as directions for algorithms and the implementation of H2O.ai, are available online [40].

We randomly split the dataset into training (70%) and test (30%) sets. AutoML trained diverse base models on the training set, ranking them by cross-validated area under the receiver operating characteristic curve (AUC). Cross-validation was performed using a 5-fold approach, with models iteratively trained on 4 subsets of the training set and validated on the remaining subset. A stacked ensemble ("leader") was constructed by blending the top-performing base models via a meta learner. This stacked ensemble model was exported and applied to our independent holdout test set to generate class-probability predictions. The 95% CIs for each AUC were derived from 1000 bootstrap resamples of the test set. Confusion matrices were constructed to calculate sensitivity, specificity, positive predictive value (PPV), and negative predictive value (NPV) using the classification threshold that maximized the F_1-score that yields the highest harmonic mean of precision and recall on the test set. We extracted feature importance from each base learner and computed a weighted aggregate in the H2O leader model. For tree-based models, feature importance was determined by the frequency of each feature used for splitting and the overall reduction in squared error. For non–tree-based models, importance was based on coefficient magnitudes.

In addition to the AutoML model, we conducted a comparative analysis using 4 traditional machine learning models—logistic regression, support vector machines, random forest, and XGBoost, with Synthetic Minority Over-sampling Technique applied to address data imbalance during training [41,42].

The clinical guidelines generally recommend confirming an elevated test with a secondary measurement for the diagnosis of diabetes [38,43]. In the main analyses, diabetes was diagnosed based on a single elevated test result. In additional analyses, the diagnosis of diabetes was confirmed by at least 2 elevated tests recommended by the ADA guidelines. We also evaluated the performance of a 3-class prediction model for diabetes within the AutoML framework, using classification schemes that distinguished between normoglycemia, prediabetes, and undiagnosed diabetes.

Summary statistics for participant characteristics, stratified by diabetes status, were calculated. Categorical variables were compared using χ^2 tests, and continuous variables were evaluated using independent samples *t* tests. Missing data were imputed using mean values for continuous variables and mode for categorical variables. We used STATA 18 (StataCorp LLC) for data preparation and Python version 3.10.12 (Python Software Foundation) to implement the H2O AutoML (H2O.ai, Inc) and custom machine learning models (version 3.46.0.6).

Ethical Considerations

This study used publicly available, deidentified NHANES data. In accordance with the US Department of Health and Human Services (Title 45 of the Code of Federal Regulations; §46.104 (d), section 4) [44], analyses of publicly available, deidentified data are not considered human subjects research and therefore do not require review by the Washington University Institutional Review Board.

Results

In total, the study cohort included 11,815 participants, with 9559 participants without diabetes and 2256 with undiagnosed diabetes. The characteristics of the study cohort are summarized in Table 2. The average ages were 59.76 (SD 15.0) years for those with undiagnosed diabetes and 46.78 (SD 17.2) years for those without. The diabetes group had a higher proportion of males, lower levels of education, and a greater likelihood of having a relative with diabetes. Additionally, patients with undiagnosed diabetes had higher BMI, larger waist circumference, and a higher prevalence of chronic conditions. The flow diagram of participant selection is presented in Figure 1.

Figure 1. Flow diagram of participant selection. 2-h PG: 2-hour plasma glucose; A_{1c}: hemoglobin A_{1c}; FPG: fasting plasma glucose; NHANES: National Health and Nutrition Examination Survey.

The performance of the AutoML model and traditional machine learning models is summarized in Figure 2. The AutoML model demonstrated superior performance compared to the 4 traditional machine learning models—logistic regression, support vector machines, random forest, and XGBoost. The trained AutoML model achieved an AUC of 0.909 (95% CI 0.897-0.921) and an accuracy of 86.5% in the test set. The model demonstrated a sensitivity of 70.26%, specificity of 90.46%, PPV of 64.10%, and NPV of 92.61% for identifying undiagnosed diabetes from

XSL•FO
RenderX

nondiabetes (Table 3). The model summary and details were provided in Multimedia Appendix 1.

Figure 2. Performance of AutoML model and custom machine learning models in detecting undiagnosed diabetes on the test set. AutoML: automated machine learning; XGBoost: extreme gradient boosting.

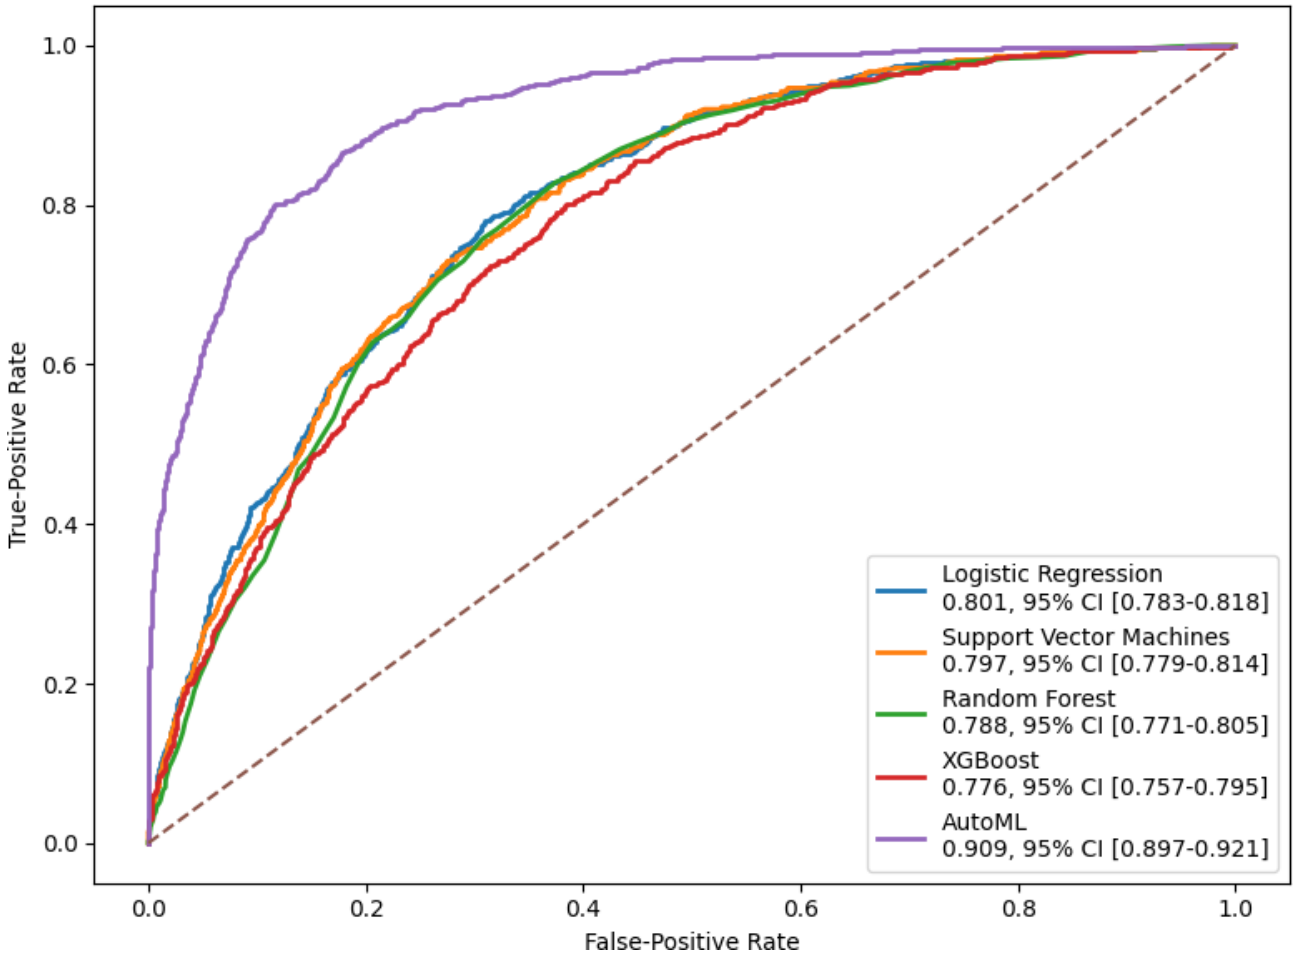

Table . Confusion matrix for the classification of undiagnosed diabetes using the AutoML model.[a]

	Predicted label, n (%)	
	No diabetes	Undiagnosed diabetes
True label		
No diabetes	2558 (73)	270 (8)
Undiagnosed diabetes	204 (6)	482 (14)

[a]Note: The cutoff threshold was 0.248718, optimized for F_1-score that maximized the harmonic mean of precision and recall. The matrix shows the distribution of true labels against predicted labels. The cell values indicate the number of instances (absolute counts) and their corresponding percentages of the total in the test data. Sensitivity (482/686, 70.26%), specificity (2558/2828, 90.45%), positive predictive value (482/752, 64.10%), and negative predictive value (2558/2762, 92.61%) are derived from the matrix to assess model performance.

The top 5 features are age, waist circumference, daily total sugar intake, income, and BMI, together accounting for 50% of total model importance. Comorbidities, except hypertension, contributed minimally relative to demographic and behavioral factors. Excluding comorbidities (except hypertension) resulted in comparable model performance, with an AUC of 0.830 and an accuracy of 85.1%.

Additional analysis results are summarized in Table 4. The model using diabetes diagnosis criteria with a confirmatory test achieved a testing accuracy of 98.0% and 89.7% with an AUC of 0.823. However, precision (ie, PPV) and recall (ie, sensitivity) were suboptimal due to the small number of patients meeting the diabetes criteria with ≥2 tests. The model demonstrated a sensitivity of 44.10%, specificity of 92.22%, PPV of 24.23%, and NPV of 96.69% for identifying undiagnosed diabetes from nondiabetes. The performance of the multiclass prediction model was poor, with an overall accuracy of 58.9% for using diagnosis criteria with ≥1 test and 67.1% for using diagnosis criteria with ≥2 tests.

XSL•FO
RenderX

[c]Not applicable.

Discussion

To our knowledge, this study is the first to utilize the AutoML model for detecting undiagnosed diabetes in US adults. The best-performing model achieved an AUC of 0.91 and an accuracy of 86.5% in the test set. National surveillance shows that nearly half of those with undiagnosed diabetes have hypertension, lipid abnormalities, or cardiovascular and chronic kidney diseases [45-48]. Delayed diagnosis of diabetes hinders the opportunities for early intervention to slow the progression of dysglycemia and its comorbidities. Our model was trained and tested using a substantial and diverse dataset comprising nationally representative survey data. The model's high accuracy and applicability to the broader US population make it a promising tool for large-scale diabetes screening efforts.

The feature importance ranking of the best-performing model highlights waist circumference, BMI, and dietary variables as key predictors, underscoring their strong links to metabolic health, insulin resistance, and dietary habits that influence diabetes risk. Lifestyle factors such as drinking frequency and physical activity also emerged as significant contributors, whereas self-reported comorbidities played a smaller role once anthropometric and behavioral measures were included. These findings align with epidemiological studies and improve the model's interpretability, providing actionable insights to prioritize targeted interventions for modifiable risk factors [49].

Machine learning has advanced clinical research but faces adoption barriers like data access, imbalances, and reliance on data science expertise for deployment [50,51]. AutoML reduces the need for machine learning expertise, enabling clinicians to use advanced technologies without programming skills and integrating them into research and clinical practice [52-55]. Despite being promising, few studies have explored the application of AutoML for diabetes diagnosis [56].

Previous studies have compared traditional machine learning models with conventional statistical models for identifying undiagnosed diabetes, demonstrating that machine learning models outperform statistical models [29,30]. These studies reported AUC values between 0.73 and 0.81, consistent with the performance of traditional models in this study. However, the reported low PPVs highlighted the limited ability of these models to accurately identify undiagnosed diabetes cases [30]. This study showed that AutoML models are superior and outperformed traditional machine learning models in detecting undiagnosed diabetes. Similarly, one study has reported that the AutoML model outperformed both individual and ensemble models in identifying patients with diabetes using electronic medical records data [57]. These findings suggest that AutoML provides a more accessible and efficient approach, eliminating the need for manual optimization while delivering superior performance.

Nonetheless, several issues with the AutoML model in diabetes screening should be noted. When applying more stringent diabetes diagnostic criteria, the accuracy reached 90%; however, precision and recall were low, likely due to the limited number of samples that met the ≥2 test criteria. H2O AutoML provides significant advantages, including its built-in class balancing functionality, which automates the handling of moderate class imbalance without requiring external implementations. Using random sampling to upsample minority classes or downsample majority classes, it effectively manages datasets with moderate imbalance, such as the 4:1 ratio under the 1+ test criterion for diabetes diagnosis in this study. However, with the stricter 2+ test criterion, the imbalance ratio rose to 24:1, likely exceeding H2O AutoML's ability to mitigate the imbalance. This severe imbalance impacted the model's ability to accurately distinguish undiagnosed diabetes from nondiabetes in unseen data, reducing precision and recall. For such highly imbalanced datasets, combining AutoML with other data resampling methods, such as Synthetic Minority Over-sampling Technique, could better improve model performance [58].

In addition, the model's performance in multiclass classification of no diabetes, prediabetes, and undiagnosed diabetes was notably poor. Prediabetes is an intermediate stage between normal glycemia and diabetes and is highly prevalent [59]. Clinically, prediabetes and diabetes, as the continuum of dysglycemia, share many overlapping risk factors, such as insulin resistance and elevated glucose levels [60], making their

XSL•FO
RenderX

differentiation challenging. The subtle metabolic differences between these conditions may not have been adequately captured by the included self-reported data. Future efforts should focus on incorporating additional features and refining the model architecture to enhance accuracy and improve its ability to identify prediabetes.

A major strength of this model is its use of NHANES data, which is nationally representative of the US population, enhancing the generalizability of the findings. The model incorporates comprehensive self-reported data, including nutritional information, for predicting undiagnosed diabetes. The application of AutoML in this study represents the first use of this approach in diabetes research, providing a foundation for further development and validation of similar models. However, the widespread adoption of our AutoML in health care requires further development and validation. False positives can lead to unnecessary tests, higher costs, and patient anxiety, while false negatives may delay treatment and worsen outcomes. Using AutoML models in real-world clinical settings requires meticulous threshold optimization and validation to achieve an appropriate balance between precision and recall. These models should be rigorously evaluated for fairness and equity, ensuring that performance does not vary significantly across demographic groups [61,62]. Practical barriers to implementing AutoML in clinical practice also include integration with electronic health record systems and the lack of trust in “black-box” models due to their opacity [31,61-63].

Several limitations should be noted. First, the definition of undiagnosed diabetes in the base model was based on a single elevated measurement, which may not fully capture the condition. However, the model still showed utility as a screening tool. Second, the model demonstrated poor performance in multiclass prediction, including prediabetes, indicating that additional feature refinement and model adjustments may be necessary to improve accuracy in 3-class predictions. Third, known diabetes diagnoses rely on self-reports, which may introduce potential recall bias and misclassification. This could lead to mislabeling cases and diminishing model performance. Although most published public health studies still rely on self-reports—hence making our study not an unusual one in using self-reports—future studies should aim to validate self-reported data against medical records where feasible to minimize errors and increase reliability of the observations. Finally, the generalizability of this model may be limited to US populations and may not extend to non-US populations.

This study demonstrates the potential of AutoML in detecting undiagnosed diabetes using self-reported and easily accessible data. Although challenges remain in accurately classifying multiple categories, including prediabetes, the model shows promise as a tool for large-scale diabetes screening. Further refinement and validation are required to improve its applicability across diverse populations.

Abstract

Background: Disease-modifying therapies ameliorate disease severity of sickle cell disease (SCD), but hematopoietic cell transplantation (HCT), and more recently, autologous gene therapy are the only treatments that have curative potential for SCD. While registry-based studies provide population-level estimates, they do not address the uncertainty regarding individual outcomes of HCT. Computational machine learning (ML) has the potential to identify generalizable predictive patterns and quantify uncertainty in estimates, thereby improving clinical decision-making. There is no existing ML model for SCD, and ML models for HCT for other diseases focus on single outcomes rather than all relevant outcomes.

Objective: This study aims to address the existing knowledge gap by developing and validating an individualized ML prediction model SPRIGHT (Sickle Cell Predicting Outcomes of Hematopoietic Cell Transplantation), incorporating multiple relevant pre-HCT features to make predictions of key post-HCT clinical outcomes.

Methods: We applied a supervised random forest ML model to clinical parameters in a deidentified Center for International Blood and Marrow Transplant Research (CIBMTR) dataset of 1641 patients who underwent HCT between 1991 and 2021 and were followed for a median of 42.5 (IQR 52.5;range 0.3 - 312.9) months. We applied forward and reverse feature selection methods to optimize a set of predictive variables. To counter the imbalance bias toward predicting positive outcomes due to the small number of negative outcomes, we constructed a training dataset, taking each outcome as variable of interest, and performed 2-times repeated 10-fold cross-validation. SPRIGHT is a web-based individualized prediction tool accessible by smartphone, tablet, or personal computer. It incorporates predictive variables of age, age group, Karnofsky or Lansky score, comorbidity index, recipient cytomegalovirus seropositivity, history of acute chest syndrome, need for exchange transfusion, occurrence and frequency of vaso-occlusive crisis (VOC) before HCT, and either a published or custom chemotherapy or radiation conditioning, serotherapy, and graft-versus-host disease prophylaxis. SPRIGHT makes individualized predictions of overall survival (OS), event-free survival, graft failure, acute graft-versus-host disease (AGVHD), chronic graft-versus-host disease (CGVHD), and occurrence of VOC or stroke post-HCT.

Results: The model's ability to distinguish between positive and negative classes, that is, discrimination, was evaluated using the area under the curve, accuracy, and balanced accuracy. Discrimination met or exceeded published predictive benchmarks with area under the curve for OS (0.7925), event-free survival (0.7900), graft failure (0.8024), acute graft-versus-host disease (0.6793), chronic graft-versus-host disease (0.7320), and VOC post-HCT (0.8779). SPRIGHT revealed good calibration with a slope of 0.87 - 0.96, with small negative intercepts (–0.01 to 0.03), for 4 out of the 5 outcomes. However, OS exhibits nonideal calibration, which may be reflective of the overall high OS in all subgroups.

Conclusions: A web-based ML prediction tool incorporating multiple clinically relevant variables predicts key clinical outcomes with a high level of discrimination and calibration and has potential in shared decision-making

Introduction

The complications of sickle cell disease (SCD) can be prevented or ameliorated by disease-modifying therapies [1], but hematopoietic cell transplantation (HCT), and more recently, gene therapy remain the only therapeutic options with curative intent [2-12]. Population-level studies demonstrate the association of outcomes of HCT with age, type of donor, type of conditioning, and graft-versus-host disease (GVHD) prophylaxis [5,6], but do not address the uncertainty regarding individualized outcomes of HCT. Such uncertainty contributes to the decisional dilemma and is a barrier to shared decision-making. An individualized prediction model that incorporates all predictive variables and provides individualized estimates of key outcomes of HCT of interest to patients and their physicians has the potential to inform shared decision-making [13-15]. Brazauskas et al [16] have proposed a predictive model based on the age of the recipient and the type of donor. However, their model does not incorporate other clinically relevant patient, HCT, and disease characteristics and does not include all key outcomes. Computational machine learning (ML) has the potential to determine generalizable predictive patterns and quantify uncertainty, but published ML predictive models for HCT are limited to predicting single clinical outcomes [17-30]. To address the knowledge gap, we developed and described the initial validation of SPRIGHT (Sickle Cell Predicting Outcomes of Hematopoietic Cell Transplantation), an individualized ML prediction model for outcomes of HCT for SCD, incorporating multiple relevant features to make predictions of key clinical outcomes.

Methods

Dataset

We developed SPRIGHT using an anonymized HCT for the SCD dataset [31] derived from data submitted to the Center for International Bone Marrow Transplant Research (CIBMTR) registry on children and adults undergoing HCT for SCD between 1991 and 2021 in the United States. The dataset was obtained through the NHLBI (National Heart Lung and Blood Institute) Biologic Specimen and Data Repository Information Coordinating Center (BIOLINCC) [32].

The CIBMTR maintains a research database to serve as a comprehensive data source that can be used to study cellular therapies, including HCT. All US transplant centers are required to submit outcomes data on all allogeneic transplants when either the stem cell donation or the transplant occurs within the United States. CIBMTR assigns patients to either a Transplant Essential Data (TED) track, which collects core transplant data, or a Comprehensive Report Form (CRF) track that captures detailed disease- and treatment-related data [31]. Assignment to each track is based on submission of the initial pretransplantation TED 2000032419 form and uses a weighted randomization algorithm designed to produce a cohort representative of current clinical practice. All centers submit a Pre-HCT TED Form (Form 2400) for each allogeneic (related or unrelated) HCT.

Of 1641 patients undergoing HCT for SCD between 1991 and 2021, on whom data were submitted to CIBMTR, detailed CRFs were submitted on 763 patients. Of the patients in the dataset, 84% (1377/1641) had undergone HCT after 2007. We performed the imputation of missing data using MissForest, an ML data imputation algorithm that operates on random forest (RF).

Feature Selection

We identified overall survival (OS), event-free survival (EFS), graft failure (GF), acute graft-versus-host disease (AGVHD), and chronic graft-versus-host disease (CGVHD) as key outcomes. We used wrapper methods of backward feature elimination (BFE) and forward sequential selection (FSS) to select and optimize the input variables [33,34]. The BFE procedure begins with a complete set of features and a chosen ML model. The model is trained, and the importance of each feature is evaluated based on the model's coefficients or feature importance scores, and then the least important feature is discarded, and the model is retrained on the remaining features. This process is repeated until a predetermined number of features is reached or until further removal of features leads to a significant decrease in model performance. Using FSS, we incrementally built a feature set starting with an empty model, sequentially adding a feature that most improves the model performance at each step, as evaluated through a predefined metric like cross-validation score. We continued this stepwise addition until new features no longer significantly enhanced the model or a specified number of features was reached. We have included the detailed descriptive statistics and missingness for each of the selected features and outcomes of interest in Table S3 in Multimedia Appendix 1 and Table S4 in Multimedia Appendix 2

Model Design

The model was designed by subsampling the majority class to create subtraining datasets, followed by pooling and thresholding to obtain the final prediction [35]. We determined the discriminative performance of the model, which refers to how well the predictions can separate between 2 groups of participants, that is, those with or without an outcome. Discrimination was quantified by the concordance (c) statistic (index), which for binary outcomes, is equivalent to the area under the curve (AUC). We also assessed accuracy, that is, the percentage of correct predictions out of all predictions correct or incorrect in the model. We also assessed balanced accuracy, which is an accuracy adjusted for imbalance and is derived by averaging sensitivity and specificity, so that each class's importance is equal. We compared RF, extreme gradient boosting, logistic regression, Naive Bayes, AdaBoost, and support vector classification algorithms (Table 1). The HCT for SCD dataset spans children and adults undergoing HCT between 1991 and 2021. During this time, there have been many changes in conditioning regimens and improvements in supportive care. Gluckman et al [6] reported that EFS was higher in patients who underwent HCT in or after 2007 as compared to those who underwent HCT in or before 2006 (HR [hazard ratio] 0.95, CI 0.90 - 0.99; P=.01). To determine if the model performed consistently across eras, we tested model performance in patients with the year of HCT <2007 versus HCT >2007. We also tested

XSL•FO
RenderX

model performance across age at HCT <10, <18, and >18 years, respectively, including outcomes at 1- and 3-year post-HCT (Table 2).

[e]CGVHD: chronic graft-versus-host disease.

The accuracy of risk estimates, relating to the agreement between the estimated and observed number of events, is called "calibration [36,37]." Calibration is crucial in predictive algorithms because it ensures the accuracy of risk estimates, which directly affects clinical decision-making and patient expectations. Poor calibration can lead to systematic overestimation or underestimation of risk, resulting in false expectations and potentially harmful decisions [36]. We performed causal isotonic calibration, a novel nonparametric method for calibrating predictors of heterogeneous treatment effect [37]. We performed a 5-fold internal cross-validation on the training set to determine the optimal calibration. The resultant calibration model was then applied to the predictions during evaluation. To adjust for the bias caused due to undersampling, we recalibrate the probabilities according to the method by Pozollo et al [38]. We evaluated the calibration curve, slope, and intercept across different outcomes of interest in the post-2007 data (Table 3).

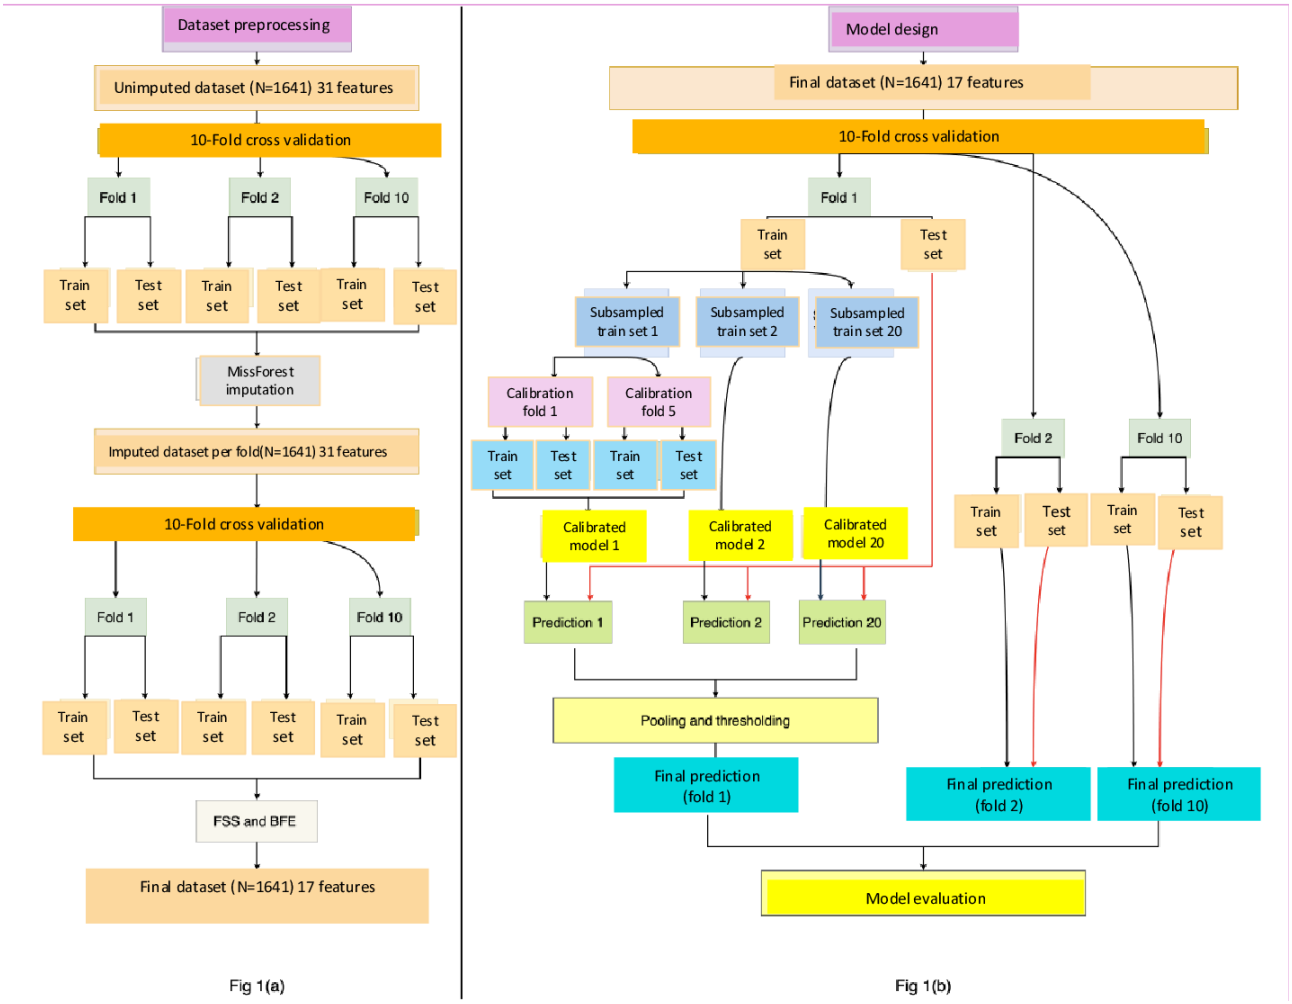
[b]OS: overall survival.

[c]GF: graft failure.

[d]AGVHD: acute graft-versus-host disease.

[e]CGVHD: chronic graft-versus-host disease.

To understand the contributions of each feature to the predictive model, we use the Shapley additive explanations (SHAP) scores (Multimedia Appendices 3-7). SHAP scores are based on game theory's Shapley values, quantifying each feature's marginal contribution to individual predictions. They are calculated by measuring how each feature affects the model output when included or excluded from all possible feature combinations.



The Problem of Imbalance

The outcomes data for HCT for SCD is imbalanced, with very few negative outcomes. This imbalance has the potential to lead to a prediction bias, where an uncorrected model default may be skewed toward predicting positive outcomes. To address the problem of imbalance, we constructed a training dataset taking each outcome as variable of interest. We included randomly sampled positive outcomes, typically 1.5 - 3 times the total instances of the variable of interest. To address the issue of class imbalance, we used a 2-step approach involving bootstrapping and consensus-based decision-making. Initially, we generated 20 bootstrapped datasets by undersampling the majority class to achieve a (2-3):1 ratio with the minority class. These datasets served as the training sets for our predictive models, ensuring a balanced representation of classes during model training. Once the models were trained, each was then tested on a consistent test dataset to obtain a series of predictions. These individual predictions were subsequently pooled across all models. A final prediction model for each test instance was determined based on a consensus threshold. If the majority of the models exceeded a predetermined threshold agreed on a particular class, that class was assigned as the outcome for the instance. We ran the test dataset and used a RF algorithm on a 2-times repeated 10-fold cross-validation to demonstrate our model's versatility and response to unknown data (Figure 1). We assigned value 1 for a negative outcome prediction and −1 for a positive outcome prediction and found the average sum across the 20 trials for each element.

Throughout the paper, we are guided by the CREMLS (Consolidated Reporting of Machine Learning Studies) guidelines [39], to ensure transparency and rigor in reporting. We have attached a completed author CREMLS checklist.

Ethical Considerations

The Institutional Review Board at Yale University determined on March 3, 2033, that this study did not constitute human participants research per IRB protocol number 2000032419.

Results

Feature Selection and Optimization

Of the 160 variables in the dataset, we selected 31 potentially clinically relevant predictive variables. Through FSS and BFE processes, we selected a final set of 17 predictive variables grouped into 3 categories. Patient Data variables included age at transplant, age group at transplant, sex, Karnofsky or Lansky score, HCT-comorbidity index, and recipient CMV serostatus. SCD variables included Number of ACS syndromes within 2 years pre-HCT, Required exchange transfusion, Vaso-occlusive crisis needing hospitalization in 2 years pre-HCT, and Hospitalization frequency for vaso-occlusive crises. Transplant Data variables included Donor type, Graft type, Conditioning intensity, Conditioning regimen, Serotherapy (ATG or Alemtuzumab), GVHD prophylaxis, and Donor-recipient HLA matching.

Evaluation Outcomes and Model Performance

Discrimination in predictive performance is evaluated using accuracy, the percentage of correct predictions out of all predictions, balanced accuracy, the average sensitivity and specificity, and each class's importance is equal, and AUC, the measure of a model's true positive rate against a false positive rate, indicates the ability to differentiate classes. AUC is the metric used in published literature. The RF model achieved the highest predictive AUC (Table 1) across multiple clinical outcomes. We measure our model's performance using the benchmark established in the literature. To determine the statistical validity, we implemented the method proposed by Bouckaert and Frank [40]. We first performed 2×10 repeated cross-validation and obtained the performance of each of the models for each fold. We then applied Nadeau and Bengio's [41] correction, which accounts for training set overlap in the variance estimation, to check whether the mean AUC of the RF is greater than the mean AUC of the other models across folds. The differences in the mean AUC were statistically significant for EFS, OS, GF, AGVHD, and CGVHD (P<.05). We performed hyperparameter tuning using grid search cross-validation for the RF model. The ideal hyperparameters are described in Table 4. AUC, accuracy, and balanced accuracy equaled or exceeded the benchmarks of the ML predictive tools in the published literature [16,42]. The RF model has been

XSL•FO
RenderX

previously reported to have the best AUC in predicting survival following HCT [24]. Brazauskas et al [16] published benchmark AUC for EFS of 0.72, and Taheriyan et al [42] reported benchmarks AUC 0.82 for AGVHD post-HCT. Accuracy and balanced accuracy were excellent for EFS (0.76, 0.69), OS (0.82, 0.68), GF (0.8, 0.71), vaso-occlusive pain post-HCT (0.9, 0.78), stroke post-HCT (0.92, 0.65), acute GVHD (0.71, 0.60), CGVHD (0.72, 0.63).

Table . Final tuned hyperparameters of the random forest model for each outcome.

Outcome of interest	Random forest hyperparameters					
	Max depth	Min samples split	Min samples leaf	Criterion	CCP_alpha[a]	Max features
EFS[b]	20	10	16	entropy	0.0	0.7
OS[c]	20	10	8	entropy	0.01	0.125
GF[d]	20	20	16	entropy	0.0	0.5

[b]EFS: event-free survival.

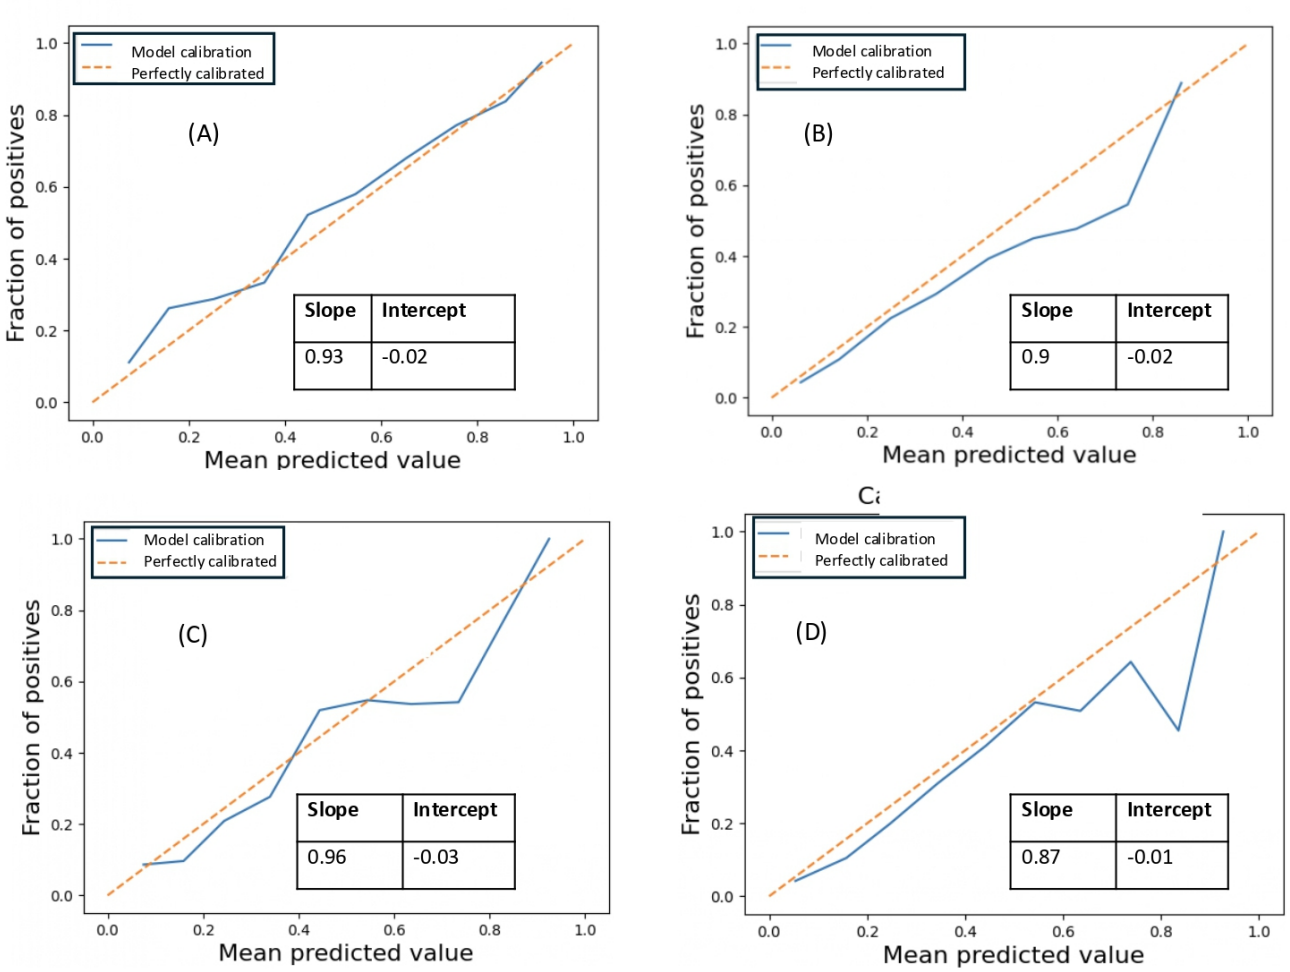
[c]OS: overall survival.

[d]GF: graft failure.

[e]AGVHD: acute graft-versus-host disease.

[f]CGVHD: chronic graft-versus-host disease.

SPRIGHT retained high AUC in subpopulations, including patients ≤10, ≤18, >18 of age in undergoing HCT after 2007, as well as 1- and 3-year survival analysis (Table 1).



Calibration is the agreement between the estimated and observed number of events, for major outcomes. A calibration slope of 1 and an intercept close to zero are associated with good calibration. SPRIGHT revealed good calibration with a slope range of 0.87 - 0.96, with small negative intercepts (−0.01 to 0.03), for 4 out of the 5 outcomes. However, OS exhibits nonideal calibration and may be reflective of the overall high OS in all subgroups (Figure 2).

Feature importance analysis using SHAP values revealed consistent patterns across all outcomes. Age at transplantation and donor type emerged as the most influential predictors, corroborating previous findings by Brazauskas et al [16] and Eapen et al [5]. Disease severity indicators, most importantly the frequency of acute chest syndrome episodes in the 2 years preceding HCT, were identified as another critical predictor. The frequency of VOC requiring hospitalization and the need for exchange transfusions also demonstrated substantial predictive importance. This suggests the utility of including pretransplant disease characteristics for predicting outcomes. The comprehensive SHAP analysis, including feature importance rankings and their relative contributions to model predictions, is presented in Multimedia Appendices 3-7.

To demonstrate the clinical utility of our model, we analyzed predictions across 3 distinct hypothetical patient scenarios. Case-specific patient characteristics and their corresponding predicted outcomes are detailed in Table 5 Table S3 in Multimedia Appendix 8 respectively. The model's predictions aligned with established clinical observations, showing less favorable outcomes in cases involving non-HLA identical donors and in older patients with more severe disease characteristics, which were consistent with previous studies [5,16].

SPRIGHT User Interface

Age is the only numeric feature that is entered manually. The rest of the inputs are categorical and are entered by selecting an option from a drop-down menu. Patient-specific, disease-specific data, and treatment donor, one of the major published treatment regimens or a customized conditioning regimen, conditioning intensity, and GVHD prophylaxis ATG/Alemtuzumab data can be entered. The tabular output describes predicted OS, EFS, GF, Death, AGVHD, CGVHD, VOC, and stroke. The predicted outcomes are also pictorially represented in pie charts. One unique feature is that the user has the option of selecting a published HCT regimen or selecting a custom regimen by combining conditioning, GVHD prophylaxis, and serotherapy (Figure 3; Table S4 in Multimedia Appendix 9). This feature decreases keystrokes, improves ease of use of the app, and facilitates a comparative analysis across donor types and treatment regimens for different donor types.

XSL•FO
RenderX

SPRIGHT can be accessed on any smartphone, tablet, or personal computer using a shortened URL or a QR code. The individualized outcomes are also represented as pie charts displaying individualized estimates (Figure 3). The pie charts can be downloaded and shared with the patient or added to the electronic medical record as an image.

Figure 3. Clinician user interface of sickle cell predicting outcomes of hematopoietic cell transplantation

Variable	Description	Probability
EFS	Event Free Survival	89.3
DEAD	Death	2.1
OS	Overall Survival	97.9
GF	Graft Failure	14.3
VOCPSHI	Vaso Occlusive Pain since HCT	10.8
STROKEHI	Stroke Post HCT	11.6
AGVHD	Acute graft versus host disease, grades II-IV	8.2
CGVHD	Chronic graft-vs-host disease	13.6

Discussion

Principal Findings

We describe the development and internal validation of SPRIGHT, which, to the best of our knowledge, is the first ML individualized prediction tool for HCT for SCD. Eapen et al [5] identified age, donor type, and conditioning regimen intensity as critical predictive factors of outcomes of HCT for SCD. Gluckman et al [6] identified age and year of transplant as critical factors. Younger patients were shown to have higher EFS. Cappelli et al [43] reported better OS and EFS and a lower incidence of AGVHD and CGVHD in younger patients. Together, these registry-based studies generated important population-level predictive factors of HCT for SCD. They do not, however, provide a means to combine patient, transplant, and disease characteristics into a personalized predictive model for outcomes of HCT. The SPRIGHT prediction model incorporates multiple relevant pre-HCT predictive factors for the individualized production of key clinically relevant post-HCT outcomes. The RF algorithm outperforms the Brazauskas model, other ML algorithms, and logistic regression in predictive performance. The RF-based SPRIGHT prediction model has high predictive discrimination and calibration performance. The excellent discriminative predictive performance is demonstrated by the high value of AUC across all outcomes across all eras, age groups, and follow-up periods of 1 or 3 years. Going beyond the commonly reported predictive discrimination with AUC, we also reported accuracy and balanced accuracy and calibration measures of calibration curve, slope, and intercept. An important innovation of SPRIGHT is the option for the end user to select a published regimen that combines chemotherapy or radiation conditioning, serotherapy, and GVHD prophylaxis. This innovation simplifies the decision-making process for clinicians and allows them to compare potential outcomes across different regimens and donor types. Thus, SPRIGHT helps physicians and patients in discerning the nuances in efficacy and safety of HCT for the individual and has the potential to inform and guide shared decision-making. To mitigate overfitting and validate model performance, we used 10-fold cross-validation, ensuring robustness by mimicking multiple tests on independent datasets. This method approximates the effectiveness of external validation by exposing the model to various training and validation splits, thus predicting its behavior on unseen data. We addressed potential feature collinearity using recursive feature elimination for feature selection and RFs, which inherently mitigate correlation effects through random feature subsampling at each tree.

XSL•FO
RenderX

Limitations

There are several limitations to this study. The SPRIGHT predictive tool is based on the HCT for the SCD dataset derived from data reported to CIBMTR. The use of the CIBMTR dataset allows us to access the entire US experience reported, but it is also subject to limitations of registry studies, including bias, loss to follow-up, and a lack of generalizability across era, center volume, and expertise. While SPRIGHT uses multiple predictive variables, it is limited to those variables collected by CIBMTR. In 2019, Bolanos-Meade et al [44] reported an improved EFS following mismatched relative donor HCT as compared to their previous report in 2009 following the escalation of the dose of total body irradiation from 200 to 400 cGy [6,45]. However, CIBMTR form 2400 and consequently the HCT for the SCD dataset do not distinguish between patients who received the 2 dose levels of total body irradiation. Further, since pain crisis post-HCT is included as a discrete variable in the HCT for the SCD dataset, it is not possible to discern its timing, frequency, or severity. In the CIBMTR dataset, an analysis of predictor completeness reveals that 10/13 TED variables chosen have a completion rate exceeding 98%. However, only approximately 46.5% (763/1641) of patients are on the CRF track, with comprehensive disease-specific data available, a category under which 4 of our predictor variables fall. While the missing data could be a source of bias, the missingness of data was only a function of whether the institution was designated as a TED-only or CRF and whether the CIBMTR algorithm assigned an individual patient to the CRF track. Thus, the missing data may be missing at random. The model we used for imputation, MissForest, has been shown to outperform all other algorithms in all metrics [46,47]. However, these imputation algorithms can produce severely biased regression coefficients and require a careful critique of the missing data mechanism and the interrelationships between the variables in the data [48]. Overall, we acknowledge the concerns regarding the lack of details of SCD-related complications and the completeness of reporting of SCD-related clinical outcomes in the CIBMTR dataset. We, however, also recognize that the CIBMTR registry, with federally mandated data submission, contains the most complete data available. We support ongoing efforts to refine the data collection measures and training of data collection staff. One of the limitations of our model is the rarity of death events in the dataset, which limits the precision of calibration for OS. As a result, the model tends to slightly overestimate OS risk, particularly in subgroups with fewer events. This calibration limitation should be considered when interpreting OS predictions. Across all outcomes, despite mitigatory efforts to combat the inherent bias due to class imbalance, the bias may not be fully eradicated.

The tool incorporates a set of treatment regimens that have been carefully selected from peer-reviewed studies, ensuring that they are backed by sufficient clinical data. These regimens provide reliable and evidence-based predictions. However, custom combinations that are entered by users may fall outside of the dataset's training and may not be fully supported by the underlying data. In such cases, it is essential to rely on clinical expertise and user discretion when interpreting the predictions.

We recognize a limitation in the registry data due to inherent selection bias, with limited insight into the clinical reasoning behind regimen choices. While the data detail the regimens administered, the underlying clinical judgment is often not recorded. This limitation is particularly notable in HCT, where the absence of universally established standards of care presents additional challenges. Thus, the model and its results should be interpreted within this context.

Comparison With Prior Work

Brazauskas et al [16] developed a risk score using age and donor type as discrete variables. They reported that patients aged ≤12 years with an HLA-matched sibling donor were at the lowest risk. Patients aged ≥13 years with an HLA-matched sibling donor or aged ≤12 years with an HLA-matched unrelated donor were at intermediate risk. All other groups were at high risk. This simple risk score has good predictive performance but has certain gaps that limit its utility in the individualized prediction of outcomes. Gluckman et al [6] used age as a continuous variable and observed that for every 1-year increment in age, there was a 9% increase in the HR for treatment failure (graft failure or death) and a 10% increase in the HR for death. Thus, the Brazauskas model does not include the potential predictive value of increasing age from 5 to 13 years. Further, Brazauskas et al [16] do not incorporate other patient, disease, and conditioning regimen characteristics in the prediction model because they considered these factors to be dynamic and subject to change. The Brazauskas model limits the predicted post-HCT outcomes to death, OS, and EFS and does not include other outcomes that are important to physicians and patients in shared decision-making, such as AGVHD, CGVHD, recurrent pain crisis, or stroke after HCT [13,49-51]. SPRIGHT predicts these outcomes with high predictive performance. Other published ML predictive models for HCT for other diseases are of limited clinical relevance in decision-making since they limit themselves to predicting single outcomes, such as death, overall survival, disease relapse, GVHD, busulfan exposure, kidney injury, or reactivation of Epstein-Barr virus [17-30].

In developing SPRIGHT, we addressed the gaps in the knowledge in individualized prediction of outcomes of HCT. We included 7 clinically relevant outcomes, including rates of OS, EFS, GF, death, AGVHD, CGVHD, and VOC. Each of these 7 clinical outcomes initially required a distinct set of 10 - 11 pre-HCT predictive features for optimal performance, leading to incomplete overlap and potential model fragmentation. For addressing this, we adopted a unified approach by selecting a comprehensive set of 17 pre-HCT patient, HCT, and disease characteristics. By applying robust feature selection techniques to optimize predictive performance and improve the model's overall clinical applicability, we demonstrated the predictive value of these features. Further, patient and disease features inform patient selection and HCT features inform regimen selection. Thus, these additional pre-HCT features are important, clinically relevant considerations in decision-making.

Future Directions

We present here an initial in-lab validation of the predictive model. We recognize that the use of a US-based dataset may

XSL•FO
RenderX

limit the generalizability of our findings to other regions or health care systems due to potential differences in population characteristics and treatment protocols. For further external validation across different geographic locations to establish the model's generalizability and clinical utility, we propose to use the European Bone Marrow Transplantation Registry (EBMT) dataset, a completely independent dataset, in collaboration with European investigators. Of note, Gluckman et al [6] have previously combined CIBMTR and EBMT registry data on SCD for analysis and included similar numbers of children, adults, and donor types from the 2 registries and do not report differences in predictive factors or outcomes in the 2 registries. We have demonstrated that the predictive performance remains equivalent whether we use the entire dataset or the more recent data after 2007, which represents 84% (1378/1641) of participants in the dataset. Acknowledging the evolving nature of supportive care practices in HCT, we propose further temporal validation with future years of data being added to this dataset. We also propose to continue to enhance SPRIGHT by incorporating expert opinion, adapting to patient health literacy, values, and preferences, and using patient-friendly data visualization to support shared decision-making [52-54].

Conclusions

In conclusion, the SPRIGHT prediction model integrates individual-specific patient and disease characteristics, conditioning regimens, GVHD prophylaxis, and donor characteristics and predicts key clinical outcomes. It exhibits superior predictive performance across multiple measures of discrimination and calibration as compared to logistic regression and other ensemble ML methods.

Data Availability

The National Institutes of Health (NIH) Hematopoietic Cell Transplantation for Sickle Cell Disease dataset used to develop the clinical decision tool was obtained from the NHLBI Biologic Specimen and Data Repository Information Coordinating Center (BIOLINCC) [31]. For additional questions on the algorithms used for the decision tool, investigators may contact the corresponding author by email.

Abstract

Background: Accurate and timely electrocardiogram (ECG) interpretation is critical for diagnosing myocardial infarction (MI) in emergency settings. Recent advances in multimodal large language models (LLMs), such as ChatGPT (OpenAI) and Gemini (Google DeepMind), have shown promise in clinical interpretation for medical imaging. However, whether these models analyze waveform patterns or simply rely on text cues remains unclear, underscoring the need for direct comparisons with dedicated ECG artificial intelligence (AI) tools.

Objective: This study aimed to evaluate the diagnostic performance of ChatGPT and Gemini, a general-purpose LLM, in detecting MI from ECG images and to compare its performance with that of ECG Buddy (ARPI Inc), a dedicated AI-driven ECG analysis tool.

Methods: This retrospective study evaluated and compared AI models for classifying MI using a publicly available 12-lead ECG dataset from Pakistan, categorizing cases into MI-positive (239 images) and MI-negative (689 images). ChatGPT (GPT-4o, version November 20, 2024) and Gemini (Gemini 2.5 pro) were queried with 5 MI confidence options, whereas ECG Buddy for Microsoft Windows analyzed the images based on ST-elevation MI, acute coronary syndrome, and myocardial injury biomarkers.

Results: Among 928 ECG recordings (239/928, 25.8% MI-positive), ChatGPT achieved an accuracy of 65.95% (95% CI 62.80 - 69.00), area under the curve (AUC) of 57.34% (95% CI 53.44 - 61.24), sensitivity of 36.40% (95% CI 30.30 - 42.85), and specificity of 76.2% (95% CI 72.84 - 79.33). With Gemini 2.5 Pro, accuracy dropped to 29.63% (95% CI 26.71 - 32.69), AUC to 51.63% (95% CI 50.22 - 53.04), and sensitivity rose to 97.07% (95% CI 94.06 - 98.81), but specificity fell sharply to 6.24% (95% CI 4.55 - 8.31). However, ECG Buddy reached an accuracy of 96.98% (95% CI 95.67 - 97.99), AUC of 98.8% (95% CI 98.3 - 99.43), sensitivity of 96.65% (95% CI 93.51 - 98.54), and specificity of 97.10% (95% CI 95.55 - 98.22). DeLong test confirmed that ECG Buddy significantly outperformed ChatGPT (all $P<.001$). In a qualitative error analysis of LLMs' diagnostic explanations, GPT-4o produced fully accurate explanations in only 5% of cases (2/40), was partially accurate in 38% (15/40), and completely inaccurate in 58% (23/40). By contrast, Gemini 2.5 Pro yielded fully accurate explanations in 32% of cases (12/37), was partially accurate in 14% (5/37), and completely inaccurate in 54% (20/37).

Conclusions: LLMs, such as ChatGPT and Gemini, underperform relative to specialized tools such as ECG Buddy in ECG image–based MI diagnosis. Further training may improve LLMs; however, domain-specific AI remains essential for clinical accuracy. The high performance of ECG Buddy underscores the importance of specialized models for achieving reliable and robust diagnostic outcomes.

Introduction

Electrocardiogram (ECG) interpretation is a fundamental skill in cardiovascular medicine, playing a crucial role in diagnosing conditions such as ST-elevation myocardial infarction (STEMI), arrhythmias, and electrolyte imbalances [1]. Accurate and timely ECG analysis is critical in clinical decision-making, particularly in emergency settings where rapid interventions impact patient outcomes.

With advancements in artificial intelligence (AI), researchers have explored using various deep learning techniques, including convolutional neural networks and transformer-based models, to automate ECG interpretation by extracting clinically relevant features from ECG signal or image data [2-5].

Recently, multimodal large language models (LLMs) trained on textual and imaging data have gained attention in the medical field [6]. These models have demonstrated the ability to generate diagnostic reports, highlighting their potential for medical image interpretation [7]. As LLMs have become increasingly sophisticated, the interest in applying similar multimodal architectures to ECG interpretation has also grown.

General-purpose LLMs, such as ChatGPT (OpenAI), have recently demonstrated some capabilities in assisting with image interpretation and text-based medical assessments [8,9]. Unlike traditional AI models specifically trained for ECG signal processing, these models leverage extensive general knowledge and are now being considered for processing visual medical data, including ECG images. For example, Zaboli et al [10] investigated the ECG interpretation ability and outcome prediction of ChatGPT in the emergency department and found moderate agreement with cardiologists, but with notable discrepancies in major adverse cardiac event risk assessment. Zhu et al [11] reported that GPT-4 achieved approximately 83% accuracy in multiple-choice ECG diagnostic questions. Günay et al [12] compared GPT-4, GPT-4o, and Gemini Advanced (Google DeepMind) against cardiologists and emergency medicine specialists using routine and challenging ECG cases. Although all LLMs underperformed compared to cardiologists, GPT-4o showed relatively better accuracy and moderate agreement, suggesting potential as a supportive tool in clinical settings. Similarly, Avidan et al [13] examined the ability of GPT-4o to detect atrial fibrillation in ECGs with confounding factors. Their findings indicated that while the overall accuracy of GPT-4o was comparable to that of internists and primary care physicians, it fell short of cardiologists' performance, particularly in challenging scenarios. In contrast, Günay et al [14] reported that GPT-4 outperformed emergency medicine specialists in interpreting everyday ECG cases and performed on par with cardiologists when facing more complex ECG challenges. However, a key limitation of their study is that ECG descriptions rather than actual ECG images were evaluated by GPT-4, potentially limiting its applicability in clinical settings.

Collectively, these studies highlight that although LLM-based approaches in ECG interpretation hold promise, their reliability in complex cases remains limited. Moreover, it remains unclear whether these models truly analyze waveform patterns or simply rely on text-based cues, such as machine-readable annotations. This raises concerns about the reproducibility of the models' interpretations when presented with raw ECG images alone.

To date, no study has systematically compared the performance of LLMs against specialized ECG diagnostic AI tools. This comparison is becoming increasingly relevant, as general-purpose LLMs are not specifically designed for cardiovascular medicine. However, speculation about their potential applications in ECG interpretation is already widespread. Thus, a comparative evaluation with dedicated ECG AI software is necessary to determine the feasibility of LLM-based ECG interpretation in clinical practice.

Recent studies comparing ChatGPT-4o with Gemini on ECG interpretation tasks identify both models as suitable reference LLMs, so we included them in our evaluation [12]. We then benchmarked their performance against ECG Buddy (ARPI Inc.), a commercially available, domain-specific AI tool for ECG analysis.

ECG Buddy is approved by the Korean Ministry of Food and Drug Safety, South Korea's regulatory agency for medical device oversight, responsible for thorough examinations and continuous supervision, and is currently in routine clinical use at multiple hospitals, including tertiary care centers. ECG Buddy has been validated in multiple studies, demonstrating superior diagnostic accuracy to clinical experts in detecting conditions such as myocardial infarction (MI), hyperkalemia, and right ventricular (RV) dysfunction [15-18].

This study aimed to evaluate the diagnostic performance of ChatGPT and Gemini relative to a dedicated ECG AI (ECG Buddy) in analyzing ECG images for MI detection. MI interpretation is one of the most essential aspects of ECG analysis. Through this comparative study, we aimed to determine whether LLMs could currently be used for ECG interpretation in clinical practice.

Methods

Study Design and Data Preparation

In this retrospective study, we evaluated the performance of ChatGPT, Gemini, and ECG Buddy in classifying MI from ECG images. A publicly available 12-lead ECG image dataset compiled by the Ch. Pervaiz Elahi Institute of Cardiology in Multan, Pakistan, was used [19]. The dataset includes ECG images categorized into the following 4 groups: patients with MI (239 images), patients with abnormal heartbeats (233 images), patients with a history of MI (172 images), and healthy controls (284 images). This publicly available, fully deidentified ECG image dataset was chosen to enable reproducible benchmarking without privacy constraints and is frequently referenced in prior studies. The dataset does not provide additional patient information beyond these labels. It lacks metadata such as infarct territory or cardiac biomarker data

XSL•FO
RenderX

needed to differentiate STEMI from non-STEMI (NSTEMI). Therefore, further analyses by infarct location or NSTEMI status were not possible.

This study was designed and reported in accordance with the TRIPOD-LLM (Transparent Reporting of a Multivariable Prediction Model for Individual Prognosis Or Diagnosis specifically tailored for LLM) guidelines, a comprehensive reporting framework for studies involving LLMs in health care, to ensure that every step, from data processing and image-to-text conversion to AI querying and performance evaluation, was transparently and reproducibly documented [20]. To ensure consistency in data processing, extraneous areas of the images, including any supplementary text not related to patient information or diagnosis, were cropped, retaining only the waveform regions. No raster-to-signal conversion was applied, and all analyses were performed directly on the image data. For classification, only the images labeled as "patients with myocardial infarction" were designated as MI-positive, representing active MI cases. The remaining 689 images, comprising abnormal heartbeats, history of MI, and healthy cases, were classified as MI-negative.

AI Query and Output (ChatGPT and Gemini)

The identical workflow was applied to 2 multimodal LLMs—GPT-4o (OpenAI, version November 20, 2024) and Gemini 2.5 Pro (Google, May 2025 release). To assess the ability of LLMs to classify MI from ECG images, we designed a structured prompt aimed at systematically capturing the model's diagnostic rationale and confidence in detecting MI. Before querying, ECG images were converted into base64 format, a lossless binary-to-text format required by both application programming interfaces (APIs) and one that preserves every pixel and ensures no loss of ECG signal fidelity.

Each LLM received the base64-encoded images and prompted explicitly to analyze them, determine the likelihood of MI, and select from 5 predefined response categories—unknown, unlikely, possible, probable, and definite—representing increasing diagnostic certainty. Both LLMs were queried with the prompt shown in Textbox 1, which presents the ChatGPT-4o version; the Gemini 2.5 Pro prompt was identical, differing only in that the model name was replaced with "GPT-4o."

To define a positive MI diagnosis based on this likelihood measure, the Youden index was applied to determine an optimal cutoff. Specifically, ChatGPT was instructed to identify and specify which ECG leads exhibited abnormalities, describe the changes observed (such as ST-segment elevation, T-wave inversion, or pathological Q waves), and provide detailed reasoning supporting its diagnostic conclusion. In cases where no abnormalities were noted or the ECG findings were ambiguous, the model was prompted to discuss potential alternative diagnoses or clearly explain why the ECG appeared normal. All queries were conducted using GPT-4o via the ChatGPT API. An example of a typical ChatGPT response is illustrated in Figure 1. All inferences were conducted as single-turn prompts, since each case consisted only of a deidentified ECG image with no ancillary clinical or serial ECG data that could support further interaction, and our study aimed to evaluate the models' final diagnostic performance.

Figure 1. Example electrocardiogram images and ChatGPT model output for myocardial infarction detection. ECG: electrocardiogram.

Based on the provided ECG image, the confidence level regarding the presence of Myocardial Infarction (MI) is "Possible." Here's the detailed explanation for this choice:

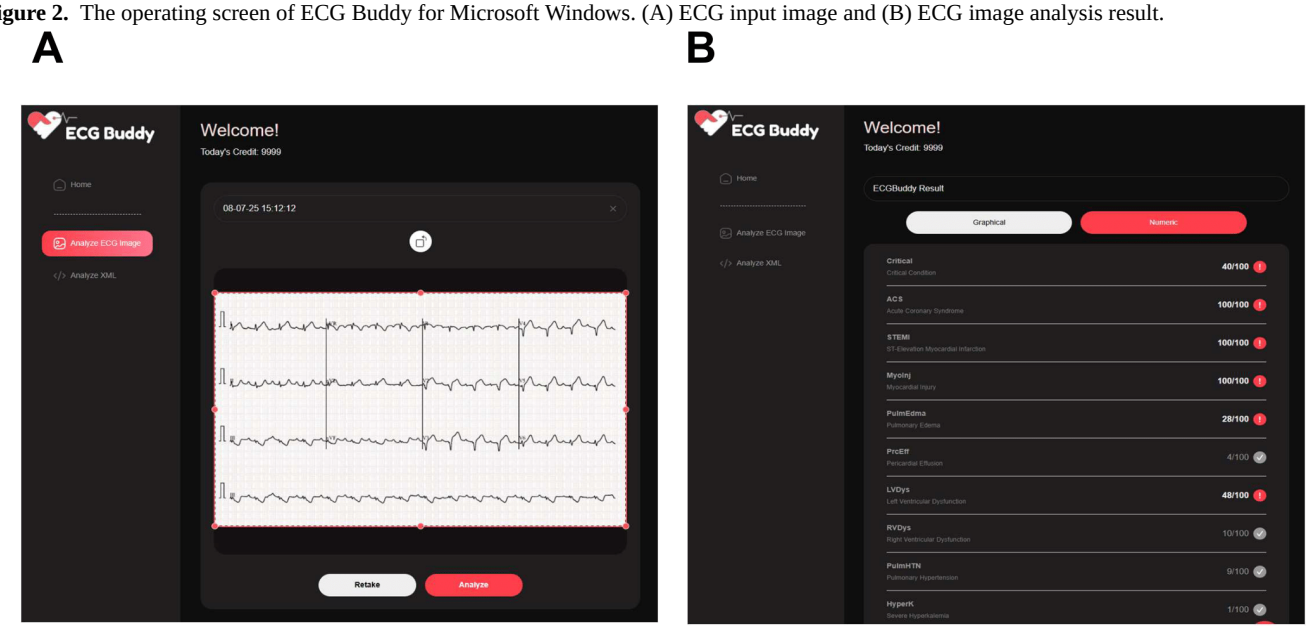
1. **Lead Abnormalities**: The ECG image shows some abnormalities that could be suggestive of an MI, but they are not definitive. The leads that might exhibit changes include the anterior leads (V1-V4) and possibly the inferior leads (II, III, aVF).

2. **Observed Changes**:
   - **ST-Segment Elevation**: There appears to be some elevation in the ST-segment in the anterior leads, which can be indicative of an anterior MI. However, the elevation is not pronounced enough to be conclusive without further clinical correlation.
   - **T-Wave Inversion**: There might be some T-wave inversions in the inferior leads, which can be associated with ischemia or infarction, but these changes are not definitive on their own.
   - **Pathological Q Waves**: There are no clear pathological Q waves observed, which are typically indicative of a previous MI.

3. **Ambiguities and Differential Diagnoses**:
   - The ECG findings are ambiguous and could be due to other conditions such as early repolarization, pericarditis, or left ventricular hypertrophy, which can mimic MI patterns.
   - Clinical correlation with patient symptoms, history, and additional tests (e.g., cardiac biomarkers, imaging) would be necessary to confirm or rule out MI.

In conclusion, while there are some ECG changes that could suggest an MI, they are not definitive, and further clinical evaluation is needed to establish a diagnosis.

Qualitative Assessment of Diagnostic Explanations–ChatGPT and Gemini



In addition, a qualitative assessment of the diagnostic explanations of LLMs was performed to further evaluate the ability to accurately interpret ECG images. For GPT-4o, 40 cases were randomly selected: 10 true-positive, 10 true-negative, 10 false-positive, and 10 false-negative. For Gemini 2.5 Pro, the same procedure yielded 37 cases (10 true-positive, 10 true-negative, 10 false-positive, and 7 false-negative) owing to the model's smaller false-negative pool. Two board-certified clinicians, an emergency medicine specialist and a cardiologist, each with more than 10 years of ECG interpretation experience, independently reviewed the diagnostic explanations to assess whether the model provided clinically appropriate rationales for their classification. They then reconciled any discrepancies by consensus, and the final consensus ratings, together with per-reviewer tallies, are reported in the Results section.

AI-Powered Image Analysis (ECG Buddy)

ECG Buddy is a deep learning–based ECG analysis platform designed for 12-lead ECG image interpretation. The software is available for both smartphones and Microsoft Windows–based desktop personal computers. In this study, ECG Buddy for Microsoft Windows [21] was used to perform bulk analysis of ECG data (Figure 2). It is approved by the Korean Ministry of Food and Drug Safety and freely available for download in Korean app stores and can analyze 12-lead ECGs by taking pictures of ECG outputs to produce 10 digital biomarkers. The software automatically detects the ECG image displayed on the desktop and provides the analysis results within 10 - 15 seconds. Figure 2A shows the operating screen of ECG Buddy for Microsoft Windows, while Figure 2B shows the ECG image analysis output. ECG Buddy generates 10 digital biomarkers that assess a range of cardiac conditions, including STEMI, acute coronary syndrome (ACS), myocardial injury (MyoInj), critical condition, pulmonary edema, pericardial effusion, left ventricular dysfunction, RV dysfunction, pulmonary hypertension, and severe hyperkalemia. This study analyzed only the STEMI, ACS, and MyoInj biomarkers owing to their direct relevance to MI classification.

Statistical Analysis

Model performance was evaluated using accuracy, sensitivity, specificity, positive predictive value (PPV), and negative predictive value (NPV). The Youden index was used to determine optimal classification thresholds. In addition, model performance was evaluated using the area under the receiver operating characteristic curve (AUROC), and the AUC values were compared using the DeLong method, with statistical significance set at $P<.05$. All analyses were conducted using R software version 4.1.0 (RStudio) [22], with ChatGPT API responses obtained using Python (Python Software Foundation).

Ethical Considerations

The study design was approved by the Institutional Review Board of Seoul National University Bundang Hospital (IRBX-2504-966-902). Given the public availability of the dataset, the Institutional Review Board of Seoul National University Bundang Hospital granted a waiver for the requirement of informed consent.

Results

Performance of ChatGPT and ECG Buddy

In total, 928 ECG recordings (239/928, 25.8% MI-positive cases) were analyzed, and all were successfully processed by both AI models. ChatGPT demonstrated limited discriminative ability in MI detection, achieving an AUC of 57.34% (95% CI 53.44 - 61.24). Using the Youden index, the optimal cutoff was determined as the category “definite.” At this cutoff, the model’s sensitivity, specificity, PPV, and NPV were 36.40% (95% CI 30.30 - 42.85), 76.20% (95% CI 72.84 - 79.33), 34.66% (95% CI 28.79 - 40.90), and 77.55% (95% CI 74.21 - 80.64), respectively (Figure 3A and Table 1). Gemini 2.5 Pro showed even weaker overall discrimination, with an AUC of 51.63% (95% CI 50.22 - 53.04). Applying the same Youden index procedure, the optimal cutoff corresponded to the “definite” category. At this threshold, sensitivity rose to 97.07% (95% CI 94.06 - 98.81) but at the expense of specificity, which fell to 6.24% (95% CI 4.55 - 8.31); the resulting PPV and NPV were 26.42% (95% CI 23.53 - 29.47) and 86.00% (95% CI 73.26 - 94.18), respectively (Figure 3A and Table 1).

The dedicated ECG AI software ECG Buddy exhibited highly accurate MI classification across the STEMI, ACS, and MyoInj markers. The AUC for detecting MI-positive cases for the STEMI biomarker was 98.87% (95% CI 98.30 - 99.43), for the ACS biomarker was 98.78% (95% CI 98.05 - 99.50), and for the MyoInj biomarker was 98.88% (95% CI 98.24 - 99.51). Using the STEMI biomarker, ECG Buddy achieved the best accuracy of 96.98% (95% CI 95.67 - 97.99), with a sensitivity of 96.65% (95% CI 93.51 - 98.54), specificity of 97.10% (95% CI 95.55 - 98.22), and F_1-score of 94.27% (95% CI 91.86 - 96.28). DeLong test confirmed that ChatGPT (AUC 53.63%) performed significantly worse than ECG Buddy across all biomarkers (all $P<.001$; Figure 3B and Table 1).

Qualitative Assessment of Diagnostic Explanations of ChatGPT and Gemini

Two board-certified clinicians independently reviewed every explanation generated by the 2 LLMs. For GPT-4o, reviewer 1 judged 5% (2/40) explanations fully correct, 40% (16/40) partially correct, and 55% (22/40) completely incorrect. Reviewer 2 judged 5% (2/40) fully correct, 37.5% (15/40) partially correct, and 57.5% (23/40) completely incorrect. The reviewers concurred in 87.5% of GPT-4o cases (35/40; weighted κ=0.76). After consensus, GPT-4o explanations were fully correct in 5% (2/40), partially correct in 37.5% (15/40), and completely incorrect in 57.5% (23/40; Table 2).

For Gemini 2.5 Pro, the 2 clinicians showed high interrater agreement (91.9%, 34/37; weighted $\kappa \approx 0.67$) while following the identical review procedure. Consensus ratings were 32.4% (12/37) fully correct, 13.5% (5/37) partially correct, and 54.1% (20/37) completely incorrect. Although Gemini produced a higher proportion of fully correct statements than GPT-4o, more than half of its explanations remained completely inaccurate, underscoring the need for expert oversight. The detailed per-rater counts are provided in Multimedia Appendix 1.

XSL•FO
RenderX

Table . Consensus qualitative assessment of large language model diagnostic explanations. Interrater agreement before consensus: κ=0.76 (GPT-4o) and 0.67 (Gemini).

	Correct, n (%)	Partially correct, n (%)	Completely incorrect, n (%)
GPT-4o (n=40)	2 (5)	15 (37.5)	23 (57.5)
Gemini 2.5 Pro (n=37)	12 (32.4)	5 (13.5)	20 (54.1)

Discussion

Principal Results

This study directly compared ChatGPT and Gemini, general-purpose multimodal LLMs, with ECG Buddy, a specialized deep-learning tool for ECG analysis. While ECG Buddy achieved high accuracy in detecting MI from ECG images, ChatGPT's performance was significantly inferior. Gemini 2.5 Pro, the latest vision-language model from Google, showed even lower overall accuracy than GPT-4o, reinforcing the conclusion that current general-purpose LLMs remain unsuitable for primary ECG interpretation.

The considerable performance gap between the dedicated ECG Buddy and LLMs underscores a difference in their architecture and training methodologies. LLMs are primarily optimized for textual understanding and general visual recognition tasks and lack the specific training necessary for detailed ECG waveform interpretation. As a result, it may generate contextually plausible yet inaccurate responses, which could lead to potentially dangerous diagnostic errors if relied upon in clinical settings. Moreover, the performance of LLMs is highly sensitive to prompt design and the specific model version used, resulting in inconsistent outcomes. Clinical studies have reported that while LLMs perform moderately well in common clinical cases, they deviate significantly from evaluations in critical scenarios [10-12]. Conversely, ECG Buddy is optimized through targeted domain-specific training, resulting in superior performance and reliability compared to LLMs.

The findings of this study indicate that current general-purpose multimodal LLM architectures may primarily rely on textual annotations or explicit labels rather than on directly analyzing waveform patterns. Due to these structural limitations, current LLMs cannot be considered reliable as primary diagnostic tools for detecting STEMI. Accordingly, LLMs should be confined to a supplementary decision-support role, where they can supply guideline-based contextual information, augment the interpretations generated by specialized tools such as ECG Buddy, and propose clinically appropriate follow-up options. Although recent advances in LLMs have broadened the applications of medical AI, domain-specific models remain indispensable, as the inherent limitations of general-purpose LLMs still compromise clinical utility and reproducibility.

Limitations

This study has some limitations. First, the study was conducted retrospectively using a publicly available ECG dataset, which lacked detailed clinical context or patient demographic information. The absence of comprehensive clinical data may limit the generalizability of these findings to diverse patient populations or different clinical settings. In addition, the dataset comprised only deidentified ECG images lacking infarct-territory labels and lab results, location-specific and STEMI or NSTEMI analyses were not possible. Second, the qualitative assessments were performed independently by 2 board-certified clinicians—1 emergency physician and 1 cardiologist. While providing useful insight, interpretations by multiple clinicians across various specialties might yield different assessments of diagnostic appropriateness or accuracy. To address this limitation and confirm its clinical utility, we plan to initiate prospective validation studies that will evaluate ECG Buddy's diagnostic accuracy and workflow integration in emergency department settings across hospitals.

Comparison With Prior Work

Our findings are consistent with those of prior research, highlighting that ECG-specialized AI models regularly outperform general-purpose models. Previous studies have demonstrated that deep learning models trained extensively on ECG-specific datasets accurately detect subtle waveform changes indicative of asymptomatic ventricular dysfunction and cirrhosis [23,24]. Similar to these specialized ECG models, ECG Buddy undergoes targeted optimization tailored specifically to ECG images, ensuring consistent predictive performance and stable error margins essential for clinical reliability. Notably, users only need to provide an ECG image or screenshot; both the smartphone and desktop versions feature an intuitive interface that requires no extra training or expertise. In addition to MI, ECG Buddy demonstrates robust diagnostic capabilities across diverse cardiac conditions, including STEMI, hyperkalemia, and RV dysfunction, validating its efficacy in various clinical settings [15-18]. Moreover, it has outperformed human experts in diagnosing STEMI and hyperkalemia.

Conclusions

To our knowledge, this study provides the first direct comparative assessment between ChatGPT, Gemini, and ECG Buddy for detecting MI from ECG images. Our findings reveal that, despite the accelerating use of LLM-based AI, current LLMs do not meet the clinical performance and accuracy requirements for ECG interpretation. Herein, the ability of a general-purpose multimodal LLM (ChatGPT and Gemini) to detect ECG abnormalities fell short of that achieved by board-certified emergency physicians, rendering it insufficient for use in interpreting critical ECG readings in clinical practice. In contrast, the specialized ECG AI tool (ECG Buddy), which has been trained and validated, achieved high diagnostic accuracy and reproducibility, suggesting its utility in clinical settings. These results, consistent with those of several other studies, underscore the superiority of medical domain-specific AI programs over general-purpose LLMs for ECG analysis and interpretation and emphasize the importance of specialized models in the field of medical AI development.

Abstract

Background: Free-text clinical data are unstructured and narrative in nature, providing a rich source of patient information, but extracting research-quality clinical phenotypes from these data remains a challenge. Manually reviewing and extracting clinical phenotypes from free-text patient notes is a time-consuming process and not suitable for large-scale datasets. On the other hand, automatically extracting clinical phenotypes can be challenging because medical researchers lack gold-standard annotated references and other purpose-built resources, including software. Recent large language models (LLMs) can understand natural language instructions, which help them adapt to different domains and tasks without the need for specific training data. This makes them suitable for clinical applications, though their use in this field is limited.

Objective: We aimed to develop an LLM pipeline based on the few-shot learning framework that could extract clinical information from free-text clinical summaries. We assessed the performance of this pipeline for classifying individuals with confirmed or suspected comorbid intellectual disability (ID) from clinical summaries of patients with severe mental illness and performed genetic validation of the results by testing whether individuals with LLM-defined ID carried more genetic variants known to confer risk of ID when compared with individuals without LLM-defined ID.

Methods: We developed novel approaches for performing classification, based on an intermediate information extraction (IE) step and human-in-the-loop techniques. We evaluated two models: Fine-Tuned Language Text-To-Text Transfer Transformer (Flan-T5) and Large Language Model Architecture (LLaMA). The dataset comprised 1144 free-text clinical summaries, of which 314 were manually annotated and used as a gold standard for evaluating automated methods. We also used published genetic data from 547 individuals to perform a genetic validation of the classification results; Firth's penalized logistic regression framework was used to test whether individuals with LLM-defined ID carry significantly more de novo variants in known developmental disorder risk genes than individuals without LLM-defined ID.

Results: The results demonstrate that a 2-stage approach, combining IE with manual validation, can effectively identify individuals with suspected IDs from free-text patient records, requiring only a single training example per classification label. The best-performing method based on the Flan-T5 model and incorporating the IE step achieved an F_1-score of 0.867. Individuals classified as having ID by the best performing model were significantly enriched for de novo variants in known developmental disorder risk genes (odds ratio 29.1, 95% CI 7.36-107; P=2.1×10^{-5}).

Conclusions: LLMs and in-context learning techniques combined with human-in-the-loop approaches can be highly beneficial for extraction and categorization of information from free-text clinical data. In this proof-of-concept study, we show that LLMs can be used to identify individuals with a severe mental illness who also have suspected ID, which is a biologically and clinically meaningful subgroup of patients.

Introduction

Background

Text classification of clinical data is a challenging problem due to highly specialized terminology, diverse document structures, and the heavy reliance of most methods on annotated data [1,2]. Standard approaches to overcome these challenges involve the use of task-specific knowledge and rule-based methods [3-6], which make them inapplicable to a wider range of tasks. This is because such methods rely heavily on handcrafted features and domain-specific rules, which do not generalize well beyond the narrow set of conditions they were designed for. Language models are neural network architectures trained to understand and generate human language by learning statistical patterns in large text corpora. Among the most influential are masked language models such as BERT (Bidirectional Encoder Representations From Transformers) and RoBERTa (Robustly Optimized BERT Approach) [7-12], which are pretrained on general-domain text and then fine-tuned—that is, further trained on labeled data for a specific downstream task such as text classification. In the biomedical and clinical domains, specialized variants such as BioBERT (BERT for Biomedical Text Mining) [13] and Clinical Bidirectional Encoder Representations From Transformers (ClinicalBERT) [14] have been developed by continuing pretraining on domain-specific corpora. These models have demonstrated improved performance in tasks like clinical concept extraction and classification. However, despite their success, they still require large amounts of annotated training data to achieve strong performance [15], which is often a limiting factor in clinical settings where labeled data are scarce [12,16-18]. Therefore, methods should ideally work without training data in a zero- or few-shot framework. Recent advances in natural language processing (NLP) have introduced alternative methods using text generation or large language models (LLMs) like Large Language Model Architecture (LLaMA) [19], which perform unseen tasks via in-context learning (prompting) [11,20-23]. Prompting involves giving the model natural language instructions that describe the task [24]. In few-shot prompting, these instructions are accompanied by a few training examples [24]. Unlike fine-tuning, prompting does not modify model weights, making it less resource intensive. Research shows that prompting can match or exceed the performance of standard fine-tuning [9,25]. Further gains in zero-shot settings have been achieved by fine-tuning models on task instructions, as in Fine-Tuned Language Net Text-To-Text Transfer Transformer (Flan-T5) [26,27]. However, their application in the clinical domain remains limited.

In contrast to previous work, we explore a novel approach for performing classification for clinical data. We use an intermediate information extraction (IE) step and human-in-the-loop framework to maximize the performance of in-context learning techniques and LLMs for one-shot setting. As a real-world example, we applied this procedure to free-text clinical summaries in a cohort of patients with severe mental illness and classified individuals with suspected comorbid intellectual disability (ID). These free-text clinical summaries were previously created from discharge patient notes and clinical interviews for research purposes. This is a challenging task as these summaries have diverse structure and terminology and may contain information related to different types of disabilities that can be hard to distinguish without detailed reports of the person's cognitive functioning (eg, "learning disability" vs "intellectual disability") [28]. Further, the presence of ID can be described using diverse terminology and be implicitly referred to within the text by recording outcomes and scores from different types of clinical tests and assessments without explicitly mentioning any disability. To provide evidence that our LLM approach can identify a biologically meaningful subgroup of patients, we used genetic data that is available in a subset of patients with schizophrenia to test whether individuals classified by LLMs to have suspected comorbid ID carry significantly more rare variants in ID-associated genes than individuals without LLM-defined ID.

Related Work

We discuss relevant work using LLMs for extracting and classifying information within clinical texts, as well as outline challenges and research gaps within the literature (see sections "Text Classification for Clinical Text" and "Human-in-the-Loop–Based Approaches"). Finally, we present a use case from psychiatric genetics, a discipline with close relationships to the broader fields of clinical genetics and rare disease research (section "Genetic Analysis").

Text Classification for Clinical Text

The generalization capabilities of text-generation models in few-shot settings make them suitable for the clinical domain, which often lacks annotated data and is also associated with limited access to datasets and language resources [29,30]. Thus, recent research in the clinical NLP field has focused on leveraging and evaluating the performance of such models for various tasks, including classification [1,31-37]. Some papers focus on providing dataset resources to support easier evaluation and benchmarking of LLMs in zero- and few-shot settings [1,37], as well as instruction or domain-trained models based on LLaMA [32,34,36]. These works show promising results for some downstream tasks.

A similar work to ours by Lu et al [33] proposes a knowledge-enhanced prompt learning method for classification of diagnosis from clinical texts. The approach is based on extracting relevant knowledge to the given diagnosis from heterogeneous knowledge resources and integrating it into a prompt sequence along with the clinical note. The authors experiment with more traditional neural network approaches, as well as masked language models. In contrast to this work, we analyze recently developed LLMs such as Flan-T5 and LLaMA, and we focus on exploring in-context learning techniques. In similar research by Fabregat et al [31], a Bidirectional Long Short-Term Memory (Bi-LSTM) architecture is used to extract the presence of named disabilities (including IDs) from clinical notes. In our paper, we extract intellectual disabilities, where for some patients these are not mentioned explicitly but instead referred to within the text by using different terminology as well as the results of relevant tests and assessments.

XSL•FO
RenderX

Another work introduces Generative Pre-Trained Transformer for Biomedical Text Generation and Mining (BioGPT) [38], a language model pretrained on large-scale biomedical literature and evaluated on a range of tasks such as relation extraction, question answering (eg, PubMedQA), document classification, and text generation. While it outperforms BERT-based models on these benchmarks, it is built on the older GPT-2 architecture and was trained exclusively on biomedical research articles. This limits its applicability to clinical contexts, particularly for understanding the more informal language often found in patient note summaries. Moreover, BioGPT is relatively small, with only 1.5 billion parameters, making it less capable compared to more recent and larger models such as LLaMA [19] and Flan-T5 [26], which offer improved generalization, reasoning, and contextual understanding across diverse domains.

Despite these recent attempts in leveraging LLMs for the clinical domain, most of the work in NLP-related applications for the health care domain is still relying on the use of more data-consuming approaches for text classification and IE [3-6]. In contrast to previous work, we explore different approaches for performing classification for patient notes using an intermediate IE step and human-in-the-loop approach to maximize the performance of in-context learning techniques and LLMs for one-shot setting.

Human-in-the-Loop–Based Approaches

Incorporating expert knowledge and human validation within automated approaches can have high benefits in the health care domain, given the undesirable consequences of misclassification inherent to some tasks and the subsequent need for highly accurate models [39]. Despite this, research in developing such hybrid approaches is very limited, focusing mainly on incorporating domain knowledge within more traditional rule-based and dictionary-based approaches for IE [40,41]. For instance, the authors of [40] use a human-in-the-loop approach for constructing a lexicon for extracting medication names from clinical records. The authors of [41] use a human-based verification step for building an ontology for structuring radiology reports. In contrast, our work is the first attempt in incorporating human knowledge with state-of-the-art NLP models to develop more accurate text classification approaches for scenarios with no training data available, except for a few examples.

Genetic Validation of ID Identified by LLM

Schizophrenia is a severe and highly heritable psychiatric disorder [42]. Impaired cognition is a core symptom of schizophrenia that strongly predicts worse functional outcomes [43]. Studies have demonstrated that rare and common genetic variation contributes to variation in cognitive ability, or proxies of cognition such as educational attainment, in schizophrenia. For example, we recently showed that genes associated with early onset developmental disorders (including ID) are enriched for damaging rare variants in individuals with schizophrenia and suspected comorbid ID [44]. In our previous work, we classified patients with schizophrenia with suspected comorbid ID by manually curating free-text clinical summaries. In this study, we analyzed the same exome-sequencing data and clinical summaries used in [44] and tested whether individuals with schizophrenia and LLM-classified comorbid ID carry significantly more damaging rare variants in known ID-associated genes compared with individuals with schizophrenia who did not have LLM-classified ID. Demonstrating that individuals with LLM-classified ID are enriched for such mutations would provide evidence that our LLM approach can identify a biologically meaningful subgroup of patients with schizophrenia.

Objectives of This Study

Our objectives were as follows. First, we aimed to develop a novel 2-step approach that does not require training data for classifying individual patients with suspected ID within psychiatric clinical summaries. Toward this end, we explored approaches that use text generation models coupled with prompting techniques to perform IE for identifying ID-related information from the summaries, after which we performed classification on the extracted text. Second, we aimed to compare the performance of approaches that involve human-in-the-loop techniques and fully automated approaches. Third, we aimed to perform a multifaceted evaluation of model performance and analyze the effect of prompt information type (eg, task definitions vs examples provided as part of the prompt) on the performance for IE and text classification tasks. Lastly, we aimed to perform a genetic validation of the results via an experiment testing whether individuals with LLM-defined ID carry more genetic variants known to confer risk of ID when compared with individuals without LLM-defined ID.

Methods

Data

Corpus of Clinical Free-Text Data

The corpus contained free-text clinical summaries of 1144 individuals with severe mental illness, including schizophrenia and bipolar disorder. The summaries for each person contained information related to symptoms, reactions to prescribed treatments and medications, as well as any other observations that can be clinically relevant, such as the comorbid presence of other illnesses and developmental conditions (including ID). The summaries were not written for the purpose of the current project but at the time of patient recruitment for general research purposes. The summaries contained information from discharge summaries and clinical interviews with psychiatrists. Some clinical summaries also included the Schedules for Clinical Assessment in Neuropsychiatry (SCAN) interview [45], which is a semistructured clinical interview used to assess and diagnose psychiatric disorders. In addition, our dataset was a strong representation of real-world free-text clinical summaries, which often present challenges such as inconsistent structure, lack of labeled training data, and the use of diverse terminology where diseases and diagnoses may not be explicitly mentioned. Since the dataset was not specifically collected for this study, it offers potential for a wide range of research applications.

Dataset Annotation

We annotated 314 patient notes by manually curating the free text and identifying evidence of ID (see Table 1 for an overview of the annotation dataset). In addition to these 314 patient

XSL•FO
RenderX

summaries, the best performing automatic approaches were used to classify an additional 830 patients.

Table . Overview of the dataset.

Class	Number of tests	Average number of tokens
ID[a]	29	222
No ID[b]	285	185
Total	314	190

[a]ID: intellectual disability.

[b]No ID: no evidence of intellectual disability present in the patient note (or lack of evidence).

Methodology

Pipeline

We explored three different approaches for performing classification. First, we performed classification on the entire dataset to allow comparison with standard approaches. Second, we performed IE for identifying ID-related information from the summaries, and then we performed classification on the extracted text. Third, we proposed the use of a human-in-the-loop approach as an alternative to a fully automated approach where we use the IE step to extract only the relevant information to the task in a more concise format, which can support experts in performing more efficient and less error-prone annotation of documents.

Prompting Techniques

We used three prompting techniques (see Table 2) for both IE and classification tasks: *basic*, *definitions*, and *definitions+examples*. This allowed us to identify what type of prompt information (ie, information provided as part of the instruction) is more beneficial for the model's performance.

1. *Basic prompt*: In this prompt, we simply provided a question to the model without further information about the task.
2. *Definitions*-enhanced prompt: In this prompt, we provided some descriptions about the tasks, that is, definition about intellectual disabilities, along with the question. We provided the same definition for both IE and classification models.
3. *Definitions+examples* prompt: In this prompt, along with the definition, we provided one example per label—for the IE task, we provided one example of an output that contains ID-related features and one that does not. The examples were selected randomly from the dataset. For generating data for the test sequences, we used a sampling method.

The definition used as part of the prompts for performing classification and IE is given in Textbox 1. The definition was taken from the *International Statistical Classification of Diseases, Tenth Revision* (*ICD-10* [46]), which is a medical classification list by the World Health Organization.

Table . Different prompt learning methods for clinical data.

	Information extraction prompts	Classification prompts
Basic prompt[a]	What is the evidence of intellectual disability the patient displays from the given patient note?	Does the patient display any evidence of intellectual disability from the given patient note?
	Patient Note: SZ, IQ of 65., paranoid elements...[Answer]	Patient Note: SZ, IQ of 65., paranoid elements...[Answer]
Definitions[b]	[DEF]	[DEF]
	What is the evidence of intellectual disability the patient displays from the given patient note?	Does the patient display any evidence of intellectual disability from the given patient note?
	Patient Note: SZ, IQ of 65., paranoid elements...[Answer]	Patient Note: SZ, IQ of 65., paranoid elements...[Answer]
Definitions +examples[c]	[DEF]	[DEF]
	What is the evidence of intellectual disability the patient displays from the given patient note?	Does the patient display any evidence of intellectual disability from the given patient note?
	Patient Note: SZ, IQ of 65., paranoid elements...[IQ of 65.]	Patient Note: SZ, IQ of 65., paranoid elements... [Yes]
	Patient Note: Started hallucinating; Education: Lawyer...[No evidence.]	Patient Note: Started hallucinating; Education: Lawyer...[No]
	Patient Note: SZ, premature birth, attended special school...[Answer.]	Patient Note: SZ, premature birth, attended special school...[Answer]

[a]The ”Basic prompt” method simply adds questions to the clinical summaries.

[b]The “Definitions” prompt incorporates medical knowledge, ie, definition of intellectual disability, within the prompt.

[c]The “Definitions+examples” method adds two annotated examples for both tasks, information extraction (IE) and classification. For example, in the IE task, we provide two patient summaries: one that contains an intellectual disability–related feature (eg, “IQ of 65”) and one that does not. The first supports the presence of the feature and is labeled with the correct answer in square brackets (eg, [“IQ of 65”]). The second lacks such a feature and is labeled as “no evidence.” Additionally, new patient summaries marked with “[Answer]” are examples of where the model is expected to generate a prediction.

Textbox 1. Definition used in prompts.

You are a health care assistant, and you have been asked to identify if the given patient has intellectual disability (ID) for the given patient note. Please use the information about intellectual disabilities given below to extract the right information.

Intellectual disability (ID), previously known as mental retardation, is a term that is used when an individual has below-average intelligence or mental ability. Intellectual disability (ID) can be identified within the first two years of a child’s life if he or she has more severe intellectual disabilities. However, mild intellectual disability may not be identifiable until the child reaches school-age, when challenges with academic learning become present. While it typically occurs during the developmental periods, it is also possible for intellectual disability to develop later as the result of illness or brain injury. Signs and symptoms of intellectual disabilities include: premature birth, delayed development, learning and developing more slowly than other children same age, difficulty communicating or socialising with others, lower than average scores on IQ tests, difficulties talking or talking late, having problems remembering things, inability to connect actions with consequences, difficulty with problem-solving or logical thinking, trouble learning in school, need to attend special school, inability to do everyday tasks like getting dressed or using the restroom without help.

Experimental Setup

In this section, we describe our experimental setting for the task of identifying patients with ID in free-text clinical data.

Comparison Models

We performed analysis with LLaMA 2 [19] as a representative of a large autoregressive generation model with 70 billion parameters. As a representative of a smaller but instruction-tuned model, we used Flan-T5 [26], in particular its XXL version with 11 billion parameters. The model was fine-tuned using the Flan instruction tuning tasks collection [26]. The collection also included datasets related to the medical domain and classification tasks. We used the XXL version with 11 billion parameters. We downloaded the models from Hugging Face [47]. Due to the sensitivity of the patient notes, we decided against using OpenAI models or other external application programming interfaces requiring data upload for performing analysis. We chose LLaMA and Flan-T5 for our experiments because they are among the most recent, largest, and most versatile language models available, demonstrating strong performance across a wide range of tasks. Notably, Flan-T5’s training data includes medical content, which enhances its ability to understand and generate clinically relevant text, which makes it especially suitable for our use case. The model parameters we used for summarization and text classification are as follows: for Flan-T5, we used a temperature of 0.7 and a maximum of 10 and 30 generated tokens for classification and summarization, respectively. These are the default values recommended for these models. We used approximately 24 hours of GPU budget and the Nvidia RTX 4090 GPU (Nvidia Corporation). The implementation is available at GitHub [48].

Evaluation

We report classification results based on precision, recall, and standard micro- and macroaveraged F_1 [49]. We judged the

XSL•FO
RenderX

quality of the data generated during the IE stage based on the performance of the classification model applied to the IE output.

Genetic Analysis

We analyzed published genetic data that we previously generated from 547 individuals with schizophrenia who also have free-text clinical data (the paper by Rammos et al [44] provides a full description of this sample and genetic dataset). In this genetic analysis, we compared the rate of de novo variants (ie, newly arising mutations that were not inherited from either parent) in known developmental disorder risk genes between patients with suspected comorbid ID and patients without ID using Firth's penalized likelihood logistic regression test, covarying for 10 principal components that were derived from the genetic data to control for genetic ancestry and sex. In the genetic analysis, we examined three classifications of ID: (1) ID defined through manual curation of the clinical summaries; (2) ID defined by the best performing fully automated NLP classification model; and (3) ID by the best performing human-in-the-loop classification model. Based on our previous study, we expected patients with suspected comorbid ID to have significantly more de novo variants in developmental disorder risk genes than patients without comorbid ID [44].

Ethical Considerations

The following committees provided ethical approval for this study: Ethics Commission, Higher Medical University, Plovdiv, 4002 V Aprilov Blvd 15a; Protocol Ethics Committee to the Alexander University Hospital, Sofia 1431, 1 St G Sofiisk St, Local Ethics Committee, District Dispensary for psychiatric disorders, Russe, bul; Ethics Committee at the State Psychiatric Hospital "Dr Georgi Kisiov," Radnevo, 6269, Magda Petkanova St 1, Radnevo (protocol of 2.10.2000); and Ethics Committee at the District Dispensary for psychiatric disorders, Blagoevgrad (protocol N2/2000). In the United Kingdom, the project was approved by the Bro Taf Local Research Ethics Committee, Churchill House, 17 Churchill Way, Cardiff CF10 2TW, protocol 02/4523. All study participants provided written informed consent with the ability to opt out at any time. Data were deidentified prior to analysis, and no identifying participant information is presented in this study. Participants were not compensated for their inclusion in the study.

The use of LLMs in processing clinical notes raises significant ethical challenges that must be carefully addressed. Preserving patient privacy is an essential priority when it comes to analyzing clinical notes. Even when deidentified, the risk of reidentification remains, especially with powerful models capable of memorizing or inferring sensitive data. Model transparency is another key concern, making it difficult to interpret LLM decision-making processes and validate their outputs in clinical settings where accountability is crucial. Further, bias in training data can propagate or even amplify existing disparities in health care, potentially leading to skewed predictions [50,51].

While a comprehensive treatment of these issues lies outside the scope of our current work, we actively considered these ethical concerns throughout our research. To mitigate risks, we have not released the dataset publicly, and we limited our experiments to open-source models. Moreover, our proposed integration of human-in-the-loop methods provides an additional layer of oversight, helping to ensure more responsible and secure use of LLMs in sensitive clinical applications.

Results

The Role of IE

Results in Table 3 show that Flan-T5 consistently outperforms LLaMA 2 regardless of classification approach or prompt use. This suggests that a smaller but instruction-tuned model, pretrained using datasets relevant to the clinical domain, is more suitable for classification in low-resource settings when compared with a bigger model. Further, results show that the performance of IE approaches is highly dependent on the prompt used, where the difference in F_1-score for the positive class between the best and worst performing IE approach is around 0.5 (see Figure 1). A trend in the performance of both models (see Table 3) shows that a prompt combining a description of the task and examples leads to the best classification results versus a basic prompt or a prompt based only on definitions. Further, the best results were achieved with the Flan-T5 model using the IE intermediate step with a "definitions+examples" prompt informing both classification and IE (precision=1.00; recall=0.758) versus performing classification on the entire notes (P=.87; r=0.77).

These results show the potential of LLMs and in-context learning techniques to support classification tasks in the clinical domain. However, the performance of Flan-T5 varies with different prompts, whereas the LLaMA model achieves consistent improvements in classification regardless of the prompt. These findings highlight the prompt sensitivity issue in language models, particularly in smaller models like Flan-T5.

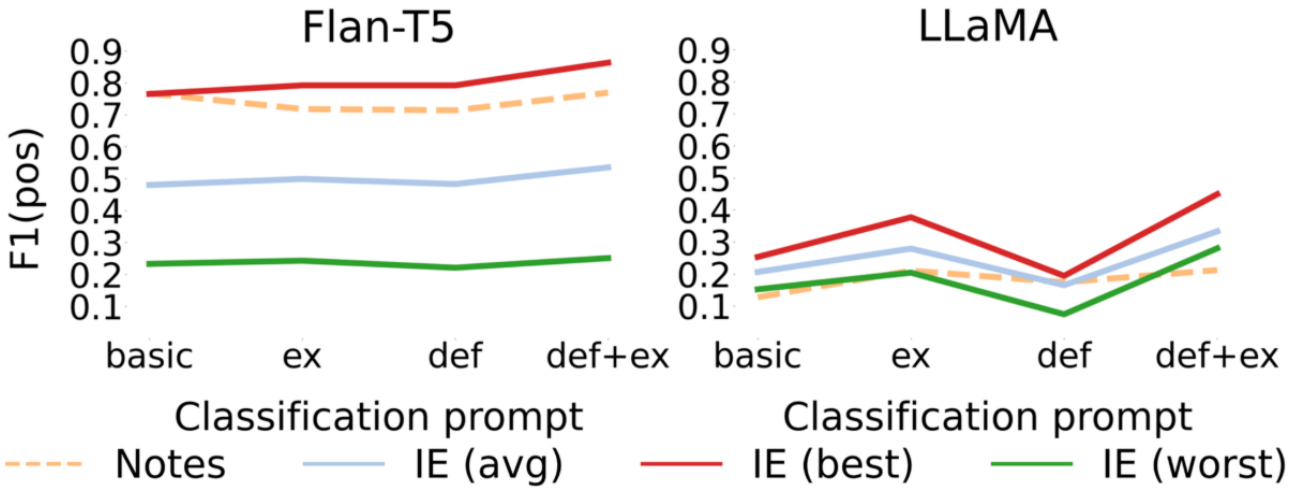

Figure 1. Comparison between classification approaches, that is, using entire notes versus using IE where "F1(pos)" refers to the F_1-score for the positive class. "IE (avg)," "IE (best)," and "IE (worst)" refer to the average, best, and worst results, respectively, for the IE approach per classification prompt. Classif: classification; Flan-T5: Fine-Tuned Language Net Text-To-Text Transfer Transformer; IE: information extraction; LLaMA: Large Language Model Architecture.

Human-in-the-Loop Approach

Results in Figure 2 and Table 3 show that combining IE for extracting task-relevant information and manual classification can support more accurate and less time-consuming classification versus using fully manual or fully automated methods. The human-in-the-loop approach led to better classification performance, especially for the LLaMA model where the difference in F1(pos) between the best performing IE approach and human-based method is 0.436. For the Flan-T5 model, the improvement in F1(pos) is 0.003 (F1(pos)=0.867 vs F1(pos)=0.863). Further, the average length of extracted passages using the FLan-T5 model is 3 tokens, whereas the average length for the entire note is 190 tokens. This shows that the IE step combined with the human-in-the-loop approach can be beneficial for supporting verification or the conduct of more efficient expert annotations. This could be a good alternative to a fully automated classification, especially in the health care domain where accuracy of models and reliability of results are of high importance.

Figure 2. Comparison between fully automated IE-based classification and human-in-the-loop approach where "F1(pos)" refers to the F_1-score for the positive class, "classif (best)" and "classif (worst)" refer to the best and worst classification results, respectively, per given IE prompt. Flan-T5: Fine-Tuned Language Net Text-To-Text Transfer Transformer; IE: information extraction; LLaMA: Large Language Model Architecture.

Genetic Validation of Different Classification Approaches

In all three classifications of ID (manual curation of clinical summaries, best performing fully automated NLP model, and performing human-in-the-loop model; see Table 3), damaging de novo variants were significantly enriched in patients with schizophrenia with suspected comorbid ID compared with patients with schizophrenia without ID (Table 4). De novo variants were most strongly enriched in the schizophrenia ID group defined by the human-in-the-loop classification (odds ratio 29.1, 95% CI 7.36-107), with the weakest enrichment observed in the fully automated classification (odds ratio 15.7, 95% CI 3.58-57.5). The same set of de novo variants was observed in the ID and non-ID patient groups in the human-in-the-loop and manual curation classifications, but a greater enrichment was observed in the human-in-the-loop classification test as fewer individuals were classified to have ID (14 in the human-in-the-loop classification vs 18 in the manual curation classification; Table 4).

XSL•FO
RenderX

To investigate why fewer people were found to have ID in the human-in-the-loop classification dataset, we examined the overlap of individuals with ID in this dataset and the manually curated classification dataset. We also reexamined the clinical information for individuals found to have ID in only one dataset. Eleven individuals with schizophrenia were recorded as having ID in both the manually curated and human-in-the-loop classification datasets. Among the 7 individuals who were found to have ID only in the manually curated classification dataset, 2 had clear evidence of having ID, 2 had ambiguous evidence of having ID, and 3 had no evidence of having ID. Among the 3 individuals found to have ID only in the human-in-the-loop classification dataset, 1 had clear evidence of having ID and 2 had ambiguous evidence of having ID. These results provide suggestive evidence that the human-in-the-loop approach produces fewer false positive ID classifications when compared with the manually curated ID set.

Table . Enrichment of de novo variants in individuals with SZ[a] and comorbid ID[b].

Classifier[c]	Patients with SZ and ID, n	Patients with SZ but without ID, n	*P* value	Odds ratio (95% CI)	Variants in ID group, n (rate)	Variants in no-ID group, n (rate)
Manual curation	18	529	7.1×10^{-5}	21.1 (5.48-74.0)	4 (0.22)	7 (0.013)
Automatic model	16	531	9.3×10^{-5}	15.7 (3.58-57.5)	3 (0.19)	8 (0.015)
Human-in-the-loop	14	533	2.1×10^{-5}	29.1 (7.36-107)	4 (0.29)	7 (0.013)

[a]SZ: schizophrenia.

[b]ID: intellectual disability.

[c]The numbers of patients with ID and without ID are presented across three ID classifications where “manual curation” refers to manual annotations performed by a domain expert, “automatic model” refers to the best performing fully automatic model in Table 3, and “human-in-the-loop” refers to the best performing human-in-the-loop approach in Table 3.

Discussion

Principal Findings

Our findings show the potential of LLMs to facilitate different tasks in the clinical domain, such as classification and IE when only a few training examples are available. We compared three approaches for classifying ID from the clinical summaries of individuals with severe mental illness and found that using an IE step as part of a classification pipeline based on the Flan-T5 model and informed by a prompt combining definitions and examples achieved a precision of 1.00 and F_1 of 0.867 for the positive class. Further improvements to classification were found when using the human-in-the-loop approach, a process where a human must review short NLP-derived summaries instead of the full clinical dataset. These findings open interesting research avenues in building hybrid approaches, which combine the benefits LLMs offer for extracting relevant information in a fast and efficient manner with the knowledge of experts. These kinds of methods can be suitable for classification tasks which are considered challenging even for domain experts, as well as for sensitive tasks that require high accuracy, which is typically hard to achieve when labeled training data is scarce. Moreover, the ability of our methods to accurately classify ID was supported by our genetic analysis, which found the NLP-defined subgroup of people with schizophrenia and ID to be enriched for genetic variants in genes known to be associated with ID. From conversations with geneticists in the area, we found that manual annotation of comorbidities is often based on keyword search, since reading of thousands of clinical notes is typically unfeasible. Our findings therefore suggest that NLP-based approaches can be used to validate or improve classification annotations derived from the manual curation of free-text clinical summaries, which is prone to human error. Further work is required to test these findings in routinely collected health care data, such as that captured in electronic health records, and how to best integrate into genetic analysis research and beyond the detection of IDs which was used as a first approximation to the more general problem of extracting information from free-text clinical summaries.

Importance of Both Automation and Human Intervention in Health Care Applications

We have performed further analysis comparing the execution time efficiency of the best performing automatic and human-in-the-loop approaches to the manual methods used by experts for annotating the data (see Table 5). Specifically, the manual curation involved careful reading through the entire dataset to classify them. In the keyword search, experts perform simple searches using the operating system's search functionality to find potential class candidates. For these experiments, they used the keywords “IQ” and “mental handicap”. The results in Table 5 show the benefits of the automatic and human-in-the-loop approach versus the human-based annotation where the fully automated method is more than 20 times faster than manual curation and keyword-based search. In addition, keyword search has a slightly lower F_1-score than automatic approaches. The reason for this is the limited number of keywords used in experiments. However, these results still highlight potential problems with such an approach where a careful selection of keywords is needed as well as a good knowledge of the corpus. Further, the human-in-the-loop approach performs at a very similar execution time to the fully automated approach but produces a higher F_1-score. Perhaps even more importantly, the fact that an expert can be involved in the process provides increased reassurance compared to a fully automatic process. This shows that semiautomatic approaches can be an efficient and more reliable option versus full automation for the health care domain where high accuracy

XSL•FO
RenderX

of models is required. However, research in this field is still very limited. Our work is one of the first attempts to incorporate manual verification and LLMs to create more reliable and less data-consuming approaches for classification of clinical free-text data.

Table . Comparison of the performance of classification approaches in terms of time taken for annotating 314 clinical summaries.

Approach	Time	F1(pos)[a]
Manual curation[b]	~10 h	1.000
Keyword search[c]	~2 h	0.845
Automatic model[d]	~5 min	0.863
Human-in-the-loop[e]	~20 min	0.863

[a]F1(pos): F_1 for the positive class.

[b]"Manual curation" refers to manual annotations performed by a domain expert.

[c]"Keyword search" refers to CTRL-F–based search using the keywords "IQ" and "mental handicap."

[d]"Automatic model" refers to the best performing fully automatic model in Table 3.

[e]"Human-in-the-loop" refers to the best performing human-in-the-loop approach in Table 3.

Limitations

First, this study is based on a single free-text clinical dataset containing a summary of real-world clinical data, which was developed for research purposes. This dataset is not a direct copy of routinely collected clinical data, which may limit the generalization of the results. To mitigate this issue, we used unsupervised approaches that are aimed at modeling the problem at hand, without relying on training data that may easily be overfit to our own data. Nonetheless, these experiments would ideally need to be replicated on similar cohorts to better understand the strengths and limitations. Second, and related to the first point, the experiments were performed in English only, which is the language of the corpus of clinical summaries. Third, for this analysis, we simplified the task into a binary problem, in which patients have suspected comorbid ID or no evidence of ID. However, the clinical course of many medical conditions is complex, with high heterogeneity in the type and severity of symptoms both across individuals and within individuals over time. This is particularly true for mental health conditions, where individuals often receive different diagnoses during their life. It is therefore important for future studies to consider how models can adapt and capture these complex clinical phenotypes from longitudinal health care data. Although outside the scope of this paper, we note that our approach offers a promising path for this task, since it leverages in-context learning and integrates both labeled data and regularly updated, domain-specific external resources.

Another limitation of our study was that all manual annotations were performed by a single expert. This was due to the complexity and domain-specific expertise required for the task, making it unfeasible to involve multiple annotators. To ensure the reliability of the automated methods, we validated them not only against human annotations but also by using genetic data to confirm that individuals with NLP-defined ID are enriched for genetic variants known to be associated with ID.

Conclusions

In this study, we analyze how language models such as Flan-T5 and LLaMA 2 combined with in-context learning can be utilized for classifying individuals with severe mental illness and suspected ID from free-text clinical summaries. We propose the use of an intermediate IE step for extracting relevant parts of the notes before classification. Our results show that such techniques can help improve the performance of LLMs in one-shot settings when combined with a prompt that provides both information about the task and relevant examples. In addition, we propose a human-in-the-loop approach as an alternative to fully automated classification, where the IE step is used to extract succinct parts of the notes related to the task, which can be used to support faster and less error-prone manual classification. Approaches based on this pipeline and the Flan-T5 model showed promising results and were validated in a proof-of-concept genetic analysis, which found individuals classified by NLP to have ID were enriched for genetic variants known to contribute to developmental disorders.

Abstract

Background: Systematic literature reviews (SLRs) are foundational for synthesizing evidence across diverse fields and are especially important in guiding research and practice in health and biomedical sciences. However, they are labor intensive due to manual data extraction from multiple studies. As large language models (LLMs) gain attention for their potential to automate research tasks and extract basic information, understanding their ability to accurately extract explicit data from academic papers is critical for advancing SLRs.

Objective: Our study aimed to explore the capability of LLMs to extract both explicitly outlined study characteristics and deeper, more contextual information requiring nuanced evaluations, using ChatGPT (GPT-4).

Methods: We screened the full text of a sample of COVID-19 modeling studies and analyzed three basic measures of study settings (ie, analysis location, modeling approach, and analyzed interventions) and three complex measures of behavioral components in models (ie, mobility, risk perception, and compliance). To extract data on these measures, two researchers independently extracted 60 data elements using manual coding and compared them with the responses from ChatGPT to 420 queries spanning 7 iterations.

Results: ChatGPT's accuracy improved as prompts were refined, showing improvements of 33% and 23% between the initial and final iterations for extracting study settings and behavioral components, respectively. In the initial prompts, 26 (43.3%) of 60 ChatGPT responses were correct. However, in the final iteration, ChatGPT extracted 43 (71.7%) of the 60 data elements, showing better performance in extracting explicitly stated study settings (28/30, 93.3%) than in extracting subjective behavioral components (15/30, 50%). Nonetheless, the varying accuracy across measures highlighted its limitations.

Conclusions: Our findings underscore LLMs' utility in extracting basic as well as explicit data in SLRs by using effective prompts. However, the results reveal significant limitations in handling nuanced, subjective criteria, emphasizing the necessity for human oversight.

KEYWORDS

large language models; generative artificial intelligence; systematic reviews; evidence synthesis; human-AI collaboration

Introduction

Systematic literature reviews (SLRs) are indispensable across various fields, synthesizing evidence to inform decision-making in areas as diverse as public health, policy, and biomedical sciences, where rigor and comprehensiveness are paramount. With the rapid expansion of the literature, SLRs are more important than ever to help not only synthesize evidence but also identify areas in which the literature is robust or deficient [1]. However, conducting SLRs is resource intensive, involving manual and careful screening of potentially relevant studies [2]. In particular, SLRs that assess and report on analytical methods and key findings require more domain-specific expertise and multiple researchers for coding, making them more challenging.

Given the recent rapid advancement of large language models (LLMs), researchers have proposed their potential utility in conducting SLRs [3,4]. Several reviews have found that artificial intelligence (AI)–enabled methods exhibit reasonable performance and improved efficiency in literature screening [5-9], an integral component of SLRs. In particular, the role of SLRs in health and biomedical sciences underscores the need for reliable, accurate data extraction tools that maintain the

XSL•FO
RenderX

rigorous standards expected in these fields. However, studies that have tested the capabilities of AI for data extraction have identified challenges necessitating human intervention for completion [6,8].

To understand whether recently developed LLMs can overcome this barrier, many studies have evaluated the performance of various LLMs in automating SLR tasks [10-12]. Their findings reveal LLMs' potential in extracting data that are relatively easily retrievable (ie, study design, participant characteristics, and primary outcomes). However, these studies have not explored the ability of LLMs to extract more complex data (eg, methods used to obtain study outcomes), which may pose greater challenges as extracting such complex information is often subject to individual researchers' perspectives [13,14].

LLMs currently demonstrate advantages in assisting researchers, such as having rapid response times and providing high-level summaries of results [15]; however, a recent study revealed the shortcomings in ChatGPT's depth of knowledge and contextual understanding for conducting SLRs in comparison to researchers [16]. Yet, there is growing potential for ChatGPT's utility as an assistant in complex qualitative content analysis, as shown by a recent study that assessed its ability to categorize strategies and behaviors in forum posts about reducing sugar intake [17]. Thus, although LLMs show potential in data extraction tasks for SLRs, there is more to be explored on the current LLMs' capability to undertake a comprehensive approach that involves extracting not only basic study characteristics but also information critical for interpreting the results of studies within SLRs.

In this study, we aimed to evaluate an LLM's (ChatGPT) ability to extract more complex, nuanced data from scientific studies, representing a novel approach that goes beyond the simpler tasks of extracting descriptive information, such as study design or participant characteristics, which have been the primary focus of prior research. Our study applied a structured series of prompts and validations to systematically gauge where LLMs excel and where human oversight remains essential.

We used ChatGPT (GPT-4) for its accessibility and ease of use, recognizing that most individuals conducting SLRs may not be proficient with more customizable, technical platforms, such as the GPT application programming interface (API). Sophisticated LLM frameworks (eg, retrieval-augmented generation) offer technical capabilities that may better address needs for SLRs, but these features generally require AI-specific expertise. Consequently, our study prioritized a more common usage scenario in which a widely accessible GPT model is used for data extraction tasks.

Methods

Overview

We focused on COVID-19 simulation modeling studies as a case study, leveraging a large collection of study reports that our team recently assembled for a SLR that aimed to assess the incorporation of human behavior dynamics in COVID-19 simulation models [18]. For this study, the data elements selected for extraction were aligned with the specific objectives of our review: to evaluate ChatGPT's capacity to manage both explicit and nuanced data in SLRs. To determine whether LLMs can effectively screen papers and extract information, we randomly chose 10 of the papers and extracted data both manually and using ChatGPT. We selected a sample of 10 studies [19-28] as this number was manageable for an in-depth exploration of each paper, allowing us to conduct detailed comparisons of extraction accuracy and making it feasible to perform multiple iterations of prompt engineering and assessment throughout the process.

Our examination of COVID-19 modeling studies leveraged our team's expertise and enabled us to confidently determine correct answers for meaningful comparisons with ChatGPT's outputs. Although COVID-19 may no longer be at the forefront of global attention, these studies remain a *methodologically rich test case* rather than a focus of current clinical relevance. They combine straightforward features (eg, study design, interventions) with more abstract elements of human behavior (eg, compliance with public health measures, mobility changes), allowing us to systematically assess ChatGPT's performance across varying levels of complexity. Furthermore, the pandemic's urgency previously highlighted the value of accurate, rapid synthesis of research findings during health emergencies, making it an ideal context for evaluating the practical utility of LLMs in accelerating SLRs.

Many researchers who conduct SLRs may not necessarily have the expertise required to implement LLMs through advanced tools. Thus, we conducted our analysis using ChatGPT, given that it is one of the most widely adopted models, attracting 393 million users each month, as shown by October 2024 data [29]. We used the web browser interface for its user-friendly design, as opposed to an API. Although using the API might have offered more controllable responses, our study prioritized accessibility and usability, reflecting the real-world context in which many researchers engage with ChatGPT. We selected the GPT-4 model specifically, as at the time of our analysis, it was one of the few that directly analyzed full text as a PDF file. Although our approach could also be applied to studies available in other formats, our focus on PDF files reflects their frequent use in academic publishing and SLRs.

Ethical Considerations

This study did not involve human participants, identifiable human data, or interaction with individuals. As such, it did not fall under the scope of research requiring review by an institutional review board, and ethical approval was not required.

Data Elements

We defined the sets of measures to be extracted as (1) study settings (ie, analysis location, modeling approach, and analyzed interventions) and (2) behavioral components (ie, changes in travel and mobility, perception of risk and severity, and compliance and resistance to public health measures). Therefore, for each of the 10 studies [19-28], we extracted 6 distinct data elements, resulting in 60 data elements.

We distinguished these measures to reflect their nature: study settings are straightforward, whereas extracting information on behavioral components in COVID-19 models is influenced by

XSL•FO
RenderX

researchers' perspectives [13]. We confined our study settings to information explicitly stated in the text. For behavioral components, we categorized them into no mention (A), mentioned but not modeled (B), modeled exogenously but not analyzed (C), modeled exogenously and analyzed (D), modeled endogenously but not analyzed (E), and modeled endogenously and analyzed (F). Endogenous modeling incorporated human behavior as an internal part of the model, where it both influenced and was influenced by the spread of COVID-19. Exogenous modeling indicated behavioral changes were external factors impacting the spread of COVID-19 without being influenced by it. This classification ranged from minimal (A) to comprehensive (F) incorporation into COVID-19 models.

Data Extraction Process and Comparison

Two trained researchers independently extracted data from the 10 studies [19-28] and then reconciled discrepancies in their findings—6 related to study settings and 11 to behavioral components—for convergence. The researchers discussed any unresolved discrepancies with a third senior researcher to reach a consensus. Subsequently, we initiated a dedicated session for every study and prompt, uploading the individual files (in PDF) into the GPT-4 model using ChatGPT's user interface (accessed in January-April 2024) and documented the responses. To gain confidence in our manual screening, wherever ChatGPT, consistently through iterations of prompts, provided answers that disagreed with our manual coding, we reassessed our original codings. Following this reassessment and after making necessary adjustments, we finalized the manual screening results and considered them as the correct responses. We calculated individual researchers' average accuracy rates (the percentage of their correct responses before any consensus was reached), allowing us to directly compare ChatGPT's performance against the individual researchers' average accuracy for each measure throughout prompt iterations [8].

Prompt Engineering

We started by providing ChatGPT with a general prompt to extract each desired data element. Due to initially unsatisfactory results, we iteratively engineered prompts based on the initial responses and our manual coding. This process involved altering the wording of prompts for clarity and concisely adding specific descriptions of our objective, approach, and definitions of key terms [30]. Particularly, we often guided ChatGPT to base any interpretations strictly on what was explicitly stated in the text, as it often made incorrect inferences. Furthermore, we followed up with ChatGPT regarding its incorrect responses by inquiring about potential improvements to the prompts after clarifying the desired answers [30].

We continued to refine the prompts until we achieved complete alignment with our manual screening results, reached saturation in improvement, or explored viable avenues for prompt enhancement to the best of our capabilities. Given the exploratory nature of this study and the fact that LLMs are designed to interact with users in real time, prompt refinement without a formal training phase reflects a common use case for this technology. Recent tutorials and case studies have demonstrated ChatGPT's feasibility in domain-specific and rapid literature reviews, reinforcing its relevance as a practical, real-world tool that benefits from iterative, user-guided prompt refinement [31,32]. Table 1 illustrates an example of the iterative process used to prompt ChatGPT for extracting data elements in this study. We applied a similar method to extract additional data elements, with the processes reported in Multimedia Appendix 1.

XSL•FO
RenderX

Table . Example of the iterative process of prompt engineering to extract data elements.

Version	Description of prompt modification	Prompt
1	Initial prompt	What is the simulation modeling approach used in this paper?
2	Improved clarity	What model is used?
3	Focused output	Specify the overall type of model used in the study. If the modeling approach is unspecified, please state so.
4	Avoid overreporting	Specify the overall type (as opposed to the name) of the model used in the study. If the paper does not explicitly introduce the type of model used, state so by returning "unspecified."
5	Exclude inferred information	Specify the overall type (as opposed to the name) of the model used in the study. If the PDF file does not explicitly introduce the type of model used, state so by returning "unspecified," and do not infer the type of model.
6	Emphasis on explicit information	Read this PDF file line by line. Only specify the overall general type, as opposed to the name, of the model used in the study. If the author(s) of this PDF file do not explicitly introduce the type of model used, state so by returning "unspecified," and do not infer the type of model. Be sure to only specify the type of foundational analytical model rather than any supplementary methods.
7	Step-by-step instructions	Read the provided PDF document line by line, focusing on identifying the general category or type of model mentioned in the study. Your task is to: • Identify the type of model: Look for any mention of the foundational analytical model used in the research. Specify only the general category or type (eg, regression model) rather than the specific name or variant. • Explicit mention required: If the document does not explicitly mention the type of model used in the analysis, respond with "unspecified." Avoid making inferences based on the context or the data presented. • Focus on the foundational model: Concentrate on identifying the primary analytical model that the study is based on. Disregard any supplementary methods, tools, or analytical techniques that are mentioned unless they are integral to the foundational model itself.

Results

Table 2 summarizes ChatGPT's responses across 6 measures for the last iteration of prompts. These measures were divided into study settings and behavioral components.

Through the course of iterations, we identified 4 instances where ChatGPT consistently disagreed with our manual coding but was determined to have provided the correct answer upon reassessment. These instances were among the prompts related exclusively to study settings: 3 pertained to answers generated for prompts about interventions analyzed, and 1 addressed the correct location of analysis.

As a result of iterative prompt engineering, the average accuracy of ChatGPT's responses showed a marked improvement of 33% and 23% between the initial and final iterations for extracting study settings and behavioral components, respectively (Figure 1). Specifically, in our initial prompts, 26 (43.3%) of 60 ChatGPT responses were correct. However, the latest prompt version yielded 43 (71.6%) correct answers. The iterative responses from ChatGPT and a comparison with our manual screening are detailed in Multimedia Appendix 1. By the fourth iteration, ChatGPT outperformed the individual screeners' average accuracy in identifying study settings (Figure 1). However, ChatGPT consistently could not achieve a level of

XSL•FO
RenderX

precision comparable to that of manual screeners (Figure 1) when extracting behavioral components.

RenderX

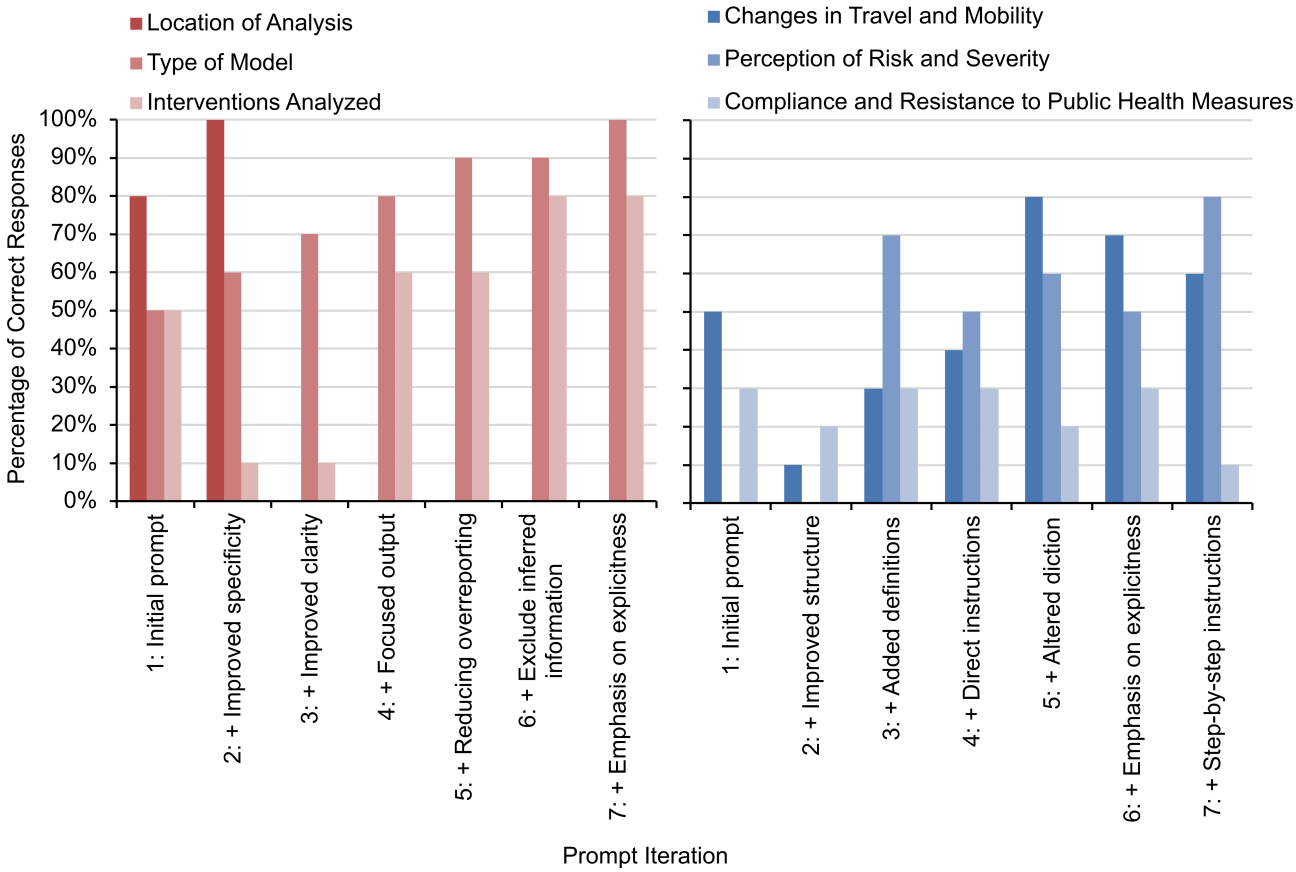
Figure 1. Average percentage of correct ChatGPT responses throughout iterations (bars) in comparison to the average accuracy of screeners before consensus (dashed lines) across study settings and behavioral components in COVID-19 models.



Specifically, ChatGPT provided correct responses for all 10 papers [19-28] when prompted to identify the analyzed location and model type used by the second and seventh iterations of prompts, respectively. At most, ChatGPT correctly identified 8 of 10 interventions analyzed within the studies, achieving a peak accuracy of 80% by the sixth iteration (Figure 2). Conversely, it took 6 and 7 iterations to reach a peak accuracy of 80% (ie, 8 of 10 correct classifications) for classifying how each study assessed changes in travel and mobility and the perception of risk and severity, respectively. Our alignment with ChatGPT's responses for coding compliance and resistance to public health measures only achieved a maximum consistency rate of 3 (30%) correct answers across the 10 studies [19-28] (Figure 2).

Finally, the contrast between the distribution of the manual coding and ChatGPT is presented in Figure S1 in Multimedia Appendix 1, and the distributions of ChatGPT's responses are presented in Figure S2 in Multimedia Appendix 1.

XSL•FO
RenderX

Figure 2. Percentage of correct ChatGPT responses throughout iterations of each prompt. The red bars depict the progression of ChatGPT's accuracy for the three study setting elements, and the blue bars present the progression for the three behavioral component elements. Since the location of analysis achieved 100% by the second version, we concluded further iterations for this prompt.

Discussion

Principal Findings

Our analysis underscores the finding that ChatGPT's assistance in full-text screening of study reports is particularly useful when handling simple inquiries, specifically general study settings, for which details are typically explicit in the text. However, the task of assessing nuances that necessitates drawing inferences (eg, the integration of human behavior in COVID-19 models), where the study may or may not have an explicit discussion, presents a significant challenge for ChatGPT.

Rather than prolonging the iterative process to elicit correct responses, we adopted a strategy of structuring prompts based on ChatGPT's previous responses to ensure explicitness over the course of 7 iterations. Although it may have been possible to continue iterating to improve response accuracy, such a strategy is impractical in real-world scenarios. In addition, we acknowledge the potential risk of overfitting due to iterative prompt engineering on the same set of studies; however, our primary objective was to explore the utility of ChatGPT in real-world use cases where prompt refinement is common practice. This utility is especially relevant, given the broad reliance on SLRs to guide evidence-based practices across fields, with particular importance in health and biomedical sciences, where decisions impact health outcomes [31]. Hence, we limited this study to a manageable number of papers to better understand the limitations of prompt engineering itself. Importantly, the framework we used for evaluating ChatGPT (GPT-4) in COVID-19 modeling studies can be applied similarly to other SLRs regardless of the specific topic.

We highlighted that ChatGPT's performance is influenced by the explicitness of information within the text, not just by the clarity or objectivity of the prompts. This underscores a nuanced limitation: the technology's current dependency on explicit textual evidence for accurate data extraction. This limitation is notable, even with the use of straightforward prompts, underscoring a significant barrier in LLMs' application to literature analysis. For instance, despite clear prompts, ChatGPT often struggled to correctly identify the model type in studies—expected to be straightforward—unless explicitly mentioned. Even when instructed to label model types as "unspecified" in the absence of clear documentation, early iterations often resulted in incorrect answers rather than adherence to the "unspecified" directive. This illustrates that ChatGPT's accuracy is dependent not only on the prompt structure but also on the presence of explicitly detailed textual information. Hence, a central insight from this analysis is the significant obstacle that LLMs encounter when navigating ambiguity, further complicating the tasks of engineering effective prompts.

XSL•FO
RenderX

Furthermore, among ChatGPT's responses that did not correspond to our manual coding, we observed a tendency for ChatGPT to extrapolate beyond the presented data. Despite instructions to confine responses to the explicit content of each study, ChatGPT often listed additional interventions not stated by the authors. This pattern of overreporting was also evident when categorizing studies based on the extent of their integration of behavioral components into the model. ChatGPT frequently assigned a higher integration level than that supported by the studies' text (Multimedia Appendix 1). These skewed errors align with ChatGPT's tendency to "hallucinate," or provide confidently articulated yet factually unsupported responses [10].

Despite these challenges, LLM tools may be useful for SLRs. For 3 (30%) studies, ChatGPT correctly identified and analyzed interventions that we initially overlooked. For example, in Wong et al's study [23], ChatGPT identified COVID-19 testing as an intervention in 6 of 7 prompt iterations—a detail our original manual assessment missed. This led us to reevaluate the study, and upon confirming ChatGPT's accuracy, we modified our assessment accordingly. Conversely, we revisited our categorization of behavioral components in 6 incidences with which ChatGPT consistently disagreed, but we confirmed that our original manual coding was correct.

The main contribution of this study is to extend the understanding of current LLMs' capabilities and limitations in handling complex data, providing valuable insights for those who conduct SLRs and are exploring the use of LLM platforms. Our observation that ChatGPT outperformed the average accuracy of individual reviewers when identifying study settings underscores its utility as an assistant or a second reviewer in extracting basic measures for SLRs. These results support previous research, which indicates the potential of LLMs for handling basic data extraction tasks effectively [10,11] and their use as a collaborator [32] or a second rater [33] in SLRs. However, for ChatGPT to be effectively used in this role, there remains a need for researchers to provide clear and detailed prompts that provide the relevant context. This approach requires researchers to have a thorough understanding of the context relevant to their inquiries and have access to reliable, coded data elements to directly compare against ChatGPT's responses.

In terms of extracting complex components, ChatGPT failed to achieve comparable accuracy to that of individual screeners, highlighting the continued necessity of manual data extraction and additional research to overcome the limitations of this technology. Although further testing with a test sample may yield different results, the insufficient performance observed in our training data alone suggests that current LLMs remain unreliable for handling complex data extraction tasks. These findings align with other studies that discuss LLM performance, which similarly conclude that although automation is advancing, prevailing errors emphasize that structured oversight remains critical [15,34].

Limitations

This study is subject to several limitations. First, this study focused on one aspect of the SLR process, given that other steps (eg, writing Boolean query formulations [35] and screening titles and abstracts [10,36]) have already been examined in greater detail. Second, we evaluated ChatGPT with only one review topic, which limits the generalizability of our results. Third, we often noticed inconsistencies in ChatGPT's responses for the same prompts, but we did not formally assess reproducibility. Fourth, although accurate data extraction highly depends on the LLMs' capabilities in accurately parsing PDF files [12], our paper does not quantify the impact of any errors in converting PDF files to text. Nonetheless, our results still highlight the stark differences in LLMs' capabilities in accurately extracting simple versus complex data elements. Fifth, we selected ChatGPT for this study due to its wide accessibility and usability. We recognize that our exclusive focus is a limitation, as other models may have provided different insights or comparative performance benchmarks. Future research should explore the capabilities of multiple models to provide a more comprehensive understanding of LLM performance in this context. For example, certain advanced approaches (eg, retrieval-augmented generation) exist to better handle evidence or references from external sources. Since our focus was on a common, practical scenario in which typical reviewers use a publicly accessible GPT model, these specialized methods fall outside the scope of this study. Finally, due to the rapidly changing nature of LLMs, our findings may not hold over time.

Conclusion

Overall, LLMs, and ChatGPT in particular, show promising performance in assisting the extraction of explicitly stated information from the full text of study reports, particularly when limited scientific reasoning is required. However, ChatGPT currently exhibits limited potential for fully automating data extraction across more complex, subjective measures. Our findings emphasize the ongoing necessity of human oversight in handling complex, nuanced data extraction tasks, even as LLMs continue to improve. This position is consistent with broader calls in the literature to adopt a cautious, well-evaluated approach to integrating LLMs into evidence synthesis workflows [15]. We highlight an important contribution to human-AI collaboration research, demonstrating the need to integrate AI tools with human oversight in SLRs, particularly in areas where current models fall short.

Abstract

Background: Tacrolimus forms the backbone of immunosuppressive therapy in solid organ transplantation, requiring precise dosing due to its narrow therapeutic range. Maintaining therapeutic tacrolimus levels in the postoperative period is challenging due to diverse patient characteristics, donor organ factors, drug interactions, and evolving perioperative physiology.

Objective: The aim of this study is to design a machine learning model to predict the next-day tacrolimus trough concentrations (C0) and guide dosing to prevent persistent under- or overdosing.

Methods: We used retrospective data from 1597 adult recipients of kidney and liver transplants at UC San Diego Health to develop a long short-term memory (LSTM) model to predict next-day tacrolimus C0 in an inpatient setting. Predictors included transplant type, demographics, comorbidities, vital signs, laboratory parameters, ordered diet, and medications. Permutation feature importance was evaluated for the model. We further implemented a classification task to evaluate the model's ability to identify underdosing, therapeutic dosing, and overdosing. Finally, we generated next-day dose recommendations that would achieve tacrolimus C0 within the target ranges.

Results: The LSTM model provided a mean absolute error of 1.880 ng/mL when predicting next-day tacrolimus C0. Top predictive features included the recent tacrolimus C0, tacrolimus doses, transplant organ type, diet, and interactive drugs. When predicting underdosing, therapeutic dosing, and overdosing using a 3-class classification task, the model achieved a microaverage F_1-score of 0.653. For dose recommendations, the best clinical outcomes were achieved when the actual total daily dose closely aligned with the model's recommended dose (within 3 mg).

Conclusions: Ours is one of the largest studies to apply artificial intelligence to tacrolimus dosing, and our LSTM model effectively predicts tacrolimus C0 and could potentially guide accurate dose recommendations. Further prospective studies are needed to evaluate the model's performance in real-world dose adjustments.

Introduction

Background

Tacrolimus is a mainstay of immunosuppressive therapy for patients undergoing solid organ transplants. Despite widespread use and health care provider comfort in managing tacrolimus dosing in the posttransplant period, maintaining the tacrolimus trough concentrations (C0) within the narrow therapeutic range comes with its own set of challenges. In the immediate postoperative period, maintenance of tacrolimus C0 within the therapeutic range is challenging due to baseline patient characteristics, donor organ characteristics, drug-drug interactions, and evolving perioperative physiology resulting in variable day-to-day exposures [1-4]. This variability and, more so, the time out of therapeutic range put patients undergoing solid organ transplants at increased risk of both the development of de novo donor-specific antibodies (dnDSA) from persistent underdosing and tacrolimus toxicity from significantly supratherapeutic levels [5]. Given the risk that inappropriate dosing poses to patients undergoing transplants in terms of organ rejection and tacrolimus toxicity, a considerable amount of time and effort is spent by clinicians to determine and adjust a patient's dose.

Challenges and Study Objective

There have been several efforts to reduce this burden on clinicians and improve the time in therapeutic range for

XSL•FO
RenderX

recipients of solid organ transplants by using both clinical and genetic variables in the form of publicly available population pharmacokinetics and machine learning models to predict dose-adjusted tacrolimus C0 and recommend optimal tacrolimus dosages [6-11]. However, some of these models require genotyping (ie, CYP3A5 single nucleotide polymorphisms [SNPs]), which may not be widely available in all institutions [6]. In addition, user interface and data requirements for commercially available third-party vendors limit generalizability and practicality for use in the inpatient setting [7]. Methods based on the area under the concentration-time curve require multiple concentration measurements at different time points, making them resource intensive [8,9]. Some studies attempted to predict the optimal stable tacrolimus dosage directly, but this approach is flawed because the "stable" dose may be reached weeks or months after the transplant, during which dnDSA may develop [10,11].

In this work, we describe the development of a machine learning model using electronic health record (EHR) data from Epic Systems to predict the next-day tacrolimus C0 and guide dosing via a recommendation system for clinicians to prevent persistent over- or underdosing in the inpatient setting. Our model accurately predicts tacrolimus C0 by using comprehensive clinical features from a patient's medical history, including transplant type, demographics, comorbidities, vital signs, laboratory parameter results, and medications, resulting in more personalized tacrolimus C0 predictions and dose recommendations.

Methods

Study Design and Dataset

We extracted retrospective data for adult recipients of kidney or liver transplants who received inpatient care at UC San Diego Health from January 2016 to May 2024. These dates were selected to ensure a sufficient sample size and standardization of immunosuppressive therapy. We included adult patients (aged ≥18 years) who received their first liver or kidney transplant. We excluded patients who were transplanted with more than one organ or were receiving a second transplant. Data from 2016 to 2023 were randomly split into 90% for the training set and 10% for the validation set, and the test set contained patients from 2024. The intended use of our model is to predict the next-day tacrolimus C0 based on the features extracted from the patients' EHRs. To make predictions on the tacrolimus C0 for the next day, we require data of both the tacrolimus C0 and dosage for the current day.

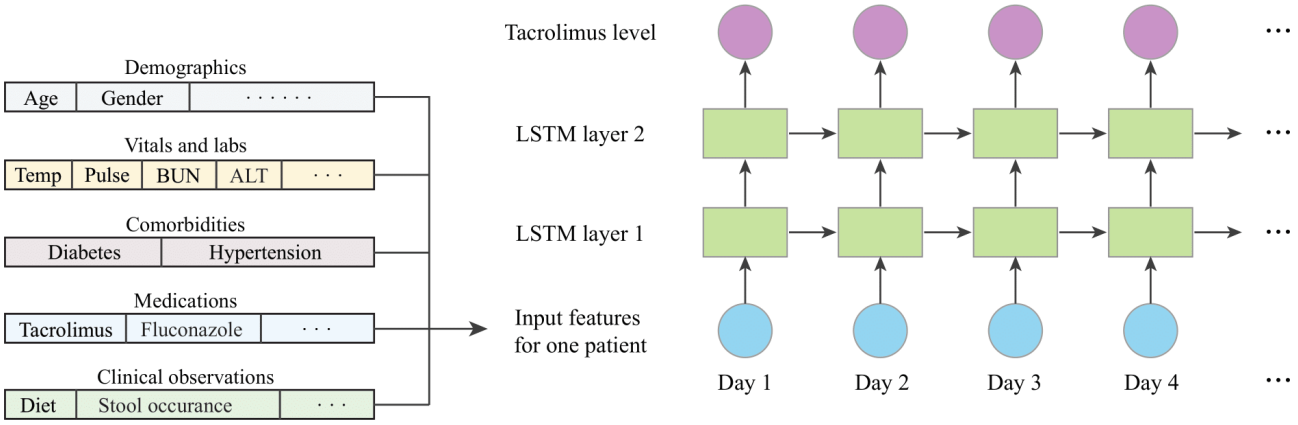
Ethical Considerations

This study was completed in accordance with the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) guidelines [12] (Checklist 1) and was approved by the institutional review board at the University of California San Diego (protocol 802489). This retrospective study involved secondary analysis of existing EHR data, for which the institutional review board granted a waiver of informed consent. Only the minimum necessary protected health information was accessed and stored on HIPAA (Health Insurance Portability and Accountability Act)–compliant UC San Diego Health servers; the information will be destroyed upon study closure. No compensation was provided.

Features

We selected 62 variables as features for each patient, including transplant type, demographics, comorbidities, vital signs, standard inpatient laboratory parameters, ordered diet, and medications, all of which were used to train the model. Transplant type identifies the organ received by the patient (eg, liver or kidney) and is represented as a binary variable. As previously mentioned, only patients who received a single transplant of one type were included. Demographics include age, gender, race, weight, and height. Medications for inpatients were recorded each time they were administered, with timestamps and dose details. This allowed us to calculate the daily dose for each medication. Our medication list included tacrolimus and other drugs known to interact with tacrolimus [13], with a comprehensive list provided in Multimedia Appendix 1. This list includes a total of 12 medications. We recorded the daily tacrolimus dosage in mg, excluding the tacrolimus extended-release dosage, which is rarely used at our institution, particularly for inpatient admissions and in the immediate postoperative period. At our institution, tacrolimus levels are measured using a chemiluminescent microparticle immunoassay on whole blood samples. Any level <2 ng/mL is reported as "<2 ng/mL," and we used 1 ng/mL to represent data in this range. For other medications, we used a binary variable to indicate whether the patient took the medication within the 3 days prior to the prediction date, accounting for the cumulative drug effect. Vital signs and standard inpatient laboratory parameters were recorded using the built-in measurement unit. Forward filling was applied for imputation, and if no previous data were available for a patient, the global median of nonmissing data was used. Comorbidities considered included hypertension and diabetes. Diabetes was categorized as type 1, type 2, and others, with each category encoded as a binary variable. For categorical features, we used one-hot encoding.

Long Short-Term Memory Model



We used a long short-term memory (LSTM) [14-16] model in a multistep forecasting approach to predict daily tacrolimus C0 after transplant. The LSTM model architecture is well suited for handling sequential data, as it is designed to capture long-range dependencies by using memory cells to retain information over time.

For each patient, we modeled a sequence of daily features, where each feature vector represents the clinical and demographic information available for that specific day. The LSTM model processes this sequence chronologically, leveraging the information from all preceding days to predict the tacrolimus C0 for each subsequent day. Importantly, when predicting the tacrolimus C0 for a particular day, only the features from previous days were considered, ensuring that future information was not used and thus aligning with real-world clinical scenarios. This approach allows the model to dynamically incorporate the evolving clinical profile of the patient as more data become available over time, effectively capturing the temporal dependencies inherent in the patient's posttransplant

XSL•FO
RenderX

clinical course progression. The architecture of our LSTM model is illustrated in Figure 1.

Figure 1. Long short-term memory (LSTM) model architecture with detailed feature representation. ALT: alanine aminotransferase; BUN: blood urea nitrogen; Temp: temperature.

Studying the influence of different features is necessary for clinicians to understand the potential relationship with predicted tacrolimus concentrations. To evaluate the feature importance of the model, we used permutation importance (also known as model class reliance) [17]. This was obtained by randomly shuffling the values of each feature and observing the impact on the model's predictive performance, thereby quantifying the reliance of the model on each specific feature. A higher performance decrease indicates the feature is more important.

Data Processing, Training, and Hyperparameters

Feature normalization was performed to scale values into the (0,1) range. The LSTM models were trained using the Adam optimizer. Regularization was applied to minimize overfitting and enhance generalizability. A hyperparameter search was conducted for the LSTM model by optimizing the size and number of LSTM layers, dropout rate, learning rate, and the regularization parameter using 5-fold cross-validation on the training cohorts using Bayesian optimization [18]. The loss function used in the hyperparameter search is mean squared error (MSE). In addition, other model architectures (Multimedia Appendix 2) were trained and compared, and the LSTM model was selected as the best-performing model based on the MSE on the validation set. All experiments were performed using Jupyter Notebook 6.5.6 (Jupyter) in a secure cloud environment within AWS SageMaker (Amazon Web Services). The model was implemented using Python (version 3.8.18), with data preprocessing performed using NumPy (version 1.24.4) and pandas (version 2.0.3), and model training was conducted using PyTorch (version 2.0.0).

Metrics for Tacrolimus C0 Prediction

Mean absolute error (MAE) and mean absolute percentage error (MAPE) were calculated on the test set to evaluate the performance of the models. MAE is calculated as the average of the absolute differences between the predicted and actual concentrations. MAPE is calculated as the average of the absolute differences between the predicted and actual concentrations divided by the actual concentrations and is expressed as a percentage.

Tacrolimus Underdosing, Overdosing, or Therapeutic Dosing Concentrations Classification

We designed a 3-class classification task to assess the model's ability to predict underdosing, overdosing, or therapeutic dosing, based on our institution's defined therapeutic window for patients undergoing kidney transplant with good kidney function and patients undergoing liver transplant with high risk factors for rejections across different posttransplant periods. The target tacrolimus C0 for patients undergoing kidney transplant are 10 to 13 ng/mL during the first 0 to 3 months after the transplant and 8 to 10 ng/mL after 3 months. For patients undergoing liver transplant, the target concentrations are 7 to 10 ng/mL within the first year after the transplant and 5 to 7 ng/mL 1 year after the transplant. The models were evaluated using precision, recall, and F_1-scores. Given the multiclass nature of the task, we report both the microaverage (equal weight to each instance) and macroaverage (equal weight to each class) for precision, recall, and F_1-scores to represent the overall and per-class performance, respectively.

Due to the limited data available on underdosing and overdosing cases, we implemented an oversampling strategy [19] to balance the training dataset. Specifically, we duplicated instances with tacrolimus C0 below 5 ng/mL or above 13 ng/mL 3 times, resulting in a total of 4 instances for each of these cases during training. This approach aims to enhance the model's ability to recognize these critical yet underrepresented cases. We report the classification results for both the original dataset (uniform sampling) and the oversampled dataset, providing a comprehensive evaluation of the model's performance under different training conditions.

Dose Recommendation

We calculated the recommended dose based on the predicted tacrolimus C0. This was achieved by considering all possible dose options within a 15-mg range for a single dose, with increments of 0.5 mg, administered twice daily. We ensured that the difference between the morning and evening doses was limited to 0 mg, 0.5 mg, or 1 mg, with the additional restriction that the recommended daily dose remains within 1.5 times the previous day's dose. This threshold was chosen after discussion with our multidisciplinary group, which included transplant

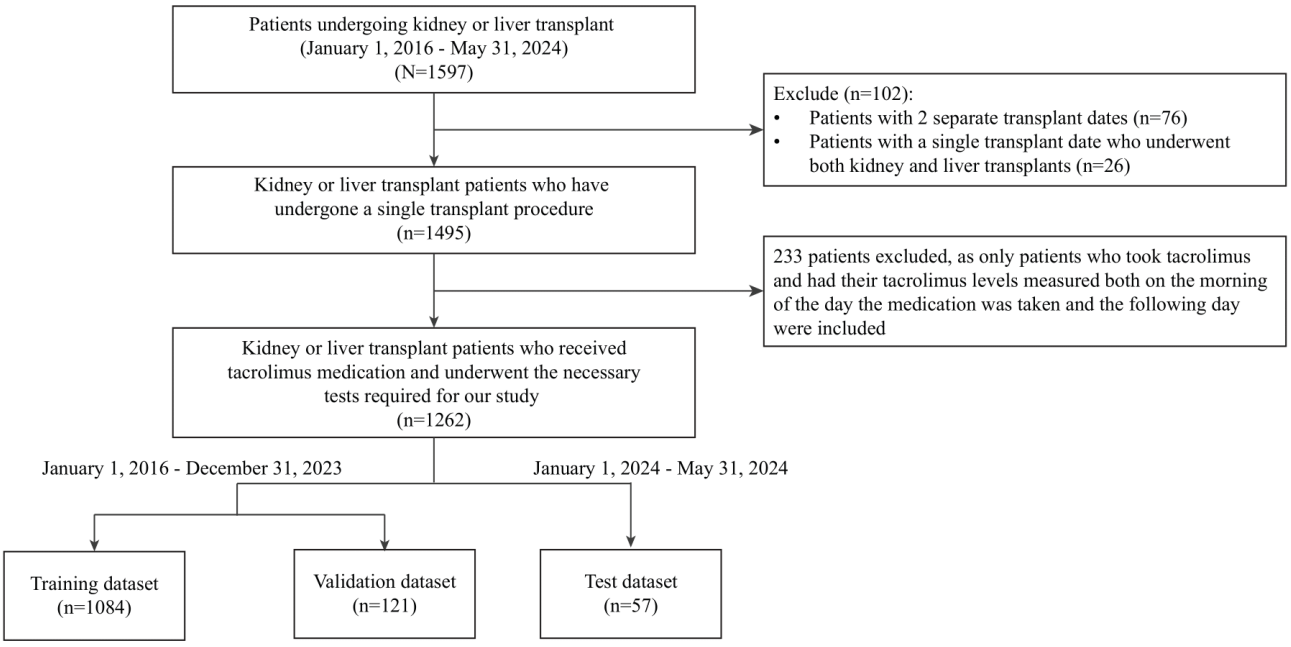
XSL•FO
RenderX

pharmacists and health care providers, to increase the usability of this recommendation system. The recommended dose selected was the one that resulted in the best predicted C0, specifically the mean value within the therapeutic window defined for the patient.

We evaluated the effectiveness of the recommended dose by defining a reward function, R(.), using the formula from Lin et al [20]. It translates the measured outcomes into a continuous reward using the following function:

$$R(x)=c1+e-(x-blower)-c1+e-(x-bupper)$$

Here, x is the tacrolimus C0, and blower and bupper are the lower and upper bounds, respectively, given by our institution's defined therapeutic windows. The constant c scales the reward function appropriately within the range [0,1]. See Multimedia Appendix 3 for the shape of the reward function. This function yields a high reward close to 1 when x is within the target range, and the reward gradually decreases to 0 as x moves outside this range.



Results

Patient Characteristics

We identified 1597 patients undergoing transplants who received at least one kidney or liver transplant between January 1, 2016, and May 31, 2024. Of these, 1495 patients received only one type of transplant, with 1033 patients undergoing kidney transplant and 462 patients undergoing liver transplant. The cohort was further refined to 1262 patients after ensuring that they had consistent patient records, including taking tacrolimus, having their tacrolimus C0 measured on 2 consecutive mornings, and administering the medication after the first measurement. This includes 825 kidney recipients and 437 liver recipients. A detailed flowchart of the patient selection process is provided in Figure 2.

The final dataset consisted of 9601 tacrolimus C0 measurements to be predicted, with 4602 from kidney recipients and 4999 from liver recipients. On average, patients undergoing kidney transplant contributed 5.6 predictions and patients undergoing liver transplant contributed 11.4 predictions to the entire cohort. The median daily tacrolimus dose was 5.0 mg for both kidney and liver recipients. The median (IQR) tacrolimus concentration was 8.4 (6.4 - 10.8) ng/mL for kidney and 7.5 (5.5 - 9.7) ng/mL for liver recipients. The median (IQR) age was 58 (47-65) years, with 47% of kidney recipients and 44.8% of liver recipients identifying as White. Notably, hypertension was more prevalent among kidney recipients (86.5%) than liver recipients (54%), while the prevalence of diabetes was similar between the two groups (51.9% for kidney and 49.2% for liver recipients). The dataset spanned a median (IQR) of 15 (3-123) days after the transplant for kidney recipients and 19 (5-113) days for liver recipients. See Table 1 for a detailed description of patient characteristics.

Tacrolimus (ng/mL), median (IQR)	8.4 (6.4 - 10.8)	7.5 (5.5 - 9.7)

Performance

The LSTM model demonstrated an MAE of 1.880 ng/mL in predicting the next day's tacrolimus C0, taking both patients undergoing kidney and liver transplants into consideration. If analyzed separately, the MAE was 1.973 ng/mL for patients undergoing kidney transplant and 1.744 ng/mL for patients undergoing liver transplant. In addition, we computed the MAE if the measured levels were below, within, and above the tacrolimus target window, which was 1.427, 1.521, and 4.365 ng/mL, respectively. When evaluated using the MAPE, the model achieved an average rate of 24.3% for both patients undergoing kidney and liver transplants, with a MAPE of 23.8% for patients undergoing kidney transplant and 25.0% for patients undergoing liver transplant. We observed a 21% decrease in the MAE when evaluating predictions from days 5 to 10 after the transplant compared to days 1 to 5. The final hyperparameters were 2 LSTM layers with a hidden state size of 48, a dropout rate of 0.1, a learning rate of $2e^{-3}$, a batch size of 16, and an L2 regularization (weight decay) of $1e^{-5}$.

The model's capability to predict underdosing or overdosing was evaluated using the target concentration ranges in a 3-class classification task. As shown in Table 2, the model achieved an overall microaverage F_1-score of 0.653. The F_1-score for predicting underdosing was notably higher at 0.795, reflecting the model's strong ability to forecast underdosing.

XSL•FO
RenderX

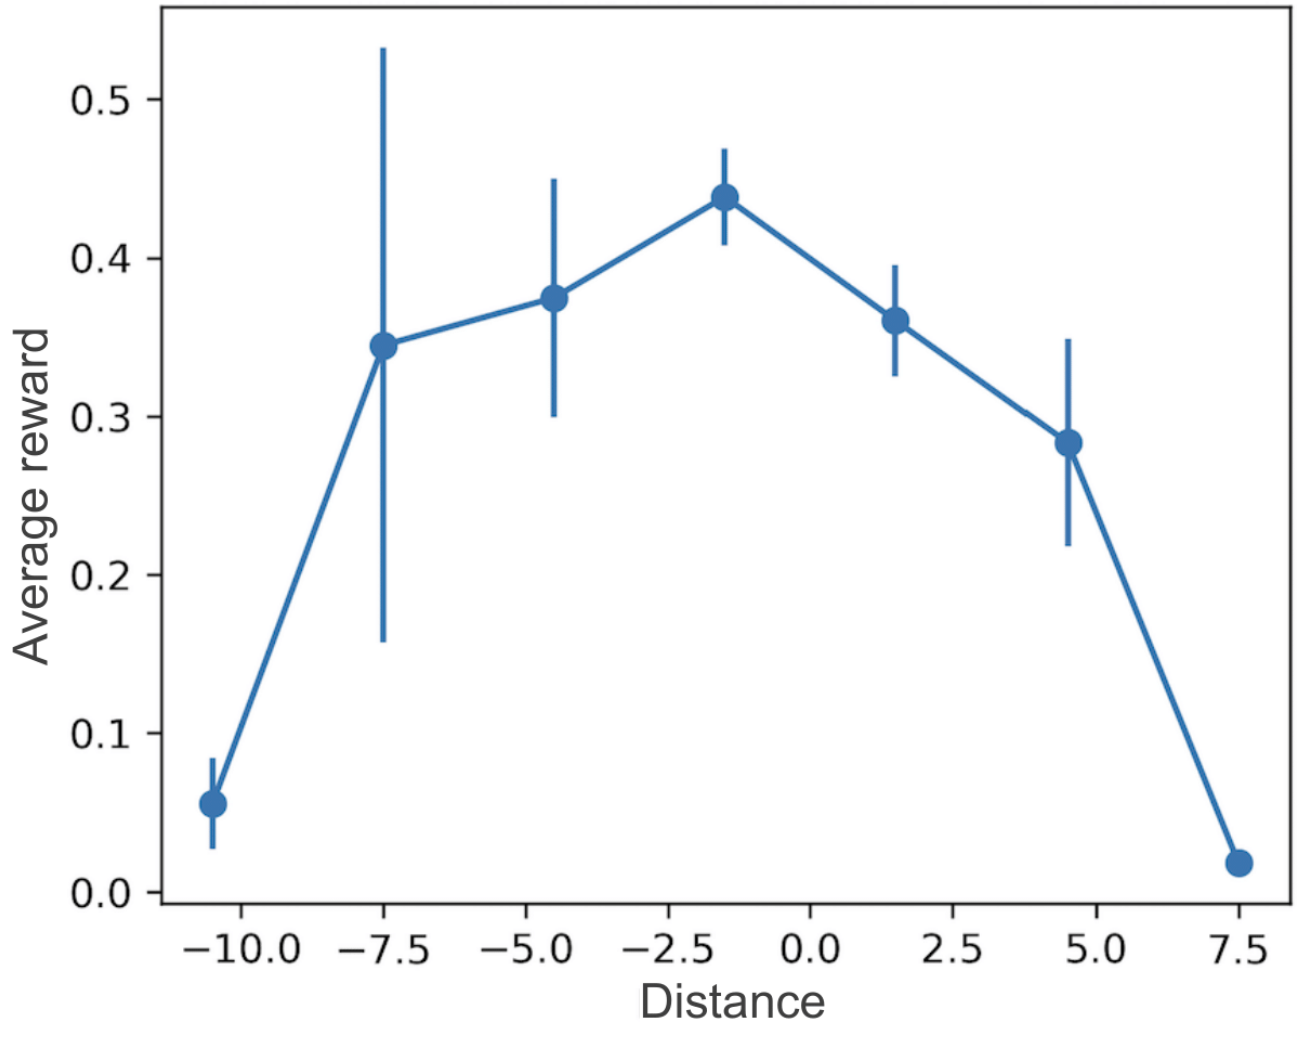
	Underdosing	Therapeutic	Overdosing	Macroaveraged	Microaveraged
Precision	0.851	0.427	0.405	0.561	0.673
Recall	0.746	0.571	0.357	0.558	0.642
F_1-score	0.795	0.489	0.380	0.555	0.653



Important Features for Tacrolimus C0 Prediction

Here, we report on the top 10 most important features for the proposed LSTM model. The feature importance analysis revealed that the most recent tacrolimus C0 (tacro_level_today) is the most critical factor in predicting future concentrations, indicating that the model heavily relies on the latest available concentration. The type of organ transplanted (eg, kidney) and variables related to the tacrolimus dose—specifically, tacro_dose_prev_16_24, tacro_dose_0_8, and tacro_dose_16_24, which represent the dose administered 16 to 24 hours earlier, 0 to 8 hours on the current day, and 16 to 24 hours on the current day, respectively—also demonstrate significant importance. Medications such as ketoconazole, fluconazole, posaconazole, and prednisone, which are known for their interactions with tacrolimus, are also key predictors, aligning with clinical expectations. The number of recorded meals (ie, standard diet) also contributes meaningfully to the model's predictions, potentially due to the impact of nutritional status on drug absorption and metabolism [21]. Overall, the analysis highlights the model's reliance on recent tacrolimus C0, tacrolimus doses, organ type, diet, and drug interactions in predicting tacrolimus C0.

Dose Recommendation

We analyzed the relationship between the difference in actual and recommended daily doses and the corresponding reward in terms of means and SEs (Figure 3). We observed that when this difference approaches zero, the average rewards are the highest, suggesting that when clinicians select doses closer to the recommended values, the tacrolimus C0 are optimal. Conversely, as the difference increases, the reward tends to decline. These findings suggest that our recommended algorithm, based on the level prediction model using LSTM, provides reasonable and useful guidance for tacrolimus dosing.

Discussion

Principal Findings

We presented a data-driven clinical decision support tool for optimizing posttransplant immunosuppressive therapy with the potential to improve patient outcomes. In comparison to other previously described attempts that use Bayesian modeling or machine learning methods, we have accomplished the development of an accurate prediction model using only clinical variables available within the EHR. The LSTM model is designed to process sequential data, capturing long-term dependencies that are crucial in clinical settings where patient responses to medication evolve over time [22].

In using institutional data for model development, we recognized that SEs associated with daily laboratory measurements likely impact prediction accuracy. This error is present in all tacrolimus C0 measurements regardless of institution; however, previous studies aiming to predict daily tacrolimus C0 measurements for patients undergoing solid organ transplants fail to address this [6,23]. At our institution, precision and accuracy rates of daily quality control C0 measurements are both 5%. This SE, in combination with the variability of tacrolimus administration times and tacrolimus C0 lab draw times, likely plays a significant role in the accuracy of our prediction model and may prove to be a challenge when moving to real-world implementation of prediction and dose recommendation models.

In practice, dosing adjustments are based on a clear and comprehensive clinical picture, considering possible medication interactions and patient physiology. For the experienced and thorough health care provider, these adjustments are made fairly easily, whereas an inexperienced or nonspecialist health care provider adjusting these medications in an inpatient setting may experience difficulty consistently maintaining tacrolimus C0 measurements within the therapeutic window. Our dosing recommendation system offers a tool for health care providers to guide dosing adjustment, and next steps for this study include clinical validation. Previous dosing recommendations have largely been focused on initial dosing strategies, based on genotypes and clinical variables [24,25], but do not give daily recommendations. For large-volume transplant centers, these recommendations can save considerable time and effort, particularly with complex patients.

Comparison With Prior Work

Previous studies have developed predictive models based on genotype data, highlighting the potential for incorporating genetic information into future models to further enhance prediction accuracy [6]. We opted not to incorporate this for several reasons: the prediction and dose recommendation models were developed with the intention of clinical implementation, and health care providers at our institution do not routinely use genomics in their practice. Min et al [6] reported on 3 tacrolimus C0 prediction models using clinical variables alone, genomic variables alone, and a combination of clinical variables with CYP3A5 SNPs. The hybrid model performed the highest with a log-transformed MSE of 0.61 for their LASSO (least absolute shrinkage and selection operator) model. Meanwhile, our model using clinical variables alone achieves a log-transformed MSE of 0.10, outperforming the LASSO model. This suggests that while CYP3A5 SNPs may be important in determining initial dosing regimens, they may be less important when considering day-to-day tacrolimus C0 and dosing, although this may also be due to differences in the models used for our predictions.

Limitations

Hospital admissions following the index transplant typically occur due to significant illnesses, particularly infections, at which point pharmacokinetics are difficult to predict and lead to higher MAEs. Conditions such as diarrhea, infections (particularly those requiring azole antifungals), emesis, presence of continuous tube feeding, periods of fasting states, and additional surgeries that lead to bleeding further complicate accurate dosage prediction. We conducted a manual review of patient charts where the model showed significant inaccuracies and found that many relevant factors are better documented in clinical notes than in flow sheets and flowcharts. This indicates that using natural language processing techniques to extract this information could improve prediction accuracy, highlighting a promising area for future research [26,27]. Due to the frequency with which patients who have undergone solid organ transplants are admitted to the hospital, this population may benefit from the development of their own unique model, that is, separate models for the immediate postoperative period and subsequent readmissions. In addition, because each patient contributes to multiple predictions and later-stage predictions tend to be more accurate, the overall MAE may be biased depending on the distribution of predictions across different stages of hospitalization.

Given the variability in patient conditions, some patients may experience a departure from the baseline “steady state” physiology. However, as our model requires input of the current day’s dose and tacrolimus C0, critically ill patients whose tacrolimus C0 is on hold will not be incorporated in the model. Nevertheless, we captured patients who are not critically ill, such as those with delayed graft function [28] or biliary stricture [29]. Therefore, our model can account for moderate deviations from baseline with reasonable accuracy, providing clinicians with a valuable tool for managing various cases. For future research, we consider developing a separate model for nonstable patients and using an ensemble model to jointly predict outcomes for both steady and nonsteady patients.

Conclusions

By accurately forecasting tacrolimus C0, the proposed LSTM model can provide valuable guidance for dosage adjustments among patients undergoing kidney and liver transplants, with the potential to improve clinical outcomes by maintaining therapeutic drug levels and reducing the risk of underdosing or overdosing. The model performs particularly well in identifying patients likely to be subtherapeutic, suggesting that clinical implementation of the tool may aid in improving metrics, such as time to therapeutic concentration and days spent within the therapeutic window, and in limiting the risk of acute rejection. Integrating genetic data and using natural language processing techniques to capture additional clinical nuances may further refine the model’s accuracy and applicability. Future directions include clinical implementation and assessment of real-time

utility of this clinical decision support tool for dosing recommendations.

Abstract

Background: Since the release of ChatGPT and other large language models (LLMs), there has been a significant increase in academic publications exploring their capabilities and implications across various fields, such as medicine, education, and technology.

Objective: This study aims to identify the most influential academic works on LLMs published in the past year, categorize their research types and thematic focuses, within different professional fields. The study also evaluates the ability of artificial intelligence (AI) tools, such as ChatGPT, to accurately classify academic research.

Methods: We conducted a bibliometric analysis using Clarivate's Web of Science (WOS) to extract the top 100 most cited papers on LLMs. Papers were manually categorized by field, journal, author, and research type. ChatGPT-4 was used to generate categorizations for the same papers, and its performance was compared to human classifications. We summarized the distribution of research fields and assessed the concordance between AI-generated and manual classifications.

Results: Medicine emerged as the predominant field among the top 100 most cited papers, accounting for 43 (43%), followed by education 26 (26%) and technology 15 (15%). Medical literature primarily focused on clinical applications of LLMs, limitations of AI in health care, and the role of AI in medical education. In education, research was centered around ethical concerns and potential applications of AI for teaching and learning. ChatGPT demonstrated variable concordance with human reviewers, achieving an agreement rating of 47% for research types and 92% for fields of study.

Conclusions: While LLMs such as ChatGPT exhibit considerable potential in aiding research categorization, human oversight remains essential to address issues such as hallucinations, outdated information, and biases in AI-generated outputs. This study highlights the transformative potential of LLMs across multiple sectors and emphasizes the importance of continuous ethical evaluation and iterative improvement of AI systems to maximize their benefits while minimizing risks.

KEYWORDS

large language models; ChatGPT; Web of Science; medicine; education; technology; research categorization; artificial intelligence

Introduction

Within academic literature, artificial intelligence (AI) is broadly defined as a mechanical emulation of the human thinking processes to facilitate the analysis, simulation, exploitation, and exploration of human thinking processes [1]. ChatGPT has been trained on a massive amount of internet data from 2021 and is being updated from here on to include current data and information retrieval from the internet, which should reflect current, up-to-date information. It uses deep neural networks, machine learning, and a training dataset to interact with prompts and generate relevant human-like text responses [2], qualifying it as a large language model (LLM) [3]. ChatGPT may have significant potential to improve the efficiency of human innovation in a multitude of fields that require quick access to information, such as medicine and education, by providing instant feedback and helping to expedite clerical work, such as writing notes or research processes.

LLMs have been a topic of interest for researchers in many fields, with prior bibliometric analyses finding there to be an increase from 19 papers in 2017 to 2486 papers on LLMs as of 2023. The primary topics of studies published at that time were the utility of LLMs and the fields of interest where the use of LLMs could be implemented [4]. Studies focused on just ChatGPT rather than LLMs as a whole and identified the most

XSL•FO
RenderX

influential authors and countries for research on ChatGPT and tracing the rapid evolution of ChatGPT scholarship [5]. More recently, a bibliometric analysis in 2025 similarly identified the most productive institutions, in addition to countries and authors [6]. Identifying the most productive institutions, geographical regions, and authors in LLM research has been one of the major topics of interest with the overarching goal of pinpointing the best potential uses for LLMs in their respective fields of study. Another bibliometric analysis published in 2024 used Scopus to identify 82 publications on ChatGPT in educational research. They found that the *Journal of University Teaching and Learning Practice* had published the most papers on this topic and identified the most cited publications in the field of education. Common areas of study included benefits and uses, academic writing, and best practices. They cited the timing of their research and their search parameters only including English articles in their screening as limitations. These bibliometric trends highlight the exponential growth and global interest in LLM-related research, particularly around ChatGPT, and highlight a shift from broad explorations of utility toward more targeted analyses of influence, productivity, and practical applications.

It has been over a year since the public release of ChatGPT by the company OpenAI, followed by Gemini (formerly BARD) by Google and subsequent widespread use of AI, from usage by students for writing support to researchers for literature review and manuscript preparation assistance. From its release through August 2023, there have been over 1000 PubMed citations [7], indicating its rapid rise in use and interest in its capabilities. With any new technology, many use cases are developed and tested until a narrowing of the field emerges. This determines which aspects of technology resonate within the community and which aspects need further refinement. We sought to determine which types of studies were performed, which fields of research have the most studies, and which journals are the most highly cited, as this may highlight fields that are the most intense focus of researchers regarding the use of AI. We also sought to determine how well ChatGPT performs thematic categorization of research type and field of research when analyzing academic publications.

Methods

Overview

We used Clarivate Web of Science (WOS) and searched for all research articles with the terms “chatgpt,” “bard,” and “large language model” independently in March 2024. Papers with the 100 highest citation counts were exported from WOS into a spreadsheet and categorized by journal, author, research type, and field of study by 2 authors (EB and AR). Any discrepancies were resolved by a third reviewer. We also used ChatGPT-4 (GPT-4 model) to thematically categorize the papers for comparison with the manual grouping related to AI. ChatGPT was chosen for thematic categorization due to its popularity, with 89/100 papers explicitly mentioning ChatGPT in the title and 98/100 discussing or using ChatGPT in their studies, and its superior performance in Answer-Only settings and static data compared to other LLMs [8]. The literature review was conducted from June to July 2024.

Author’s Categorization

Python (version 3.11.7; Python Software Foundation) was used to count the number of times an author was listed in the top 100 cited publications in the Excel spreadsheet generated by WOS and rank the authors according to frequency. Python was also used to count the number of times a journal was listed in the top 100 cited publications and rank in order of frequency. This code is depicted in section 2a-b in Multimedia Appendix 1. Section 4 in Multimedia Appendix 1 was generated via Python.

Based on a review of each study’s abstract, the papers were categorized by the general field of research in which the study was conducted and the type of research conducted, which was counted manually in an Excel (Microsoft Corp) spreadsheet. Some papers could be categorized under the purview of multiple fields; for example, papers discussing medical education could have been categorized as either medicine or education. In such cases, the primary field of focus of the publishing journal was referred to for determination. These tasks were carried out by 2 authors (EMB and AR), with any discrepancies reconciled by a third party. A 2+1 independent observer model was implemented to reduce potential misclassification bias. The type of research was determined and recorded for each study, and Python was used to count and sort by frequency (section 2c in Multimedia Appendix 1). Ranganathan and Aggarwal [9] were referred to for the research types, which were expanded by the authors to include a more comprehensive list of research types. These categories are listed in the “Results” section.

Literature Review

Following the categorization stage, the most cited areas of research were determined, and a full literature review was performed of the included papers. In total, 84 papers were included in the literature review; 16 papers were excluded due to the lack of similar content that made it difficult to draw meaningful and cohesive conclusions. Each paper was analyzed to determine the primary topics of interest regarding AI and LLMs. A list of topics was generated as each paper was read, and the number of papers that covered each topic was recorded in a spreadsheet. For example, if a paper in the medicine category covered the clinical uses of ChatGPT, it was marked and counted toward the total number of papers that covered that topic. This was done by 2 authors (EMB and AR) performing the literature review, and any discrepancies were reconciled by discussion between the 2 reviewers. These areas are further discussed in the “Results” section of this paper. The goal of this study is to explore the fields that are most interested in AI LLMs and assess current and future implications of AI LLMs in each respective field. In addition, we aimed to evaluate ChatGPT’s ability to analyze and categorize scientific literature.

Thematic Categorization Performed by ChatGPT (GPT-4)

ChatGPT (GPT-4 model) was asked to count and report authors and journals in order of frequency. The full list of authors and journals was pasted into ChatGPT and ChatGPT was prompted

XSL•FO
RenderX

to sort by frequency. These generated lists were then compared to the corresponding lists generated by the authors.

ChatGPT was also asked to determine author, journal, research type, and field of research. A PDF copy of each paper was uploaded to ChatGPT, which was asked to extract the author and journal and to determine the study type and field of research. A set list of study types, which was used by the authors for research type categorization, was added to the prompts as there are many possibilities for this output. The prompts in ChatGPT were generated by one author (EMB). ChatGPT results were then directly compared to the results generated by the corresponding author to assess accuracy. To minimize potential biases from prompts provided by the author and to record ChatGPT's responses for research classification most authentically, it was not pre-trained, as daily users may not use a pretraining process, or require an extensively trained version of ChatGPT. ChatGPT's categorization for research type was compared to the author's categorization. All extractions were performed in a new thread to reduce hallucinations. Examples of these prompts are listed in section 3 in Multimedia Appendix 1.

Ethical Considerations

This study did not involve human or animal participants. Institutional review board approval, informed consent, data confidentiality, and participant compensation were not applicable.

Results

Publication Sources

Overall, there were 12 authors whose names appeared twice in the top 100 citations, but none appeared more than twice. Across the top 100 cited papers, the *Cureus Journal of Medical Science* had the most, with 7 papers (5-year Impact Factor of 1.1, with a multispecialty subject area). *Educational Sciences* and *Journal of Medical Internet Research* each had 3 papers (5-year Impact Factors of 2.6 and 6.7, and educational and health informatics subject areas, respectively). Every other journal had either 1 or 2 publications on the top 100 cited papers list (section 4 in Multimedia Appendix 1).

Field of Research

Medicine was the most frequently cited field with 43 papers, followed by education and educational research with 26 papers and technology and information sciences with 15 papers. Less frequently mentioned categories included business and economics, and tourism, both of which had 4 papers. All other areas had either 1 or 2 papers in the top 100. These findings are summarized in Table 1 with further breakdown of individual categorizations in sections 5-7 in Multimedia Appendix 1.

Multiple medical subfields have published papers regarding ChatGPT. General and internal medicine was the most mentioned subcategory with 11 publications, followed by health care sciences and services with 7, surgery with 5, oncology with 4, radiology with 3, and ophthalmology with 3. All other areas of medicine had only 1 publication mentioned. These findings are summarized in Table 2.

Table . Areas of research as generated by the author (EMB).

Area of study	Publications (N=100)
Medicine, n (%)	43[a] (43)
Education, n (%)	26[a] (26)
Technology and information sciences, n (%)	15[a] (15)
Business and economics, n (%)	4 (4)
Tourism, n (%)	4 (4)
Government and law, n (%)	2 (2)
Public health, n (%)	2 (2)
Basic sciences, n (%)	1 (1)
Ethics, n (%)	1 (1)
Geography, n (%)	1 (1)
Pharmacology, n (%)	1 (1)

[a]Top 3 areas of research included in literature review.

Table . Breakdown of specific fields of medicine in which papers were published.

Field of Medicine	Papers
General and internal medicine, n (%)	11 (26)
Health care sciences and services, n (%)	8 (19)
Surgery, n (%)	5 (12)
Oncology, n (%)	4 (9)
Radiology, nuclear medicine, and medical imaging, n (%)	3 (7)
Ophthalmology, n (%)	3 (7)
Nursing, n (%)	1 (2)
Gastroenterology and hepatology, n (%)	1 (2)
Endocrinology and metabolism, n (%)	1 (2)
Otorhinolaryngology, n (%)	1 (2)
Medical ethics, n (%)	1 (2)
Sport sciences, n (%)	1 (2)
Dentistry, oral surgery, and medicine, n (%)	1 (2)
Biomedical social sciences, n (%)	1 (2)
Nursing, n (%)	1 (2)
Total number of papers in medicine, n	43

Research Type

A total of 25 descriptive analyses were included, followed by 23 narrative reviews, 17 analytical observational studies, 16 opinion or editorial papers, 11 theoretical or conceptual papers, 4 systematic reviews, 3 mixed methods studies, and 1 analytical interventional study.

Descriptive studies, analytical observational, analytical interventional, systematic review, and meta-analysis were defined in Ranganathan and Aggarwal [9]. This list was expanded to include narrative reviews, which were defined as an overview of a current topic without the use of inclusion and exclusion criteria for article identification. Case reports and case series were defined as real-life use cases in a practical or clinical setting. Opinion, Editorial, or Perspective papers included those that discussed a topic and the author's personal view or opinion on a topic but did not perform any study or statistical analysis. Theoretical or conceptual papers discussed potential uses of LLMs but did not provide real-life examples or experimentation with LLMs. Mixed methods papers used qualitative and quantitative evidence.

Medicine

Of the 43 papers [7,10-46] reviewed from the field of medicine, 38 (88%) papers discussed the limitations of ChatGPT, 30 (70%) discussed the uses of ChatGPT in clinical medicine, 21 (49%) numerically evaluated the quality and capability of ChatGPT in regards to medical reasoning, and 9 (21%) evaluated the uses of ChatGPT in medical research. Medical education was an additional area of focus with 14 (33%) papers discussing ChatGPT's ability to answer board certification questions or help with studying from both the student and educator perspective. A total of 19 (44%) papers discussed the uses in research and 18 (42%) discussed ethical considerations.

Studies that covered quality assessment in medical knowledge evaluated the accuracy of ChatGPT's answer to specific medical questions from patients and board examination questions and the capability to use higher-order medical reasoning. Many of these papers cited promising results and indicated that further research and technology improvements are necessary prior to full implementation into the medical field. Many papers discussed the already proven or hypothetical uses of ChatGPT in medicine, such as the enhancement of telemedicine, answering patient questions, and administrative tasks such as charting and other paperwork [10,11]. Potential weaknesses preventing current widespread adoption included lack of nuanced information that an experienced physician would understand and potential inaccuracies due to biased or outdated training data [12,13]. Authors cited the high level of confidence that ChatGPT appears to answer with, which may result in the dissemination of misinformation [14]. Further improvement of the technology would be necessary due to lack of deep understanding and inability to interpret complex medical imaging. Some studies compared physician responses to AI responses and found that evaluators may prefer the AI-generated response.

Other uses in medicine included assistance for nonnative English speakers with translation to their native language [15-17]. AI is able to quickly comprehend information, which indicates a potential use for providing information about medical guidelines in acute situations, such as in the intensive care unit [10]. AI may also be useful in assisting with documentation, decision support, and patient communication.

Quality assessment in research discussed the automatic generation of citations, manuscripts, ideas, and hypotheses. The ability of ChatGPT and other LLMs to conduct literature searches was also evaluated [37]. Some studies synthesized the

XSL•FO
RenderX

already proven uses in research, the most prominent of which included literature review, data synthesis, and assistance with data analysis [10,47]. Review papers covering research utility discussed the ability to generate large amounts of text and can help authors organize their thoughts [21]. ChatGPT has been shown to quickly summarize whole papers well and can save researchers significant amounts of time [48].

Limitations of AI models were the most commonly discussed topic, with many papers referencing lack of updated information because ChatGPT was trained on data from 2021, which may lead to outdated or incorrect information. The possibility of ChatGPT hallucination, generation of fake citations, and perpetuation of biases contained in the information that it was trained on was also discussed [15,17]. Papers that discussed ethics included privacy concerns with cybersecurity risks with patient confidentiality as ChatGPT stores its conversations in its memory bank with minimal evidence that it can comply with Health Insurance Portability and Accountability Act (HIPAA) regulations [24]. One paper reported concerns with shortcuts in the research or learning process, which could lead to inflated numbers of publications without the same level of expertise [21].

Papers regarding medical education discussed potential use via interactive simulation, immediate feedback and information, and creation of educational materials for instructors. Students can generate quiz questions, which can alleviate the work burden for educators and students alike. Studies such as Huh [49] showed that ChatGPT performed comparably to medical students in certain assessments indicating the potential for integration and use in medical education. Multiple studies cited promising results of ChatGPT answering board questions.

Education

A total of 26 papers [49-74] were categorized as education as their field of study. Of these, 21 (81%) education papers discussed the ethical concerns associated with AI implementation in schools and 3 (12%) discussed privacy considerations; 7 (27%) discussed the potential negative implications on students' learning and performance capabilities, and 17 (65%) discussed solutions for these concerns. In total, 18 (69%) papers discussed the potential implementations for students and 17 (65%) discussed potential implementations for educators. In addition, 9 (35%) performed a quality assessment, 18 (69%) discussed the capabilities of AI, and 18 (69%) discussed limitations.

In the field of education, the main privacy concerns were related to the storage of student data and personal information that may be stored by ChatGPT through regular usage. Papers discussed the importance of data security and compliance with privacy regulations to prevent personal information from being disseminated.

Education ethics primarily discussed academic dishonesty including plagiarism and incorrect citations. Evidence advocating for ChatGPT as a reliable author or primary source is minimal, and the academic ethical implications of copying and pasting the ChatGPT response were unclear; however, the consensus questioned the ethics of directly quoting ChatGPT without attributing it as the source [50,75]. Additional sources of ethical concerns were regarding the discordant access to ChatGPT, as the optimized version is currently a paid service [51,52]. The perpetuation of discriminatory and biased ideas in the information that ChatGPT was trained on was also a common concern, which led papers to recommend cautious use of AI and special care to identify and mitigate such biases [22,53]. Educators have expressed concerns over students' overreliance leading to loss of writing skills and hindrance of creativity in addition to academic dishonesty.

Solutions to AI overreliance included the implementation of AI literacy early in the education system, similar to how typing and technology training became ubiquitous with the rise of computers [54]. Other workarounds to overreliance on ChatGPT include assignment design that is incompatible with ChatGPT [55,56]. Educators are being urged to specify the permitted usage of ChatGPT in their course syllabi for transparency [57]. On the side of OpenAI, regular updates to ensure the accuracy of information available to ChatGPT are also crucial. Perkins [57] discussed the need for transparency and guidelines for AI use in academic settings.

Quality assessments evaluated accuracy, relevance, and potential biases of text generated by ChatGPT in multiple educational fields generally, or within specific areas such as chemistry, language, administration, and academic research. Researchers investigated the capability to enhance learning, teaching, and grading. Fergus et al [58] evaluated ChatGPT's ability to generate assessment questions in chemistry and the quality of the answers generated by ChatGPT. Farrokhnia et al [59] performed a SWOT (Strengths, Weaknesses, Opportunities, and Threats) analysis of ChatGPT in education and research, reporting the ability to provide real-time feedback and grading with specific responses, which can decrease workload for both students and educators. Other papers explored academic integrity and third-party programs' ability to detect work written by ChatGPT, the ability of ChatGPT to generate educational materials, such as textbooks, study guides, and practice questions, and the ability for AI to assist students with learning experience and motivation. Papers marked under uses for students and uses for educators included relevant quality assessments and review papers covering proven uses.

ChatGPT's limitations in education include its potential for generating inaccurate or biased information, its dependency on up-to-date training data, and its inability to fully replace human educators [62,64]. For example, while ChatGPT can provide factual information, it lacks the ability to engage in nuanced discussions or provide emotional support [52].

Technology and Information Sciences

A total of 15 papers [3,47,76-87] were categorized as reviewed technology and information sciences. Subtopics included computer science, engineering and electric vehicles, and data science. Of these, 12 (80%) papers discussed the technical uses of ChatGPT, with 2 (13%) of those being quality assessment papers. In addition, 6 (40%) discussed ethics and privacy concerns, and 9 (60%) discussed limitations. Only 1 (7%) discussed the public perception of AI and 9 (60%) discussed

XSL•FO
RenderX

the future applications and implementations of AI in the workplace and daily life.

Ethics in the field of technology and information sciences included privacy concerns with the handling and storage of user data. Like other sections, authors emphasized the importance of strong cybersecurity measures including encryption and secure storage to minimize the risk with security breaches. Uniquely, some papers discussed the potential of AI to create harmful "deep fake" content, which has the potential to be weaponized [76,88]. Deep fake is defined as high-quality fabricated image and video content that can be misinterpreted by viewers as being real [89].

Technical uses of ChatGPT in this field included code generation, debugging, and automated routine IT processes. The ability to assist with data science through data cleaning, preprocessing, and preliminary result interpretation was explored [77,78]. Du et al [79] discussed the potential of AI implementation in electric vehicles. Holzinger et al [90] covered AI from the biotechnology perspective, which provided an overview of the uses of AI to agricultural engineering, medical biotechnology, and bioinformatics. AI is already being used by plant tissue scientists to simulate complex interactions and treatment options for their agricultural experimentation. AI can benefit medicine from a microperspective, including genomic analysis, biomedical image analysis, data analytics, and drug discovery and development [90]. The advantage comes from the ability to rapidly analyze large quantities of data through automation and the implementation of predictive models that can analyze image data and recommend the best management and planning course for any given task. Quality assessment papers that analyzed potential uses of ChatGPT looked at AI's writing abilities in order to contribute to the conversation surrounding job security [91].

Limitations of AI in the field of technology and information sciences include difficulty with performance in complex problem-solving scenarios, outdated training data, and potential inaccuracies [77]. Authors emphasized that AI requires human oversight to ensure reliable outputs [80]. For example, while ChatGPT can assist with coding, it might not always understand the context of complex software projects, leading to errors [85]. Future directions that the academic technology community is hoping ChatGPT and other AI models take include improvement of privacy concerns and continued efforts to address ethical concerns [76]. In addition, improving reliability to decrease the likelihood of hallucinations and increasing complex understanding to improve usability and reliability [79].

Finally, one paper examined public perception of ChatGPT by evaluating responses on X (previously Twitter; X Corp) to determine generally how internet users felt about the dawn of AI [84].

ChatGPT's Thematic Categorization

When asked to report the frequency of authors mentioned out of the top 100, ChatGPT generated a different list than the manually generated list of author frequency, which was confirmed to be incorrect upon verification. It was also unable to correctly count the frequency of each journal. For example, it counted 11 occurrences in the *Cureus Journal of Medical Science* and 4 occurrences in the *Journal of Medical Internet Research*. The manual extraction yielded 7 occurrences in the *Cureus Journal of Medical Science* and 3 occurrences in the *Journal of Medical Internet Research*. ChatGPT's outputs for these categories are included in Section 8 in Multimedia Appendix 1. ChatGPT identified the research type correctly in 86% of cases. The field of research was correctly identified by ChatGPT only 47% of the time. In some cases, ChatGPT was asked to reconsider its categorization and often changed its determination when prompted by the user. It was highly susceptible to hallucinating information for the wrong paper when used in a single thread. To minimize these hallucinations, a new thread had to be made for each paper's analysis. Percentages reflect a simple ratio of matching results to total results.

Discussion

Principal Findings

This discussion explores the current trajectory of AI integration, potential breakthroughs, and the implications for the following fields.

Medicine

In medicine, AI is primarily being tested to assist in areas from administrative support to clinical applications. The potential of AI to enhance telemedicine, streamline administrative tasks, and assist in diagnostic processes is well documented [11,22,53]. However, the accuracy and reliability of AI in medical decision-making are areas that require further research. Future pathways include the integration of AI into clinical workflows to assist with patient triage, diagnostic support, and personalized treatment plans [11]. The field appears to be moving toward leveraging AI to augment, rather than replace, human expertise, with potential breakthroughs anticipated in predictive analytics and personalized medicine [16,37,46,92]. The ongoing challenge will be ensuring AI systems are trained on up-to-date and diverse datasets to minimize bias and inaccuracies. Before widespread integration of AI in medicine occurs, further research is necessary to prove reliability and improvement from early models [22].

In addition, prior research suggests that programs such as ChatGPT can assist with medical education. For instance, Huh [49] demonstrated that ChatGPT, while not outperforming medical students, provided reasonable answers on parasitology examinations, indicating its potential for educational integration. The literature also indicates that research processes are being disrupted, with AI showing promise in tasks such as automatic generation of citations, manuscripts, and hypotheses, which can streamline the research process [50]. However, reducing the hallucination frequency and improving accuracy will need to be made before any significant disruption in clinical practice can occur.

Education

Education has the potential to enter a transformative phase with the incorporation of AI tools such as ChatGPT into current curricula. These tools can offer substantial benefits, including

XSL•FO
RenderX

personalized learning experiences, automated grading, and enhanced teaching aids. However, the potential for academic dishonesty and the ethical implications of AI use in education remain significant concerns [48,53,54,59,67,71]. As AI technology improves, it is expected to offer even more sophisticated support for both students and educators, such as adaptive learning platforms that cater to individual student needs and real-time feedback systems. The field is also exploring AI's role in reducing teacher workload and providing continuous professional development opportunities [48,51,59,67]. Ensuring equitable access to AI tools and addressing ethical dilemmas will be crucial as AI becomes more integrated into educational systems.

Technology and Information Sciences

AI's impact on technology and information sciences, particularly in software development, data analysis, and cybersecurity, has positive indications for progress. AI tools are increasingly used for code generation, something that was successfully implemented in this study to help with counting author, journal, study type frequencies, and generating figures. Debugging, automating routine IT tasks, and enhancing productivity and efficiency are other capabilities [3,82,85]. Future breakthroughs are expected in the development of more reliable and context-aware AI systems capable of handling complex problem-solving scenarios. Ethical concerns, such as protecting privacy and security, will continue to be pivotal, with ongoing efforts to develop robust cybersecurity measures and ethical AI guidelines.

Thematic Categorization

The results of ChatGPT's thematic categorization suggest that further improvements must be made before ChatGPT can reliably sort and organize data. At the time the study was performed, it appeared as though ChatGPT was overwhelmed by large amounts of text, which raises questions about its capability to sort through information such as lists of names and journals; when asked to sort through the list of authors, which contained over 190 names, the sorted list was incorrect. It was unreliable in determining the study type. However, it did perform well in determining the field of research, suggesting that ChatGPT can be trusted with simpler and more straightforward tasks.

Limitations

Limitations of this study include the large breadth of research study types and similarities between different study types that each paper could have been classified as, leading to potential difficulties reproducing similar results in future similar studies. ChatGPT and research on AI models are always rapidly developing, making the likelihood that some conclusions drawn may have newer, updated information. There are also legal and ethical factors to consider when uploading copies of research papers to ChatGPT. At the time of writing, there are no explicit laws or journal terms of service that prohibit uploading PDF copies to ChatGPT, making this an area of legal ambiguity. Each paper was legally downloaded and used solely for private purposes. No research was redistributed, and there was no commercial benefit from using these papers. Notably, 75% of the papers were open access. Under fair use, the content was used privately and was not used for commercial research, redistribution, reproduction, or sale. However, as ChatGPT continues to grow in popularity and utility, academic institutions, publishers, and developers will need to reassess the ethical and legal boundaries of uploading copyrighted material to these tools. In addition, there are long-term memory storage issues, as it can only store a limited set of facts or preferences. This makes using singular threads extracting information more likely to hallucinate incorrect information, as ChatGPT may provide incorrect information rather than admitting it does not know the answer. It may require frequent prompting for optimal performance. Methods such as frequently generating new threads to prevent overloading information stored in long-term memory can be effective for avoiding this problem, as used in this study.

Future Directions

In the context of this study, ChatGPT should be improved to better aid in thematic categorization. Thematic categorization of the field of research sometimes required information that was not directly stated in the paper, which would make it very difficult for ChatGPT to correctly determine the field of research. For example, some papers covered technology topics but were published in a medical journal, resulting in incorrect categorization as technology, rather than medicine [45]. This discrepancy may be attributed to author criteria rather than technology failure; however, it indicates the importance of providing detailed, specific instructions to LLMs in order to receive the desired output. It is important to acknowledge that ChatGPT continues to have difficulties with hallucination and persistent long-term memory and limited context retention, which can impair usability and reliability for users. Due to such limitations, users should monitor the outputs and verify accuracy. Broadly, future research should focus on refining ChatGPT to alleviate any privacy concerns, hallucinations, and bias.

Conclusions

Medicine, education, and technology are preparing for a future with potential LLM integration, as demonstrated by the high citation counts in these fields. While LLMs such as ChatGPT offer promise in streamlining workflows and categorizing research, this study underscores the importance of human oversight to address risks such as hallucination, outdated information, and bias. Realizing AI's full potential will require responsible implementation that supports human expertise, ensures equitable access, and maintains up-to-date information. In medicine, AI is expected to integrate further into clinical workflows, assisting with diagnostics, patient communication, and administrative tasks like charting, although concerns remain about accuracy and ethical implications. In education, AI tools may be able to revolutionize personalized learning, automate grading, and support educators, but addressing academic dishonesty and ensuring ethical AI use in learning environments is crucial. In technology, LLMs are advancing software development, data science, and cybersecurity, but future work needs to enhance AI's ability to handle complex problem-solving while ensuring privacy and security.

XSL•FO
RenderX

These fields are tightly linked, with educational pedagogy aiding the development of physicians, and the field of technology developing the software and apps that physicians will use. If AI positively affects education, it may result in a network of physicians who can use advanced technology to increase efficiency in practice and improve patient care. Furthermore, AI is being developed to enhance research processes, providing resources for researchers to improve productivity, output, and in effect, impact. LLMs are moving toward transforming the efficiency and quality of these fields through continued improvement and integration. Ultimately, the true potential of AI can be realized through a collaborative approach, where human expertise works in tandem with AI, ensuring that both ethics and efficiency are upheld.

Acknowledgments

ChatGPT (GPT-4) was used for grammar and editing assistance for this paper. Thank you to Cameron Bernstein for helping with proofreading and editing this paper. Thank you to Nathaniel Sands for acting as the independent observer for research categorizations.

Abstract

Background: Rare diseases, which affect millions of people worldwide, pose a major challenge, as it often takes years before an accurate diagnosis can be made. This delay results in substantial burdens for patients and health care systems, as misdiagnoses lead to inadequate treatment and increased costs. Artificial intelligence (AI)–powered symptom checkers (SCs) present an opportunity to flag rare diseases earlier in the diagnostic work-up. However, these tools are primarily based on published literature, which often contains incomplete data on rare diseases, resulting in compromised diagnostic accuracy. Integrating expert interview insights into SC models may enhance their performance, ensuring that rare diseases are considered sooner and diagnosed more accurately.

Objective: The objectives of our study were to incorporate expert interview vignettes into AI-powered SCs, in addition to a traditional literature review, and to evaluate whether this novel approach improves diagnostic accuracy and user satisfaction for rare diseases, focusing on Fabry disease.

Methods: This mixed methods prospective pilot study was conducted at Hannover Medical School, Germany. In the first phase, guided interviews were conducted with medical experts specialized in Fabry disease to create clinical vignettes that enriched the AI SC's Fabry disease model. In the second phase, adult patients with a confirmed diagnosis of Fabry disease used both the original and optimized SC versions in a randomized order. The versions, containing either the original or the optimized Fabry disease model, were evaluated based on diagnostic accuracy and user satisfaction, which were assessed through questionnaires.

Results: Three medical experts with extensive experience in lysosomal storage disorder Fabry disease contributed to the creation of 5 clinical vignettes, which were integrated into the AI-powered SC. The study compared the original and optimized SC versions in 6 patients with Fabry disease. The optimized version improved diagnostic accuracy, with Fabry disease identified as the top suggestion in 33% (2/6) of cases, compared to 17% (1/6) with the original model. Additionally, overall user satisfaction was higher for the optimized version, with participants rating it more favorably in terms of symptom coverage and completeness.

Conclusions: This study demonstrates that integrating expert-derived clinical vignettes into AI-powered SCs can improve diagnostic accuracy and user satisfaction, particularly for rare diseases. The optimized SC version, which incorporated these vignettes, showed improved performance in identifying Fabry disease as a top diagnostic suggestion and received higher user satisfaction ratings compared to the original version. To fully realize the potential of this approach, it is crucial to include vignettes representing atypical presentations and to conduct larger-scale studies to validate these findings.

Introduction

Background

Taken as a group, rare diseases are common and affect about 350 million people worldwide [1]. It is estimated that 1 in 17 individuals will encounter a rare disease during their lifetime [2]. Diagnosing rare diseases continues to be a challenge for health care professionals and health care systems [3].

Patients with rare diseases often have to go through a long diagnostic journey, waiting an average of 6 years from the onset of symptoms to an accurate diagnosis [4]. For some rare diseases, the average time to diagnosis is even far beyond this—the median duration from the initial manifestation of Fabry disease to its diagnosis being approximately 10.3 (IQR 5.9-62.0) years. The mean duration from the onset of the disease to the initiation of enzyme replacement therapy takes even longer, approximately 21.3 years [5].

Rare diseases are often misdiagnosed at first, resulting in inadequate treatment, significant impairment of the patients' quality of life, progression of their disease, and sometimes even irreversible complications [6]. Additional medical consultations and inappropriate therapies cause significant costs for both individuals and health care systems [7]. Insufficient knowledge about rare diseases and a lack of awareness are considered to be the main factors leading to delay in diagnosis, particularly in primary care. Due to their rarity, rare diseases are often overlooked by general practitioners (GPs) because of their limited knowledge [2,3]. Another challenge patients face is that there are only a handful of specialized experts for each rare disease [8], and these experts are not evenly distributed in the health care system, so that access is limited. Artificial intelligence (AI)–powered symptom checkers (SCs) have the potential to aid the detection of rare diseases, thereby reducing the time to diagnosis [2,6,9]. AI approaches, as are SCs, are increasingly implemented in health care settings to help alleviate the burden on the systems and to improve the quality of care [10]. The goal of SCs is to provide information to the users that enables them to identify the likely cause of their symptoms [11,12]. Additionally, many SCs offer triage recommendations based on these symptoms and guide patients on whether they should seek medical assistance and, if so, at what level—be it a hospital, general practice, or self-care at home—taking into account the urgency of the situation [12,13].

One such SC is Ada. Ada's foundation draws on digitized medical knowledge, predictive algorithms, Bayesian inference, and validation against diverse case sets to deliver precise guidance [14]. The SC provides up to 5 disease suggestions as possible causes for the user's symptoms, without claiming to replace physicians or to make a diagnosis. Similar to a physician's initial patient history-taking process, the SC begins with gathering fundamental health information and then proceeds to ask follow-up questions based on the provided symptoms. Once the symptom assessment is completed, the user receives a structured summary report of the currently relevant symptoms, symptoms that have been ruled out, and those that remain uncertain. The SC suggests between 3 and 5 disease suggestions, along with the corresponding probabilities and recommended next steps for the user [15]. The SC is based on an ever-evolving medical database, continuously incorporating the latest research findings. Other commonly used SCs include Buoy, K Health, Mediktor, Symptomate, Your.MD, and WebMD [16].

When integrated into hospital websites or booking portals, SCs give users guidance on whether, when, and where to seek care within their network while also explaining the most likely causes of their symptoms [17,18]. By directing patients to appropriate care, hospital resources can be used more efficiently and allocated to those who are truly in need of medical attention. Triage accuracy varies depending on the SC, from 48.8% to 90.1%, and has shown to be comparable to those of telephone triage [12].

Another significant benefit of SCs is their ability to support the diagnostic accuracy of health care professionals, which is particularly relevant for rare diseases. SCs can flag potential rare diseases that might otherwise go unnoticed, prompting health care providers to consider diagnoses they may not have initially considered. By bringing these less common possibilities to the forefront, SCs can aid in the earlier detection of rare diseases, ultimately improving patient outcomes. This capability is especially valuable in complex cases where symptoms may be ambiguous or overlap with more common diseases, ensuring that rare diseases are not dismissed too quickly.

The impact of this capability is evident in a study involving 450 patients, where the SC (Ada) demonstrated a 10% improvement in physicians' diagnostic accuracy [13]. Patients who received an early diagnosis experienced significantly fewer complications and had a shorter hospital stay (P<.001). Additionally, the same SC outperformed both rheumatologists and GPT-4 in diagnostic accuracy when evaluating rheumatologic cases [19]. Notably, using a version of an SC that incorporates diagnostic results, 33% of patients with rare diseases in the study of Ronicke et al [2] could have been correctly diagnosed on their first visit, significantly reducing the time to diagnosis.

These promising results align with the broader trend of increasing public acceptance and use of SCs. In the last decade, several SCs have been developed. In Germany alone, between 6.5% and 13% of adults have used an SC at least once [20,21]. A study involving over 1000 patients revealed that 63% of them would use a trusted SC, with a significantly higher willingness among those younger than 40 years of age compared to those older than 70 years [14].

While AI-powered SCs have shown promise in improving diagnostic accuracy and potentially patient outcomes, they face significant difficulties, particularly when it comes to rare diseases. The approach of SCs often involves extracting medical knowledge from vast amounts of data, often obtained through comprehensive literature reviews [16]. However, there is only limited research data and literature available on rare diseases, which makes them a particular challenge. This scarcity of data makes it difficult to source accurate information and, consequently, to model these diseases effectively within SCs. The variability in how rare diseases manifest in different patients adds another layer of difficulty. With symptoms that can vary significantly in severity, onset, and progression, modeling these

XSL•FO
RenderX

diseases requires a more dynamic and flexible approach than is typically necessary for more common diseases.

Given these constraints, there is a need to explore and develop new methods to enhance the representation of rare diseases within SCs. Improving the diagnostic performance of SCs for rare diseases is not only crucial for individual patient outcomes but also for reducing the overall burden on health care systems by minimizing misdiagnoses and the associated unnecessary tests and treatments.

Lysosomal storage disorders (LSDs), a group of rare inherited metabolic disorders characterized by the accumulation of toxic substrates within the lysosomes [22], present an ideal case study for testing and refining these methodologies due to their complex and varied symptomatology. They require comprehensive treatment from a multidisciplinary team of neurologists, ophthalmologists, nephrologists, cardiologists, otorhinolaryngologists, pediatricians, geneticists, and dermatologists [23].

Objectives of the Study

To address the challenges of modeling rare diseases in SCs, we conducted an exploratory pilot study with the following objectives: (1) to enhance the representation of Fabry disease within an SC by incorporating insights from guided interviews with experts. These insights were translated into clinical vignettes and used to optimize the disease model within the SC; and (2) to assess the performance of the newly optimized disease model by conducting symptom assessments and delivering questionnaires to patients with Fabry disease. This objective focused on determining whether the integration of guided interviews, in combination with literature review, results in improved diagnostic accuracy and patient satisfaction compared to models based solely on literature review.

Methods

Ethical Considerations

This mixed methods prospective pilot study was approved by the ethics committee of Hannover Medical School, Germany (10363_BO_K_2022), with patient enrollment between May 2022 and June 2023. The study was conducted in compliance with the Declaration of Helsinki and Good Clinical Practice. Written informed consent was obtained from all study participants with the possibility to opt out. No identifying participant information is presented in this study.

Study Design and Setting

In the first phase, physicians were included as medical experts for the creation of the clinical vignettes when they met the criteria of having at least 10 years of clinical experience in the field of Fabry disease. In the second phase, this study included patients aged 18 years and older, experiencing Fabry disease, and fluent in German. Diagnosis of Fabry disease was defined as molecular genetic detection of any α-galactosidase A (GLA) gene mutation. Patients were randomized into 1 of 2 groups, with both patients and study physicians being blinded. Recruitment was conducted at the outpatient clinic of Nephrology and Pediatrics of Hannover Medical School. The SC Ada was selected for this study.

All interviews were recorded for quality assurance purposes. This study was conducted in collaboration with a German patient organization, Morbus Fabry Selbsthilfegruppe e.V., which provided valuable suggestions.

Phase 1: Creation of Clinical Vignettes Through Expert Interviews

The guided interviews were conducted with 2 medical experts (JK and AD) specialized in Fabry disease from Hannover Medical School in Germany. The median time of professional experience in the field of LSDs was about 20 years for each expert.

The aim was to create clinical vignettes—structured case descriptions or scenarios—that typically include a patient's medical history, symptoms, and relevant clinical details presented in a concise and standardized format. To ensure clinical realism and generalizability, experts constructed prototypical patient profiles based on their cumulative clinical experience rather than model vignettes on individual real cases. Demographic variables and symptom constellations were deliberately combined to reflect typical presentations of Fabry disease as seen in primary care, with the goal of capturing commonly observed patterns that could be recognized by SCs.

The interviews followed the structure of the clinical vignette template, beginning with the assessment of key demographics, including biological sex, age, pregnancy status (if applicable), smoking status, and history of high blood pressure, diabetes, or other known diseases. After establishing the demographic and medical history, the experts were asked to describe 1 or several primary complaints—symptoms that a patient would typically report when booking an appointment—as well as additional symptoms a patient might confirm or deny when directly questioned by a physician.

Experts were asked to select an appropriate urgency advice level for their presented case constellation. They could choose from an 8-level scale ranging from managing their symptoms at home to calling an ambulance.

The experts were then asked to assign potential differential diagnoses they would deem acceptable in view of the symptom constellation. Finally, they were asked whether any of the symptoms reported would present a very typical symptom, whose presence would lead the expert immediately to conclude that Fabry disease was the cause of the symptoms. The clinical vignette template, including all 8 possible urgency advice levels, can be found in Multimedia Appendix 1.

To ensure that the vignettes could be used effectively to optimize the Fabry disease model, the experts were instructed to mention only those symptoms that patients themselves could and would report. This is important because SCs generally rely solely on self-reported symptoms and do not take into account professional findings such as laboratory results or imaging techniques [11].

Interviews were conducted by the study physician (AP), a rheumatology resident employed by Charité Universitätsmedizin

XSL•FO
RenderX

Berlin. The interviews were translated into English to enable integration of the information into the SC's knowledge base. The translation was performed by a second study physician (NM-B), a German native-speaking employee of the evaluated SC developer who was familiar with the SC's medical knowledge base to ensure that no information was lost during the translation process. Following the guided interviews, 5 clinical case vignettes were created. These vignettes were then integrated into the Ada SC's medical knowledge base by converting them into structured, machine-readable information. The SC developer continuously monitors its SC performance by automatically running a large validation test case set and evaluating these against defined thresholds. Updating the Fabry disease model did not have any negative impact on the SC's performance metrics.

The vignettes, along with insights from a structured literature review—a standard method for acquiring knowledge for SCs—were used to update the existing Fabry disease model. The processing of the Fabry disease model within the SC's knowledge base was done independently by physicians employed by the SC software company. The study team was not involved in this process. A sample Fabry disease vignette is provided in Multimedia Appendix 2.

Phase 2: Comparison of the Optimized Model With the Previous Fabry Disease Model

The objective of this phase was to compare the preoptimized SC version, which contained the original Fabry disease model based on a literature review, with the optimized version. The comparison focused on performance metrics, including diagnostic accuracy and overall user satisfaction. The disease model comparison was facilitated by 1 of the 2 study physicians (AP and NM-B), with one of them always being on site. Two tablets were prepared with a study version of the SC—one containing the original Fabry disease model and the other featuring the newly optimized model. The study version of the SC was identical to the on-market version in German, with the only difference being that the study team could select earlier versions of the medical knowledge and medical models, a prerequisite for this direct comparison. The specific tablet, and thus the version of the SC used first, was randomly assigned by the study physicians. The study was conducted in a double-blind manner, ensuring that neither the 2 study physicians nor the participants knew which tablet had which version of the SC. Blinding of study physicians was maintained until the conclusion of the data analysis. To begin the symptom assessment, study participants were asked to enter the symptoms that had most troubled them at the onset of their illness. They were then guided through an AI-generated sequence of questions, where they were instructed to confirm the symptoms they had experienced during their patient journey and to deny those they had not. An "I don't know" option was also available for any uncertainties. Upon completion, participants received a symptom report summarizing their responses, along with a list of potential diseases that could be causing their symptoms, including their probabilities and recommended next steps. The report additionally provided them with further information about the possible diseases.

After completing the first assessment, participants performed another assessment using the second tablet with the other disease model. Study physicians did not interfere with the symptom assessment in any way after receiving the consent for study participation, in order not to influence the assessment.

Questionnaires

Following each symptom assessment, participants were asked to complete a questionnaire to evaluate the quality of the assessment, whether their illness was listed as one of the proposed disease suggestions by the SC, and whether the questions were easy to understand. The second questionnaire contained an additional question asking which assessment the participants preferred. The English version of the first questionnaire is provided in Multimedia Appendix 3.

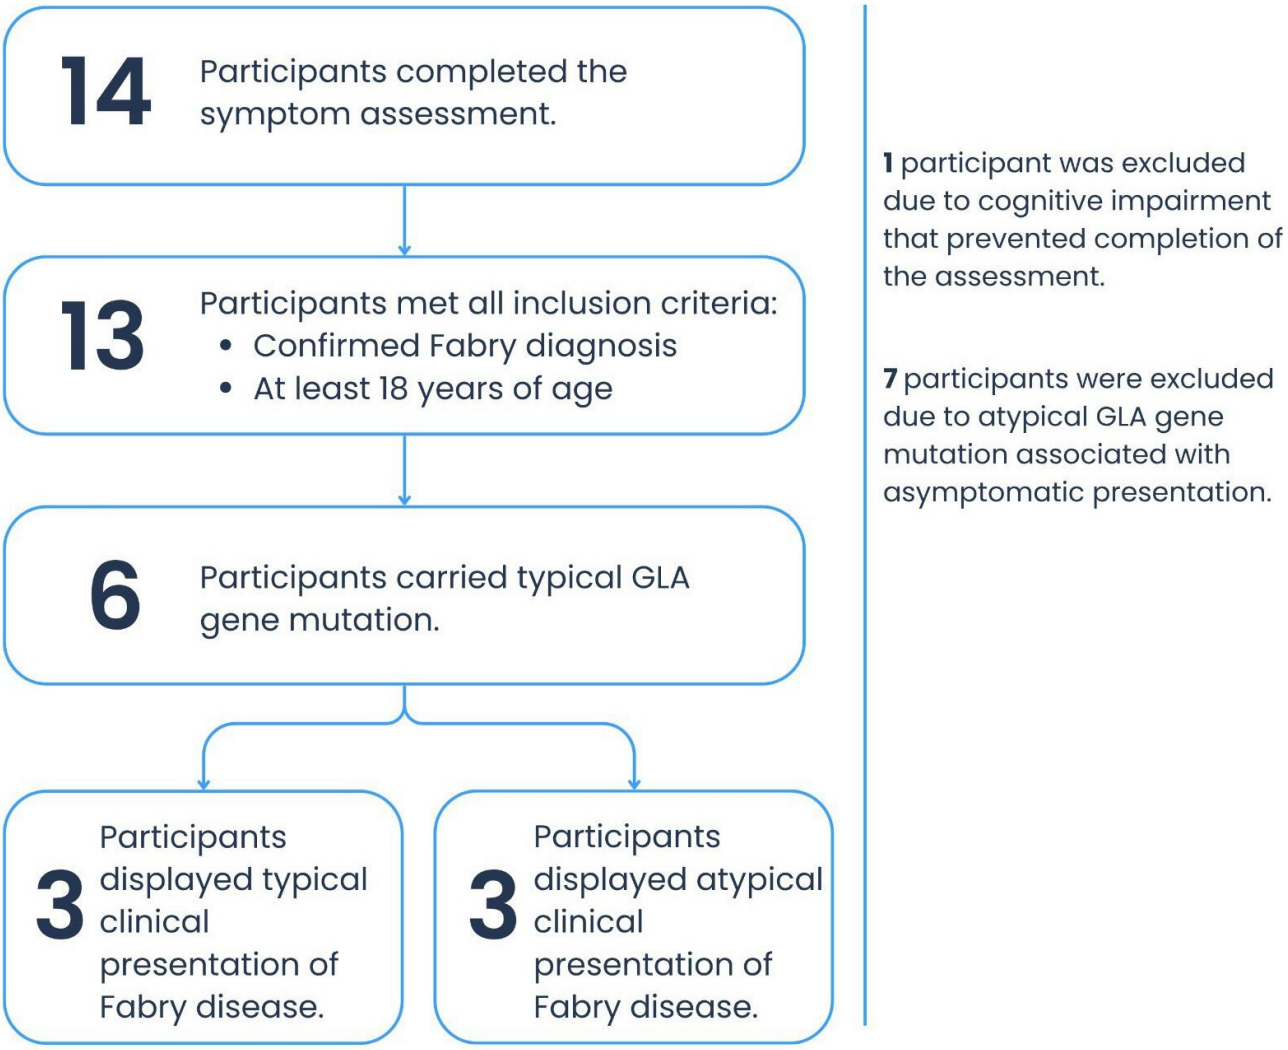
Data Analysis

The primary objective of the second part of this study was to compare the diagnostic accuracy of 2 SC versions: one with the Fabry disease model developed on the basis of a literature review, while the other was additionally trained with case vignettes from experts. Diagnostic accuracy was evaluated using Matching scores, commonly referred to as *M* scores. *M* scores represent the degree to which the model's diagnostic output aligns with the correct diagnosis, serving as a metric to assess the model's accuracy in identifying the correct diseases, also referred to as conditions in the context of SCs [11]. All suggested differential diagnoses generated by the model are ranked according to their likelihood. The *M*1 score specifically measures the accuracy of the model's top-ranked disease. In other words, *M*1 indicates how often the first disease proposed by the model is the correct diagnosis. The *M*3 score assesses the model's accuracy by determining whether the correct diagnosis is among the top 3 suggested diseases, offering a broader evaluation of the model's diagnostic performance.

With the help of descriptive statistics, we compared overall satisfaction and perceived completeness of symptom coverage between the original and optimized versions of the SC. Participants were asked which version they preferred, and satisfaction scores were determined using a 4-point Likert scale. The scores were analyzed both collectively and individually for each patient to identify which version was rated higher.

We evaluated how completely each version of the SC covered the patients' symptoms and how helpful participants thought the SC would have been if it had been used at the onset of their illness. Responses were categorized by the degree of completeness and helpfulness for each version. Additionally, we performed a Wilcoxon signed rank test to compare satisfaction scores between the original and optimized versions of the SC.

Results



Comparison of the Optimized and Original Fabry Disease Model

Between May 2022 and June 2023, 14 patients with Fabry disease were enrolled to compare the diagnostic accuracy and user satisfaction between the optimized and original SC versions.

XSL•FO
RenderX

In total, 12 of the 14 patients were female, and 2 were male. A total of 7 patients were excluded from the final analysis as they had atypical GLA gene mutations and therefore were either asymptomatic or had very atypical symptoms. One patient had to be excluded because of a diagnosed cognitive deficit that affected his ability to complete the study. This left 6 patients with typical mutations for the final analysis, 3 of whom reported typical Fabry-related symptoms, while the other 3 reported atypical symptoms. Figure 1 shows the participant recruitment flow.

Figure 1. Participant recruitment flowchart. GLA: α-galactosidase A.

Comparison of Diagnostic Accuracies for the Original and Optimized Versions

Regarding the top disease accuracy (*M*1), the original SC version identified Fabry disease as the top suggestion in only 1 of 6 (17%) cases. The optimized version improved this, identifying Fabry disease as the top disease in 2 of 6 (33%) cases.

In 3 of 6 participants, both SC versions listed Fabry disease among the first 3 disease suggestions, yielding an *M*3 score of 50%. In all 3 patients where the SC suggested Fabry disease, characteristic symptoms such as acroparesthesia, angiokeratoma, or hypohidrosis were present.

Comparison of Participant Satisfaction Between the Original and the Optimized Versions

When asked which SC version they preferred, 3 patients chose the optimized version, 2 the old one, and 1 patient was indecisive. Overall, the optimized Fabry disease model received higher total ratings (108 vs 103). Individually, 3 patients rated the optimized version highest (12 vs 9; 17 vs 13; and 23 vs 20), 2 patients gave equal scores to both versions (21 vs 21 and 21 vs 21), and 1 patient rated the original version highest (14 vs 19). This comparison is displayed in Table 1. The Wilcoxon signed-rank test indicated no statistically significant difference in satisfaction ratings between the optimized and original SC versions (W=4.0; P=.71).

XSL•FO
RenderX

Table . Overall score ratings per patient per symptom checker version.

	Original version	Optimized version
Participant 1	9	12
Participant 2	19	14
Participant 3	13	17
Participant 4	21	21
Participant 5	20	23
Participant 6	21	21

Regarding symptom coverage, the optimized version was rated more favorably in terms of completeness, with patients describing it as “complete” 3 times, “almost complete” twice, and “somewhat complete” once. In contrast, the original version’s symptom coverage was described once as “complete,” once as “almost complete,” thrice as “partially complete,” and once as “somewhat complete.”

When asked how helpful the SC would have been at the onset of their disease, all 3 participants for whom Fabry disease was listed as a possible cause of their symptoms rated both versions as “very helpful.” The 3 patients where Fabry disease was not listed considered the SC either “partially helpful” (2/3) or “somewhat helpful” (1/3).

Discussion

Summary of the Findings

The optimized SC version, enhanced with expert knowledge, demonstrated improved diagnostic accuracy for Fabry disease compared to the original version. The optimized version identified Fabry disease as the top disease in 33% (2/6) of the cases (*M*1 score), compared to 17% (1/6) in the original version. The *M*3 scores were consistent across both the original and the optimized versions, with Fabry disease being listed among the top 3 suggested diseases in 50% (3/6) of the cases.

Patients generally preferred the optimized SC version, rating it higher in view of completeness and overall satisfaction. The optimized version was often described as providing more comprehensive symptom coverage and was perceived as more helpful if it had been available at the onset of their disease.

Improving Diagnostic Accuracy

The diagnostic accuracy of SCs is crucial in the context of rare diseases, where timely and accurate diagnosis remains a significant challenge, often leading to a lower quality of life and reduced life expectancy [24]. In this study, the optimized SC model showed a modest improvement in identifying Fabry disease as the top diagnostic suggestion, with the *M*1 score increasing from 17% (1/6) to 33% (2/6). While this improvement may seem minor, even slight enhancements in diagnostic accuracy can have a substantial impact on patients with rare diseases. Given the prolonged diagnostic odyssey often associated with these diseases, any increase in accuracy can facilitate earlier intervention, which is vital to prevent disease progression and improve long-term outcomes.

The study also highlights the main limitations of SCs, in particular their dependence on clear and well-defined symptoms. SCs rely heavily on user-provided data, typically self-reported symptoms, and are therefore most effective when patients present with symptoms that align closely with the embedded diagnostic algorithms. This study demonstrated that SCs struggle to accurately identify patients with few or nonspecific symptoms, a common scenario in the early stages of many rare diseases. For example, patients with Fabry disease who were primarily diagnosed on the basis of family history, rather than clear symptom profiles, were not effectively identified by the SC.

Our findings are consistent with the broader challenges of diagnosing atypical or uncommon diseases—precisely where accurate identification is most needed [25]. The SC in this study, like others, had lower diagnostic accuracy for atypical presentations, emphasizing the need for continuous refinement to better recognize these cases. Expanding the range of clinical vignettes, especially those depicting atypical scenarios, could help address this gap. In this study, experts primarily focused on creating vignettes of typical cases, which inadvertently led to the omission of more atypical presentations. Incorporating a diverse array of both typical and atypical cases is crucial for broader diagnostic coverage, though developing and integrating such vignettes presents a challenge for SC software companies.

While SCs may currently struggle to identify patients with minimal or nonspecific symptoms, they play a pivotal role in prescreening and encouraging consideration of less obvious diagnoses for those with oligosymptoms. By providing an initial assessment based on reported symptoms, SCs can help identify potential rare diseases early in the diagnostic process. This prescreening function empowers patients by giving them a clearer understanding of their symptoms and facilitating timely and appropriate care-seeking behavior.

Moreover, SCs are increasingly valuable in supporting health care providers, particularly GPs, who may lack the specialized knowledge needed to accurately diagnose rare diseases [26,27]. By highlighting potential rare diseases, SCs can prompt clinicians to consider diagnoses that may not be immediately apparent, thereby improving the overall diagnostic process. This guidance is especially valuable for ensuring that patients are promptly referred to specialists or undergo further diagnostic testing, thereby reducing the time to an accurate diagnosis. Assessing the combined diagnostic accuracy of SCs and physician expertise is a promising approach that better reflects the reality of clinical care, where the diagnostic process goes

XSL•FO
RenderX

beyond the initial use of SCs by patients. This integrated approach recognizes the critical role of clinicians in interpreting the results of SCs to make informed decisions that ultimately lead to more effective patient care.

Improving the modeling of rare diseases within SCs is one approach to enhancing diagnostic accuracy. Another strategy involves integrating more comprehensive information into the SC, for example, by incorporating large language models (LLMs) that can facilitate more accurate information intake from patients, including interpreting patient-provided notes or accessing electronic health records. LLMs can analyze and synthesize patient data more effectively, providing a richer context for the SC to generate accurate differential diagnoses.

Additionally, SCs could gradually incorporate more detailed patient information, such as laboratory results and other diagnostic data, into their analyses. This would enable the refinement of algorithms to deliver more accurate and contextually relevant diagnoses. The collaboration between LLMs and SCs could create a powerful diagnostic tool, where LLMs enhance the understanding of complex patient inputs, and SCs apply this information to produce more reliable and timely diagnoses. This combined approach could significantly improve the accuracy and effectiveness of SCs, particularly for diagnosing rare and complex diseases.

User Satisfaction

In the blind comparison of both models, users preferred the optimized version, regardless of which was shown first. This preference is probably due to the fact that the optimized version can provide more accurate diagnostic suggestions, which resonated more with users. Users tended to prefer the optimized version, reporting that the optimized version asked more relevant questions and better covered their symptoms, even when the SC did not identify Fabry disease as the likely cause of their symptoms. Those users experienced atypical symptoms. This shows that optimizing the Fabry condition model, together with improving the wording of associated symptoms, using the clinical vignettes, has increased the SC's ability to understand user input, which may have contributed to overall user satisfaction. The streamlined questioning process may also have played a role. As users interact with the app, each response updates the app's internal differential diagnoses, which in turn refines the subsequent question flow. If the optimized version identifies the correct disease earlier in the process, it can streamline the experience by reducing unnecessary questions and focusing more quickly on relevant diagnostic paths. This could result in a more efficient and satisfying interaction.

Strengths and Limitations

Strengths

Our study has several strengths. One of the primary ones is the double-blind approach used for study phase 2. By ensuring that neither the participants nor the study physicians knew which version of the SC they were using, we minimized bias and ensured that the observed preferences for the optimized model were based purely on its performance and not on any preconceived notions.

The study focuses on Fabry disease, a complex and rare disease, which makes it even more relevant. Fabry disease poses significant diagnostic challenges and is therefore an ideal subject for evaluating the effectiveness of SCs, particularly in the context of rare diseases where early and accurate diagnosis is crucial.

Another innovative aspect of our study is the use of expert-derived clinical vignettes as a data source for enhancing the SC's diagnostic algorithms. Unlike the traditional use of vignettes, which typically serve as evaluation tools, we used them to directly improve the underlying algorithms.

Working with the German patient organization Morbus Fabry Selbsthilfegruppe eV provided further invaluable insights that ensured that the study remained closely aligned with the needs and concerns of patients. This partnership helped to guide the study's focus and ensured that the results were meaningful and beneficial to both patients and health care providers.

Limitations

Our study has several limitations that should be acknowledged. One of the primary limitations is the gender imbalance in the patient population. Due to the limited availability of patients from the outpatient clinic, the study predominantly included female patients with Fabry disease (12 of 14 participants). Fabry disease is inherited in an X-linked pattern, meaning that female patients often present with less severe symptoms or may even be asymptomatic. This gender imbalance affected the results of the study since the SC relies heavily on symptoms reported by patients. This limitation highlights the need for future studies to include a more balanced patient population, particularly with more male patients who typically show more pronounced symptoms. The results may have been affected by the fact that the patients with Fabry disease who performed the SC version comparison may not have been able to remember the symptoms they had experienced at an earlier stage. They may have only entered their current symptoms, whereas Fabry disease symptoms become more severe over time [26]. At the same time, most patients interviewed were receiving enzyme replacement therapy at the time of study participation. It is possible that these facts affected the SC's diagnostic accuracy for Fabry disease; however, it is difficult to determine to what extent.

We will address these limitations in future studies by including GPs experienced with LSDs and patients who are at an earlier stage in their diagnostic journey. Such studies will allow us to assess the impact of SCs and our new approach of enriching SC disease models with expert knowledge for the detection of LSD in primary care.

Another limitation of the study is the small sample size. Of the 14 initially enrolled patients, 8 (57%) had to be excluded from the final analysis due to atypical GLA gene mutations, which led to very atypical or even asymptomatic presentations of Fabry disease. An essential prerequisite for the effective use of an SC is that the patient has at least some symptoms. Many of the excluded patients were diagnosed based on a positive family history rather than symptomatic presentation, which is common in Fabry disease where a male family member with typical

XSL•FO
RenderX

symptoms is often the index patient. The small sample size limits the generalizability of the study's findings and suggests the need for refining inclusion criteria in future studies to better reflect the real-life presentation of Fabry disease.

To test the accuracy of an SC, previous studies often imitated real patient input in the form of clinical vignettes used by either patients or health care professionals to enter SC symptoms [11,17,18,28,29].

Although these studies use vignettes for the assessment of SCs, which is different from the use of vignettes in our study, we have nonetheless informed our own study design by acknowledging the limitations reported in these studies. Vignettes have some limitations when used as clinical evaluation approaches, as they have limited information content and do not generally provide the opportunity to clinically interrogate additional information, to examine the patient, or to assess nonverbal cues [29,30]; therefore, at the time of vignette input into the SC, assumptions must sometimes be made beyond the vignette script. In addition, vignettes do not perfectly reflect how real patients use SCs [27]. Despite these limitations, clinical vignette studies are widely applied in the evaluation of SCs, as the approach also offers advantages since it allows 1 or more SCs to be evaluated (comparatively) across a broad spectrum of clinical conditions and clinical presentations using a highly standardized study protocol. The limitations of vignettes can be minimized through careful vignette standardization and through careful design, review, and refinement [11]. The use of vignettes is particularly important in the field of rare diseases, as these conditions are uncommon and cannot be readily addressed using conventional clinical studies without very large participant numbers or the preselection of participants highly likely to have the conditions under investigation.

In contrast to the standard use of vignettes for SC assessment, our study recruited real patients with Fabry disease and asked them to enter their symptoms into the app. We took substantial care in the development of our vignettes to follow best practices and to develop vignettes that were comprehensive in their description of the clinical presentation. Our goal was to provide repeatable and accurate input, even though the primary purpose was to use the vignettes as additional evidence for disease model optimization as opposed to SC evaluation. Although using vignettes for this purpose is a well-established method [11,18] and vignettes can be of high quality due to their elaborate creation process [11], they may not perfectly reflect how real patients use SCs [31].

Additionally, one of the study physicians was employed by the SC software company at the time of the study. Although this physician did not interfere with patients with Fabry disease entering their symptoms during the SC version comparison, this affiliation may introduce potential bias. To mitigate this, future evaluations should aim to include independent studies with larger numbers of participants to validate the findings more robustly.

Conclusions

This study demonstrates that integrating expert-derived clinical vignettes into AI-powered SCs can improve diagnostic accuracy and user satisfaction, particularly for rare diseases such as Fabry disease. The optimized SC version, which incorporated these vignettes, showed improved performance in identifying Fabry disease as a top diagnostic suggestion and received higher user satisfaction ratings compared to the original version. However, to fully realize the potential of this approach, it is crucial to include vignettes representing atypical presentations to ensure broader diagnostic coverage. Additionally, larger-scale studies are necessary to validate these findings, given the small sample size in this pilot study. Expanding the scope of this method could offer a more robust tool for early diagnosis and patient care in rare diseases.

Abstract

Background: The mechanisms underlying the mutual relationships between chronic physical illnesses and mental health disorders, which potentially explain their association, remain unclear. Furthermore, how patterns of this comorbidity evolve over time are significantly underinvestigated.

Objective: The main aim of this study was to use machine learning models to model and analyze the complex interplay between mental health disorders and chronic physical illnesses. Another aim was to investigate the evolving longitudinal trajectories of patients' "health journeys." Moreover, the study intended to clarify the variability of comorbidity patterns within the patient population by considering the effects of age and gender in different patient subgroups.

Methods: Four machine learning models were used to conduct the analysis of the relationship between mental health disorders and chronic physical illnesses.

Results: Through systematic research and in-depth analysis, we found that 5 categories of chronic physical illnesses exhibit a higher risk of comorbidity with mental health disorders. Further analysis of comorbidity intensity revealed correlations between specific disease combinations, with the strongest association observed between prostate diseases and organic mental disorders (relative risk=2.055, Φ=0.212). Additionally, by examining patient subgroups stratified by age and gender, we clarified the variability of comorbidity patterns within the population. These findings highlight the complexity of disease interactions and emphasize the need for targeted monitoring and comprehensive management strategies in clinical practice.

Conclusions: Machine learning models can effectively be used to study the comorbidity between mental health disorders and chronic physical illnesses. The identified high-risk chronic physical illness categories for comorbidity, the correlations between disease combinations, and the variability of comorbidity patterns according to age and gender provide valuable insights into the complex relationship between these two types of disorders.

KEYWORDS

chronic physical illnesses; mental health disorders; machine learning; temporal dependence; disease trajectory; comorbidity risk

Introduction

Contemporary medicine is increasingly focused on understanding the underlying relationships between physical and mental health [1,2]. A growing body of evidence suggests that potential increasing links exist between mental health disorders and chronic physical illnesses. Furthermore, individuals with certain chronic physical illnesses often face increasing challenges relating to their mental health issues, and vice versa [3-5]. Chronic physical illnesses, such as diabetes, cardiovascular disease, and prostate-related diseases, are growing global public health issues. These conditions not only impact the physical health of the patient but also pose a significant challenge at a socio–health care level [6,7]. Mental health disorders such as depression, anxiety, and schizophrenia can significantly affect an individual's physical health and

XSL•FO
RenderX

overall quality of life [8]. The coexistence of chronic physical illnesses and mental health disorders often leads to further health complications. Increasing comorbidity complicates both diagnosis and clinical treatment. It also increases polypharmacy, leading to a reduction in patient life expectancy. Studies have shown that patients with severe mental health disorders as well as type 2 diabetes have a 3 - 4 times higher risk of a premature death than that seen in the general population. Cardiovascular disease is one of the leading causes of premature death in this group [9].

Focusing on the physical condition of a person with a mental health disorder prior to its diagnosis is critical as this can provide critical insight and information required to guide preventive and therapeutic interventions. For example, a physical condition that precedes the onset of a particular mental health disorder may share underlying symptoms or pathoetiological mechanisms [10]. Knowing which physical conditions are more prevalent in people diagnosed with a mental health disorder can better inform the introduction of an effective screening tool for "at-risk" populations. It may also help deliver an appropriate intervention to prevent further progression of increased multimorbidity. Such an approach should lead to significant health-associated cost savings and better health outcomes [11].

The complex etiologies and pathophysiological mechanisms that underpin and drive the development of comorbidity between chronic physical illness and mental health disorders have not, as yet, been significantly established or elucidated. A number of recent research studies have started to explore some potential underlying mechanisms of comorbidity. These have been largely through clinical observations or suggested from molecular network analyis [12-16]. Other studies have applied machine learning (ML) models trained through the analysis of large clinical datasets, such as electronic health records. These have now started to identify patterns of comorbidity associated with the development of certain disorders. These have also been applied to predict the likelihood of developing specific comorbidities based on a patient's past medical history and other relevant characteristics [17-20]. ML methods to predict the progression of disease comorbidities have great potential to ultimately improve accurate medicine and lead to the delivery of appropriate care [21].

To date, most of the studies have been restricted to high-income countries (eg, European countries, the United States, and Australia). Although China represents one of the largest populations in the world, little research has been conducted that relates to the development of comorbidity in people living with diabetes [22]. Given that approximately one-third of the world's adult population has 2 or more long-term conditions, further research into the relationship between chronic physical conditions and the onset of mental health disorders is now of major importance. It is also important to investigate a wide range of discrete populations in different countries as sociological, cultural, and genetic variations will undoubtedly exist and this heterogeneity can provide valuable insights into the relationships of physical and mental health conditions.

In this study, we investigate the temporal nature of patients' disease trajectories compared with previous reports that have analyzed comorbidity patterns directly from large-scale data using network analysis [13-15], association rules [23,24], or comorbidity indices [25]. We have focused on exploring the risk relationship that potentially exists between chronic physical illness diagnoses and mental health disorders. This analysis has only been possible through access to the patient's diagnostic record prior to the diagnosis of a mental health disorder. This permitted insight into each patient's disease trajectory and the possibility of identifying key factors and patterns that may influence the subsequent development of a mental health disorder.

The primary objective of this retrospective analysis of a large population living in Guangdong, China, was to identify chronic physical illnesses with a higher risk of co-occurrence with mental health disorders. In addition, this study aimed to evaluate and analyze comorbidity patterns between chronic physical illnesses and mental health disorders, as well as assess age and gender differences within such patterns.

Methods

Data Analyzed

All patients with a diagnosis of a mental health disorder in the southern region of Guangdong, China, during the study period (January 1, 2016 to December 31, 2022) were included in the analysis. The electronic health record included unique identity, age, gender, hospital admission and discharge dates, and 16 diagnostic codes (including the primary diagnostic code) for each patient. Diagnostic codes were recorded using the *International Classification of Diseases, Tenth Revision* (ICD-10). As more than 20,000 unique and active diagnostic codes now exist in this coding format, it was impractical to analyze each ICD diagnostic code. We therefore processed the codes as 4-digit codes and filtered these into two categories: (1) chronic physical illnesses and (2) mental health disorders. Based on existing published literature and studies, we conducted prevalence analysis for the 60 chronic diseases proposed by Vetrano et al [26]. Chronic physical illnesses with a prevalence rate greater than or equal to 1% (ICD-10 codes for diseases not beginning with F) were selected for inclusion into the study [16]. Analysis of prevalence was also performed for mental health disorders [8] to decide which conditions should be included in the study. Table 1 illustrates the age-sex groupings and Table 2 shows the prevalence and number of mental health disorders.

XSL•FO
RenderX

Table . Age-sex groups (N=46,649).

Age group (years)	Total participants (N=46,649), n (%)	Female (n=22,313), n (%)	Male (n=24,336), n (%)
0 - 18	2835 (6.08)	868 (3.98)	1967 (8.08)
18 - 45	12,732 (27.29)	4836 (21.67)	7896 (32.45)
45 - 60	9632 (20.64)	5270 (23.62)	4362 (17.92)
60 - 80	13,764 (29.51)	7483 (33.54)	6281 (25.81)
>80	7686 (16.48)	3856 (17.28)	3830 (15.74)

Table . The prevalence and number of mental health disorders (N=46,649).

Diagnosis of major mental health disorders	Disease name	Prevalence, n (%)
F00-F09	Organic mental disorders	12,273 (26.31)
F10-F19	Mental and behavioral disorders due to psychoactive substance use	1094 (2.35)
F20, F22, F24, F25, F28	Schizophrenia and delusional diseases	14,634 (31.37)
F30-F34, F38, F39	Depression and mood diseases	3601 (7.72)
F40-F45, F48	Neurotic stress–related and somatoform diseases	15,877 (34.04)
F50	Eating disorders	82 (0.18)
F51.0-F51.3	Sleep disorders_F	612 (1.31)
F60	Specific personality disorders	29 (0.06)
F70-F79	Mental retardation	3431 (7.35)
F84	Pervasive developmental disorders	622 (1.33)
F90-F98	Behavioral and emotional disorders with onset usually occurring in childhood and adolescence	229 (0.49)

A total of 41 chronic physical illnesses were included: cerebrovascular disease, esophagus stomach and duodenum diseases, hypertension, dorsopathies, other metabolic diseases, dyslipidemia, ischemic heart disease, heart failure, other cardiovascular diseases, other respiratory diseases, anemia, chronic obstructive pulmonary disease, emphysema chronic bronchitis, diabetes, dementia, other genitourinary diseases, prostate diseases, other musculoskeletal and joint diseases, other neurological diseases; ear, nose, and throat diseases; cardiac valve diseases, osteoporosis; chronic pancreas, biliary tract, and gall bladder disease; sleep disorders, solid neoplasms, osteoarthritis and other degenerative joint diseases, inflammatory arthropathies, epilepsy, cataract and other lens diseases, colitis and related diseases, thyroid diseases, chronic liver diseases, atrial fibrillation, chronic ulcer of the skin, chronic infectious diseases, Parkinson and parkinsonism, migraine and facial pain syndromes, blood and blood-forming organ diseases, chronic kidney diseases, allergy, peripheral neuropathy, and other eye diseases.

In addition, 8 mental health disorders were included: neurotic stress-related and somatoform diseases, schizophrenia and delusional diseases, organic mental disorders, depression and mood diseases, mental retardation, mental and behavioral disorders due to psychoactive substance use, pervasive developmental disorders, and sleep disorders (ICD code starts with F).

Data Preprocessing

Overview

Mental health disorders were taken as the target disease. Data were extracted from the hospital admission and discharge records of each patient. The disease trajectory over chronological time was then ordered and used as the predictor variable for that particular disease. All data analyses and visualizations were conducted in Python (version 3.8). The main steps of data preprocessing are described in the next section.

Missing Value Handling

After including only chronic physical diseases with a prevalence of ≥1% (based on the criteria by Vetrano et al, 2020 [26]) and excluding rare diseases to reduce noise, we further addressed missing fields in the diagnostic records (such as age and gender) by using the deletion method (retaining only complete data). Since the data in this study are derived from patient admission records, and the missing value ratio is below 5%, this approach was deemed appropriate.

Data Cleaning

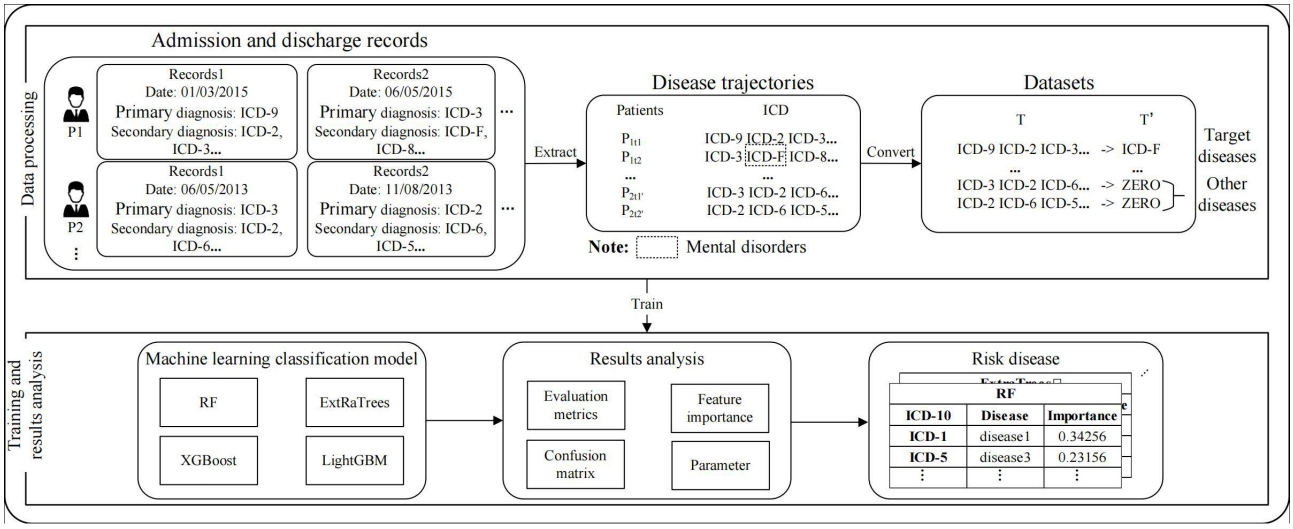
This step consisted of the filtering and screening of 348,563 admission and discharge records of 102,409 patients with mental health disorders from 2016 to 2022. We specifically selected patients who had at least 2 admission and discharge records. Subsequently, ICD-10 coding standardization was used to screen for valid diagnoses, exclude duplicate records (such as the same diagnosis across multiple hospitalizations), and perform ICD

XSL•FO
RenderX

coding. This resulted in a "cleaned" dataset of 268,588 admission and discharge records from 46,649 patients, achieving a screening rate of 77.05%.

Dataset Construction

The "cleaned" patient admission records were then converted into a dataset using classification and labeling. The specific steps are as follows:



1. Time dependency of admission records: We extracted the hospital records of each patient in chronological order. The first record without the target disease was used as a feature, and the subsequent record was converted into a classification label ("1" for the presence of the target disease, "0" for other diseases), until the target disease was identified. This method was then applied to process the hospital records of all other patients in the study.
2. Exclusion of rare data: Records with fewer than 5 occurrences were removed to further process the dataset, preventing excessively sparse features and avoiding model overfitting. After this step, the dataset contained more than 23,000 records. Then, 70% of the dataset was used as the training set, and the remaining 30% was used as the test set for performance comparison.

ML Classification Models Used for Assessing Risk Diseases

Four ML algorithms were used to model patient disease trajectories based on temporal dependencies, study the risk of comorbidity between chronic physical illnesses and mental health disorders based on patient disease trajectories, and assess chronic physical illnesses that increase the risk of mental health disorder development.

These ML models were (1) random forest (RF), (2) extremely randomized trees (ExtRaTrees), (3) light gradient boosting machine (light GBM), and (4) extreme gradient boosting (XGBoost). The main framework for the analysis framework is described in Figure 1.

Figure 1. Framework for assessing risk diseases using patient trajectories and classification machine learning models. ExtRaTrees: extremely randomized trees; ICD: International Classification of Diseases; light GBM: light gradient boosting machine; RF: random forest; XGBoost: extreme gradient boosting.

By using ML classification models, we modeled patient disease trajectories with a focus on temporal dependencies. This allowed a thorough exploration of the risk relationships between chronic physical illnesses and mental health disorders before patients were subsequently diagnosed with mental health conditions. This uncovered potential risk conditions that preceded their diagnosis. Traditional risk models often overlook the study of patient comorbidities in the context of temporal dependencies. The approach we used provided a better understanding of such relationships between different diseases over a patient's life course, particularly in the period prior to the diagnosis of mental health conditions and disorders.

Given the low frequencies of some conditions identified in the dataset, we focused on developing models that can deal with sparse data for classification in anticipation of a more significant performance advantage. Although deep learning models have shown outstanding performance in certain scenarios, we prioritized model interpretability and robustness against sparse data. Additionally, to assess the risk factors contributing to mental disorders, the top 10 most important features (ICD codes) from each model's classification process were evaluated, which is why comparative models were not included in this analysis. The profiles of the models used are summarized in Table 3.

In our study, we optimized the parameters of the ML model using 5-fold cross-validation. Additionally, oversampling and hyperparameter tuning were used to address the issue of class imbalance. The model was then trained using the optimal parameters. Then, the 10 most important features (ICD codes) of the model classification process were evaluated and categorized to obtain risk diseases, and these were subsequently analyzed for comorbid combinations with mental health disorders.

XSL•FO
RenderX

Table . Description of the model and similar literature.

Model	Model description	Advantage	Similar documents
Random forest	An integrated learning algorithm based on multiple decision trees. The final output is determined by voting or averaging the outputs of these decision trees.	Resistance to overfitting; large data handling; feature importance assessment; easy parallelization; missing value handling.	[14,20,21,27]
Extremely randomized trees	Integrated learning algorithms based on decision trees are similar to random forest analysis, but differ by choosing the cut points randomly within a random range when constructing the decision tree.	Superior resistance to overfitting; high computational efficiency; robustness to outliers and noise; feature importance assessment.	[27,28]
Light gradient boosting machine	Gradient boosting tree-based machine learning algorithms achieve efficient processing of large data by using a histogram-based decision tree algorithm and parallelized training. This approach supports the processing of high-dimensional sparse features and class features with a fast training speed, low memory consumption, and superior accuracy.	Efficient training speed; low memory footprint; high accuracy; support for parallelized learning; missing value handling; flexible parameter tuning.	[29,30]
Extreme gradient boosting	This approach is similar to light gradient boosting machine, but excels in handling large-scale data and complex features, using unique techniques such as regularization, parallelized processing, and custom loss functions to improve model accuracy and generalization.	High performance; regularization; missing value handling; flexibility; feature importance assessment; interpretability; rich hyperparameters.	[20,21,30]

Data Analysis Methods

For the risk of diseases assessed in the classification model, we used the relative risk (RR) and the Φ correlation coefficient (phi correlation coefficient) to measure the intensity of comorbidity between a physical condition and a particular type of mental health disorder [12,15]. Since we were more interested in closely related disease combinations, mutually exclusive disease combinations with negative comorbidity intensity or no comorbidity intensity (RR≤1 or Φ≤0) were excluded [16]. The formulae for RR and Φ correlation coefficient are shown here:

$$RRij=Cij\ NPi\ Pj$$

$$\Phi ij=CijN-PiPjPiPj(N-Pi)(N-Pj)$$

Where C_{ij} is the number of patients affected by the 2 diseases, N is the total number of patients in the study population, and P_i and P_j are the number of patients with disease i and j, respectively.

In addition, as there may be potential effects of age and sex on patient comorbidity [16,31-33] and also to obtain more consistent and reliable estimates, we grouped patients by age in year intervals (0 - 18, 18-45, 45 - 60, 60-80, >80 years) and sex; these were used for further analyses. Mental health disorders were broadly classified into 11 categories; prevalence statistics were performed after classification. Eight mental disorders with prevalence rates greater than or equal to 1% were included in the scope of this analysis.

Ethical Considerations

Ethics approval for this study was obtained from the Clinical Research Ethics Committee of Affiliated Hospital of Guangdong Medical University (number KT2023-138-01). Written and oral informed consent was obtained from the participants. Additionally, for minors, informed consent was also obtained from their parents or legal guardians. This study used data that were anonymized and no financial compensation was provided to participants.

Results

The ML Classification Models for Assessing Risk Diseases

To explore the risk associated with analyzing the comorbidity of chronic physical illnesses and mental health disorders based on patient disease trajectories, we randomly sampled from the dataset to create a baseline dataset. Subsequently, we used 4 ML methods for modeling, with detailed parameters as follows:

- RF: criterion=gini, max feature=sqrt, number of estimators=500, class_weight=balanced
- EXtraTrees: number of estimators=500, class_weight=balanced
- LightGBM: Objective=binary, is_unbalance=True, metric=f1, max_depth=5, num_leaves=31, learning_rate=0.01, reg_alpha=0.9, reg_lambda=1, num_iterations=5000

XSL•FO
RenderX

- XGBoost: objective=binary:logistic, max_depth=6, learning_rate=0.01, n_estimators=5000, colsample_bytree=0.4, subsample=0.8

To evaluate the performance of the model, we used accuracy, precision, recall, F_1-score, and area under the curve (AUC) as evaluation metrics. Accuracy is a basic metric used to evaluate the performance of classification models. This evaluates the ratio of the number of samples correctly predicted by the model relative to the total number of samples. Precision was evaluated for the prediction of results and indicates the proportion of truly positive samples among the samples with positive predictions. Recall was also ascertained for the original sample and indicated how many of the positive classes in the sample were correctly predicted. Since recall and precision are relative concepts, each with its own focus on the identification process of positive samples, the F_1-score was used to combine precision and recall and provide a comprehensive assessment of the accuracy and completeness of the model. A confusion matrix is a 2D table that provides an intuitive way to understand the performance of the model and measure the performance of the classification model. AUC refers to the area under the receiver operating characteristic (ROC) curve, which is a performance metric used to evaluate how well the model distinguishes between the 2 classes (positive and negative). The evaluation metrics formula is shown below:

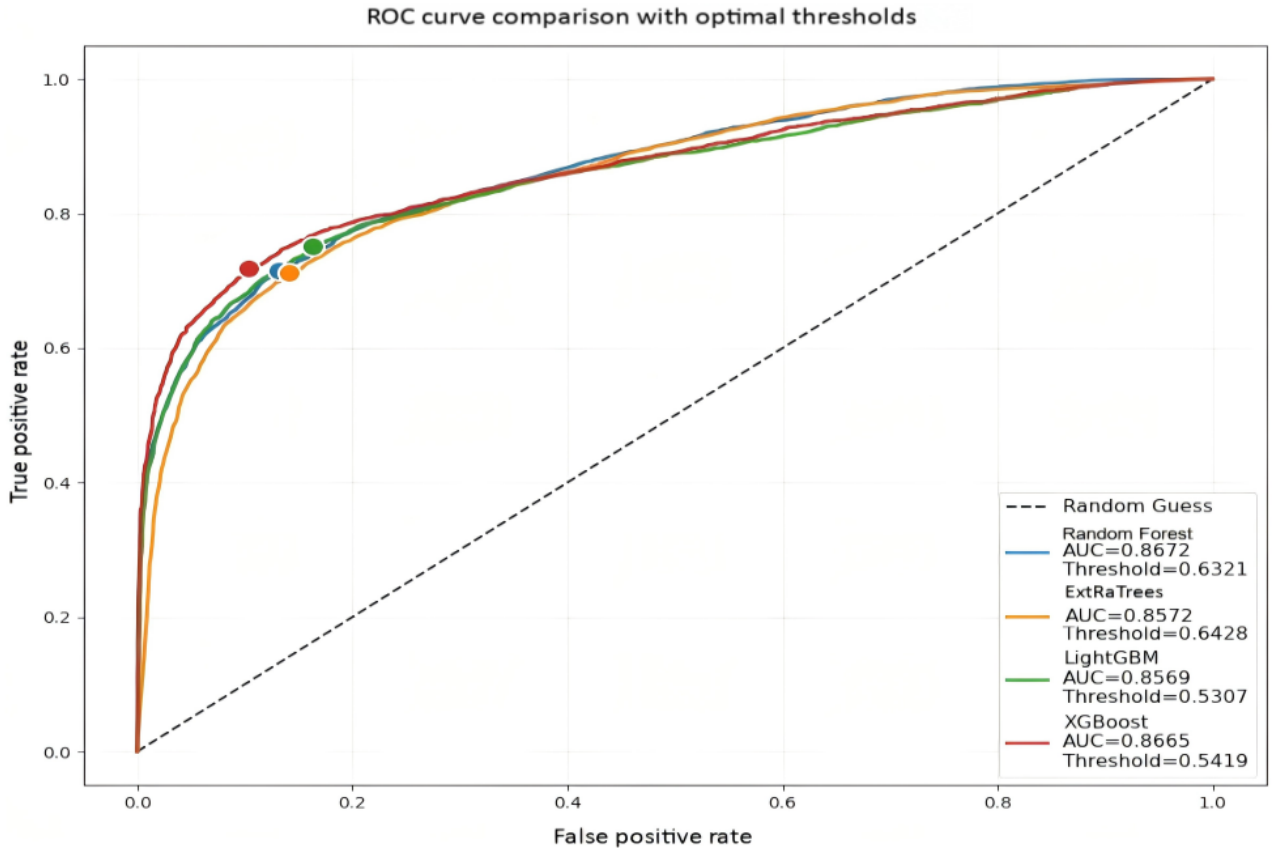
$$\text{Accuracy}=\frac{TP+TN}{TP+FN+TN+FP}$$

$$\text{Precision}=\frac{TP}{TP+FP}$$

$$\text{Recall}=\frac{TP}{TP+FN}$$

$$\text{F1-Score}=\frac{2\times\text{Precision}\times\text{Recall}}{\text{Precision}+\text{Recall}}$$

Where *TP*: true example, *FN*: false negative example, *FP*: false positive example, *TN*: true negative example.



The performance estimates of the 4 classification models are shown in Table 4 and Figure 2, where XGBoost has the highest accuracy (0.8201), RF has the lowest accuracy (0.7597), and RF has the highest recall (0.7750) and AUC (0.8672). Overall, XGBoost has the best F_1 value (0.7815) among the 4 methods. The difference between XGBoost and Light GBM results in this experiment is not large, due to their ability to deal with sparse features. However, XGBoost can be more flexible and accurate when dealing with nonlinear interactions between features by using second-order derivatives to capture the interactions between features.

Table . Performance of the 4 models for the classification of mental health disorders.

	Accuracy	Precision	Recall	F_1-score	Area under the curve
Random forest	0.7888	0.7597	0.7750	0.7672	0.8672
Extremely randomized trees	0.7855	0.7635	0.7571	0.7603	0.8572
Light gradient boosting machine	0.7978	0.7882	0.7520	0.7697	0.8569
Extreme gradient boosting	0.8125	0.8201	0.7464	0.7815	0.8665

Figure 2. ROC curve comparison with optimal thresholds. AUC: area under the curve; LightGBM: light gradient boosting machine; RF: random forest; ROC: receiver operating characteristic; XGBoost: extreme gradient boosting.

The first 10 important characteristics (ICD codes) of the classification process of each model were evaluated. The categories to which they belonged were queried to obtain the risk diseases affecting mental health disorders (see Table 5). Twelve different ICD codes, belonging to 10 categories of chronic physical illnesses, were obtained by taking into account the results of the evaluation of the 4 models. Eight ICD codes were present in the scores of each model, although the ranking of the scores for these 8 ICD codes varied slightly from model to model. Such commonality suggests that these 8 ICD codes are associated with a higher risk of mental health disorders. The 8 ICD codes fall into 7 categories of chronic physical illnesses: heart failure, hypertension, cerebrovascular disease, ischemic heart disease; esophagus, stomach, and duodenum diseases; prostate disease, and diabetes. Of these 7 categories of chronic physical illnesses, 4 of them (heart failure, ischemic heart disease, hypertension, and cerebrovascular disease) could be broadly classified as cardiovascular diseases and are among the risk factors for mental health disorders. Studies have indicated that mental health disorders, particularly psychological comorbidities such as depression and mood disorders, neurotic stress and somatoform disorders, and substance use disorders have a high prevalence and negative impact among patients with cardiovascular diseases. For instance, the prevalence of depression or neurotic stress–related and somatoform disorders is several times higher in patients with heart failure compared to the general population and may be associated with cognitive issues [4,5]. Individuals with symptoms related to esophagus, stomach, and duodenum diseases, such as pain, dyspepsia, and dietary restrictions, may experience heightened anxiety, depression, and psychological distress. These psychological challenges, in turn, have an impact on their overall psychological well-being. For instance, in conditions like gastroesophageal reflux disease (GERD), the prevalence of psychosocial disorders is higher in GERD patients compared to those without GERD [34,35]. In the case of diabetes, the long-term burden of chronic disease, lifestyle adjustments, medications, and psychosocial pressures can elevate the risk of developing anxiety and depression. Evidence suggests that individuals with diabetes are more susceptible to common psychiatric disorders, particularly mixed anxiety and depression [36,37].

Based on the scoring results of the model with the best categorization performance (XGBoost) as well as those of other models, we identified 3 categories of chronic physical illnesses (anemia, other metabolic disorders, and dyslipidemia) that were scored as risk diseases closely related to mental health disorders. Despite the fact that these 3 categories of chronic physical illnesses ranked at the bottom of the scoring list, they still contributed a very high level of risk. For example, in the case of anemia, this can lead to a decline in physical activity and general fatigue; it can also affect mental status and emotional stability. In iron deficiency, anemia can result in a loss of iron-containing enzymes and proteins during the development of the central nervous system. This can lead to an increased risk of mental health disorders developing. These can include mood disorders, autism spectrum disorders, attention deficit hyperactivity disorder, and developmental disorders [38]. However, the comorbidity and risk between other metabolic disorders and dyslipidemia and mental health disorders is not

XSL•FO
RenderX

supported by the literature and requires further research attention to investigate their associated mechanisms.

[a]ICD-10: *International Classification of Diseases, Tenth Revision*.

Comorbidity Analysis of Risk Diseases and Mental Health Disorders

To measure the intensity of comorbidity between risk diseases and a particular class of mental health disorders, we identified 30 different disease combinations with comorbidity intensity (RR>1 and Φ>0, as detailed in Figure 3A) from the complete dataset of patients with mental health disorders. The disease combinations with the highest comorbidity intensity were prostate disease and organic mental disorders (including symptoms; RR=2.055, Φ=0.212). The disease combinations with the highest comorbidity intensity were prostate disease and organic mental disorders (RR=2.055, Φ=0.212). Within the 10 highest risk disease combinations in terms of comorbidity intensity (RR>1.2 and Φ>0. 1), 7 combinations included organic mental disorders (hypertension, cerebrovascular disease, anemia, heart failure, prostate disease, ischemic heart disease and diabetes, ischemic heart disease, and other metabolic diseases). A further 3 combinations included neurotic stress–related and somatoform diseases (related to esophagus, stomach, and duodenum diseases and ischemic heart disease). The combinations of the 10 risk diseases with the highest intensity of comorbidity with mental health disorders are shown in Table 6.

XSL•FO
RenderX

Figure 3. Scatter plot between RR and Φ correlation coefficient for disease combinations (the larger the RR value, the more reddish the scatter color). (**A**) All patient populations, (**B**) male patient populations, and (**C**) female patient populations. CVD: cerebrovascular diseases; DL: dyslipidemia; DM: diabetes; DMD: depression and mood disorders; ESD: esophagus, stomach, and duodenum diseases; HF: heart failure; HTN: hypertension; IHD: ischemic heart disease; MR: mental developmental disorders; NSRSD: neurotic stress–related and somatoform diseases; OMD: other metabolic diseases; OMD_F: organic mental disorders; PD: prostate diseases; PDD: pervasive developmental disorders; RR: relative risk; SD: sleep disorders_F; SDD: schizophrenia and delusional disorders; SUD: mental and behavioral disorders due to psychoactive substance use.

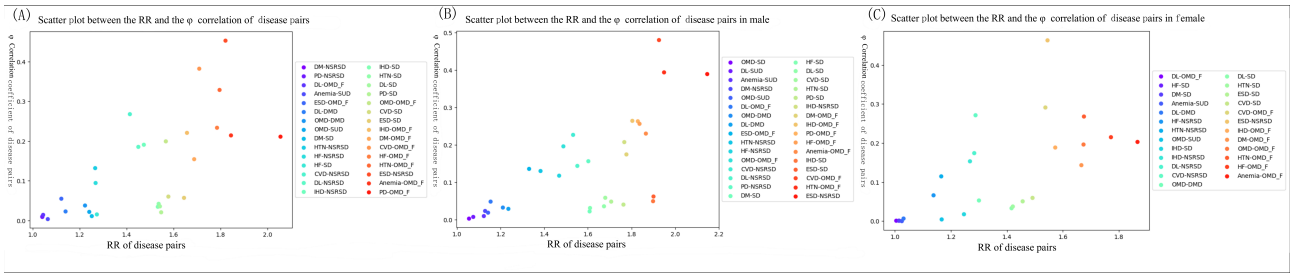

Table . Combinations of 10 risk diseases with the highest intensity of comorbidity with mental health disorders.

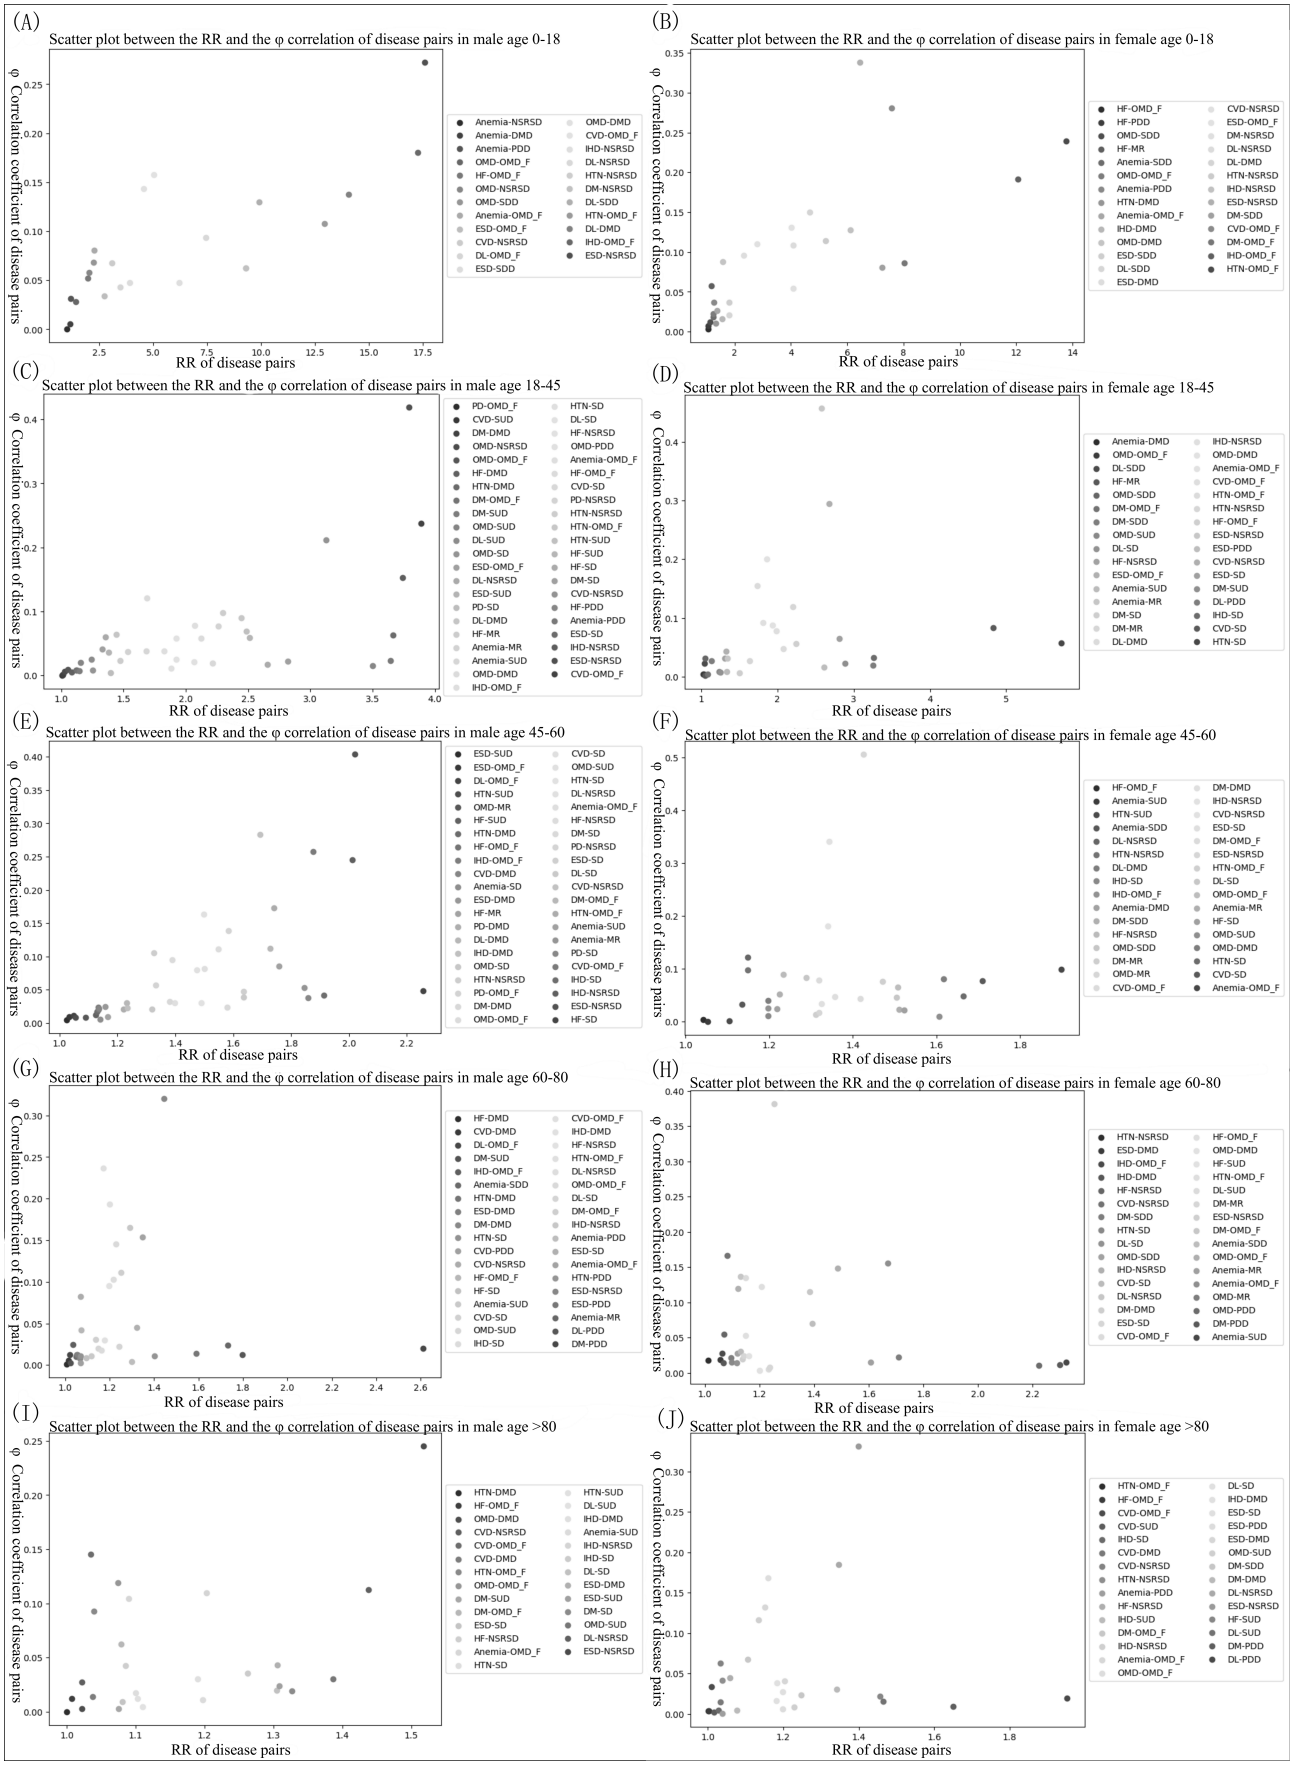
Comorbidity combinations	Comorbidity intensity
Prostate diseases and organic mental disorders	RR[a]=2.055, Φ=0.212
Anemia and organic mental disorders	RR=1.843, Φ=0.214
Esophagus, stomach, and duodenum diseases and neurotic stress–related and somatoform diseases	RR=1.821, Φ=0.454
Hypertension and organic mental disorders	RR=1.794, Φ=0.329
Heart failure and organic mental disorders	RR=1.785, Φ=0.234
Cerebrovascular disease and organic mental disorders	RR=1.708, Φ=0.382
Diabetes and organic mental disorders	RR=1.687, Φ=0.154
Ischemic heart disease and organic mental disorders	RR=1.656, Φ=0.221
Other metabolic diseases and organic mental disorders	RR=1.567, Φ=0.199
Dyslipidemia and neurotic stress–related and somatoform diseases	RR=1.448, Φ=0.186

[a]RR: relative risk.

To analyze gender differences in comorbidity patterns, the entire dataset were divided into 2 groups based on gender to identify 32 male and 25 female comorbidity combinations. In the male patient population, the comorbidity combinations with the highest comorbidity intensity were esophagus, stomach, and duodenum diseases and neurotic stress–related and somatoform disorders (RR=2.146, Φ=0.391). Within the 10 disease combinations exhibiting the highest comorbidity intensity (RR>1.2 and Φ>0.1), 7 combinations included organic mental disorders (ie, related to prostate diseases, anemia, hypertension, heart failure, cerebrovascular diseases, diabetes, ischemic heart disease, and other metabolic diseases), and 3 combinations included neurotic stress–related and somatoform diseases (related to esophagus, stomach, and duodenum diseases, ischemic heart disease, and prostate diseases).

In contrast, the combination of comorbidities with the highest comorbidity intensity in the female patient population was anemia and organic mental disorders (RR=1.867, Φ=0.203). Within the 10 highest disease combinations (RR>1.2 and Φ>0.1) in terms of comorbidity intensity, 7 combinations included organic mental disorders (associated with anemia, heart failure, hypertension, other metabolic diseases, diabetes, ischemic heart disease, and cerebrovascular diseases) and 3 combinations included neurotic stress–related and somatoform diseases (associated with esophagus, stomach, and duodenum diseases, cerebrovascular diseases, and dyslipidemia). The listed comorbidities all had RR>1. 2 and Φ>0.1, as shown in Figure 3B and Figure 3B).

Gender and Age Differences in Comorbidity Patterns



As age and gender were potential factors affecting patients' health, we divided the complete dataset of patients with mental health disorders into 10 groups according to gender (male and female) and age (0 - 18, 18 - 45, 45 - 60, 60 - 80, and >80 years). Significant comorbidity combinations are detailed in Figures 4A-J.

The combinations of comorbidities with comorbidity intensity in all groups were as follows: (1) heart failure and organic mental disorders, (2) ischemic heart disease and neurotic stress–related and somatoform diseases, (3) hypertension and organic mental disorders, (4) esophagus, stomach, and duodenum diseases and neurotic stress–related and somatoform diseases, (5) anemia and organic mental disorders, and (6) other metabolic diseases and organic mental disorders.

XSL•FO
RenderX

Figure 4. Scatter plot between RR and Φ correlation coefficients for disease combinations within each subgroup. All points in the plot have RR>1 and Φ>0. (**A**) Age 0 - 18 years, male sex. (**B**) Age 0 - 18 years, female sex. (**C**) Age 18 - 45 years, male sex. (**D**) Age 18 - 45 years, female sex. (**E**) Age 45 - 60 years, male sex. (**F**) Age 45 - 60 years, female sex. (**G**) Age 60 - 80 years, male sex. (**H**) Age 60 - 80 years. CVD: cerebrovascular diseases; DL: dyslipidemia; DM: diabetes; DMD: depression and mood disorders; ESD: esophagus, stomach, and duodenum diseases; HF: heart failure; HTN: hypertension; IHD: ischemic heart disease; MR: mental developmental disorders; NSRSD: neurotic stress–related and somatoform diseases; OMD: other metabolic diseases; OMD_F: organic mental disorders; PD: prostate diseases; PDD: pervasive developmental disorders; RR: relative risk; SD: sleep disorders_F; SDD: schizophrenia and delusional disorders; SUD: mental and behavioral disorders due to psychoactive substance use.

XSL•FO
RenderX

Although the previously mentioned 6 comorbidity combinations showed different comorbidity intensities in different age-sex groups of patients, they exhibited high comorbidity intensity in the patient groups, as shown in Table 7.

XSL•FO
RenderX

There are some comorbidity combinations that show a high comorbidity intensity only within certain age-sex groups (as shown in Table 8). In addition, some comorbidity combinations maintained a high comorbidity intensity in either the male or female patient populations (eg, esophagus, stomach, and duodenum diseases and neurological stress–related and somatoform diseases and cerebrovascular diseases and organic mental disorders were found to have a strong comorbidity intensity in all age subgroups of the male patient population, whereas in the age-specific subgroups of the female patient population, only esophagus, stomach, and duodenum diseases and neurotic stress–related and somatoform diseases had a high comorbidity intensity).

Table . The patient groups in which the 10 comorbidity combinations show a robust comorbidity intensity (relative risk>1.2 and Φ>0.1 within the group).

Comorbidity combinations	Patient populations
Esophagus, stomach, and duodenum diseases and neurotic stress–related and somatoform diseases	All age-sex groups
Ischemic heart disease and neurotic stress–related and somatoform diseases	Female patients aged 0 - 18 years and male patients aged 18 - 45 years
Hypertension and organic mental disorders	Male and female patients aged 0 - 18 years
Esophagus stomach and duodenum diseases and neurotic stress–related and somatoform diseases	Male and female patients aged 0 - 18 years
Cerebrovascular diseases and organic mental disorders	Male and female patients aged 0 - 18 years
Cerebrovascular diseases and neurotic stress–related and somatoform diseases	Male patients aged 18 - 45 years and female patients aged 0 - 18 years
Anemia and organic mental disorders	Male and female patients aged 60 - 80 years
Other metabolic diseases and organic mental disorders	Male and female patients aged 60 - 80 years

Table . Comorbidity combinations with high comorbidity intensity within specific age-sex groups.

Patient populations	Comorbidity combinations	Comorbidity intensity
Male patient population aged 0 - 18 years	Dyslipidemia and schizophrenia and delusional diseases	RR[a]=9.897, Φ=0.129
Female patient population aged 0 - 18 years	Esophagus, stomach, and duodenum diseases and organic mental disorders	RR=4.019, Φ=0.131
Male patient population aged 45 - 60 years	Prostate diseases and neurotic stress–related and somatoform diseases	RR=1.584, Φ=0.139
Male patient population aged 45 - 60 years	Heart failure and neurotic stress–related and somatoform diseases	RR=1.547, Φ=0.112

[a]RR: relative risk.

Discussion

Principal Results

The potential mechanisms underlying comorbidity are helpful in our understanding of diagnosis and prevention and control in clinical settings. This study analyzes the risk of comorbidity between chronic physical illnesses and mental health disorders. In addition, it importantly examines such comorbidity in the context of both age and gender differences in 46,649 patients with mental health disorders.

In terms of disease prediction methods, patient clinical trajectories were used to analyze the risk of comorbidity between chronic physical illnesses and mental health conditions; ten categories of physical illnesses with a high risk for developing mental health comorbidity were evaluated. A high intensity of comorbidity was found between physical conditions and organic stress–related and somatoform diseases as well as neurotic stress–related and somatoform diseases.

We found that comorbidities affect all age and gender groups, with more combinations of comorbidities, along with significant stronger comorbidity strengths in the 18 - 45 and 45 - 60 year old male patient populations. In particular, the interaction between chronic physical illnesses and mental disorders was stronger in the group of male patients aged 45 - 60 years (most disease combinations with RR>1.2 and Φ>0.1).

To our knowledge, this is the first study in the literature to use regional patient longitudinal medical record data rather than self-reported survey data to assess risk diseases for comorbidity between chronic physical illnesses and mental health disorders and to also analyze age and gender differences in comorbidity patterns.

Comorbidity Between Chronic Physical Illnesses and Mental Health Disorders and Potential Common Mechanisms

We identified chronic physical illnesses with a higher risk of being associated with mental health disorders. Some of these

XSL•FO
RenderX

exhibited a stronger correlation as well as showing frequent comorbidities. Additionally, a number of comorbid combinations displayed significant comorbidity intensity between a chronic physical illness and mental health disorder(s), for example, heart failure with organic mental disorders; anemia with organic mental disorders; esophagus, stomach, and duodenum diseases with neurotic stress–related and somatoform diseases; and hypertension with organic mental disorders. These were more frequent than their expected randomized occurrence in high-income countries or regions [39]. For example, the analysis by Cannon et al [5] found that patients with heart failure have a higher relative risk and prevalence of organic mental disorders (Alzheimer disease, etc) and also have concurrent cognitive problems.

Chronic physical illnesses and mental health disorders suggest a risk for physical and mental comorbidity. It may be that chronic physical illnesses are associated with an increased risk of mental health disorders and vice versa. To fully appreciate the sequence of such events and the temporal onset, there is a need to retrospectively analyze a longitudinal cohort of people where clinical data are ethically available to analyze. Ideally, such data should be "real-world data" that fully reflects the demographic and ethnic makeup and structure of the study area population. Furthermore, the high-quality data should be collected over a long duration. This is not always possible in prospective studies where a sampling bias distorts the relevance to the whole population.

In terms of the pathogenesis of chronic physical illness and mental health disorder comorbidity, there are 4 possible causes:

1. Chronic physical illness and mental disorder comorbidity share common biological mechanisms, such as inflammatory and immune pathways or dysregulation of the neuroendocrine system. For example, chronic physical illnesses (eg, diabetes) can activate proinflammatory cytokines (eg, interleukin-6, tumor necrosis factor alpha), affecting blood-brain barrier permeability and leading to neuroinflammation [37].
2. The mechanism of dysregulation of the regulatory systems may mean that patients with chronic pain also experience symptoms of depression and anxiety, which may be related to an imbalance in the neuromodulatory system.
3. Psychosocial factors and lifestyle behaviors (eg, suboptimal diet, lack of exercise, poverty and deprivation) can influence both chronic physical illnesses and mental disorders. For example, chronic stress and anxiety can lead to an increased inflammatory response in the body, increasing the risk of heart disease or diabetes. Individuals who have a history of a suboptimal diet are likely to be deficient in vitamins and critical minerals as well as have an impaired gut microbiome. These are likely to impact on both physical and mental health. For example, reduced physical activity in patients with cardiovascular diseases may exacerbate depressive symptoms [4], while anxiety-related eating disorders (eg, binge eating) may further worsen metabolic dysfunction.
4. Side effects and drug-drug interactions of medications can occur during treatment. Some medications for chronic physical illnesses may have side effects that impact normal brain function and behavior (eg, appetite). Similarly, some medications for mental disorders may increase the risk of developing certain chronic physical illnesses. As people develop more comorbid conditions, their range of prescribed drugs increase, thus increasing the risk of even more comorbidity; for example, antipsychotic medications (eg, olanzapine) may indirectly increase the risk of diabetes through metabolic syndrome [3].

Thus, the mechanism of comorbidity between chronic physical illnesses and mental disorders is highly complex and more research is warranted to understand and identify the underlying associations. This will only be successful through research approaches that are holistic and consider biological, genetic, sociological, psychological, and environmental aspects that could interact to drive the loss of health and the pathways to multimorbidity.

The relationship between well-being and emotional status and physical health, and vice versa, is an important source of inspiration for the study of comorbid mechanisms of chronic physical illnesses and mental health disorders. In traditional Chinese medicine (TCM), emotional status is closely related to human health. For example, TCM emphasizes the impact of "emotional injuries" on organ function, such as "anger injuring the liver" or "worry injuring the spleen." In this study, the high comorbidity between "gastrointestinal diseases and neurotic stress disorders" (RR=1.821) aligns with the TCM theory of "liver qi stagnation and spleen deficiency," where prolonged anxiety (liver qi stagnation) leads to digestive dysfunction (spleen deficiency). Furthermore, TCM's holistic approach supports the bidirectional interaction between chronic physical and emotional conditions. For instance, in patients with diabetes, the "dual deficiency of qi and yin" may exacerbate depressive symptoms. An adverse emotional state can negatively affect physical health and function, leading to the development of comorbidity of both chronic physical illnesses and mental health disorders. The rigorous compartmentalization of Western medicine has led to great progress being made through specialization. However, it is perhaps only now fully realizing that taking a more holistic approach that considers the integration and interaction of all biological, behavioral, and environmental components is a sensible approach to take in parallel. This has already started to reveal great benefits in systems biology, where the interactions between genes, proteins, metabolites, and external/environmental factors hold the key to a full appreciation of how health and illness relate to each other.

Age and Gender Differences in Comorbidities

Comorbidity of chronic physical illnesses with mental health disorders affects people of all ages, including hospitalized children and adolescents (age ≤18 years). Consistent with previous studies, we found that the association between chronic physical illness and mental health disorders varied across age-sex patient groups [16,31,32]. In our study, although the same combinations of comorbidities were present in different age-sex patient groups (eg, esophagus, stomach, and duodenum diseases with neurotic stress–related and somatoform diseases), the differences between the individual patient groups were notable.

XSL•FO
RenderX

Several combinations of disorders exhibited high comorbidity intensities specific to certain patient populations, such as dyslipidemia and schizophrenia with delusional diseases; esophagus, stomach, and duodenum diseases with organic mental disorders; prostate diseases with neurotic stress–related and somatoform disorders; and heart failure with neurotic stress–related and somatoform disorders. Our findings emphasize the importance of attention to the co-prevention of specific mental disorders with chronic physical illnesses in specific age groups, particularly in the male population aged 45‐60 years. For example, for male patients with cardiovascular disease aged 45‐60 years, it is recommended to conduct annual Patient Health Questionnaire-9 depression screenings in conjunction with the Framingham risk score to assess comorbidity risk. Alternatively, community hospitals could promote "dual heart medicine" outpatient clinics, which simultaneously manage both cardiovascular disease and anxiety/depression.

Strengths and Limitations

The primary strengths of this study can be summarized as follows. First, this study provides an inaugural regional investigation that evaluates comorbidity between chronic physical illnesses and mental health disorders by analyzing patient longitudinal electronic medical records. The study pinpoints a number of chronic physical illnesses with an elevated risk of association with mental health disorders and scrutinizes patterns of comorbidity, including variations by age and gender. Furthermore, this method places a strong emphasis on considering temporal dependencies of disease onset by using ML classification models. This allows us to gain a comprehensive understanding of the relationships between various chronic physical illnesses and mental health disorders in patients before they are diagnosed with a mental illness. Importantly, our approach is not limited to specific studies, but can be extended to other health care datasets to analyze comorbidity patterns.

By applying this method to diverse datasets, we can broaden our understanding of the complex relationships between diseases. This provides a broader and deeper insight into medical research and clinical practice.

This study has several limitations. First, a primary limitation is the unavailability of individual-level socioeconomic status, lifestyle factors, clinical data, and treatment information, all of which are crucial in fully comprehending distinctions between comorbidities. Second, since the recording of diseases in clinical data may lead to incomplete diagnoses, this study used "real-world" medical care data. The quality of disease coding lies beyond our control, and variations in recording among physicians and at different time points may result in missing or inaccurate information. Third, we only included diseases with a prevalence of ≥1% within this group, and the patients examined were primarily from a regional group in China, constituting a singular data source. The specific comorbidities and risk analyses necessitate further clinical validation.

To address the discussed limitations, our future research will collaborate with community health service centers to obtain data on patients' education levels, income, and insurance types, and construct a multisource database (eg, electronic health records combined with social service registrations). Additionally, to address the varying quality of diagnostic codes, we plan to improve data reliability through multicenter clinical audits (eg, random sampling of 10% of cases for review by specialist physicians).

Comparison With Prior Work

This study builds on existing research while providing new insights into the comorbidity between chronic physical illnesses and mental health disorders. In comparison to previous studies, the key similarities and differences are as follows.

Our study findings show a high degree of consistency with those from Western population studies, for example, the comorbidity patterns observed between cardiovascular diseases (such as hypertension and heart failure) and mental health disorders are consistent with those reported in the UK cohort by Launders et al [1]. This alignment enhances the generalizability of our findings across different populations. At the same time, our findings resonate with previous research in China. The dietary habits of the Chinese population (eg, high salt intake) and sociopsychological stress may exacerbate the interaction between metabolic diseases (eg, diabetes) and mental health disorders, as noted by Chen et al [22]. This also supports the 4 potential mechanisms we proposed.

Additionally, we identified some unique findings, such as a strong association between prostate disease and organic mental disorders (RR=2.055), which is less commonly observed in Western studies. This finding may reflect the distinct disease burden in China's aging male population, offering a new perspective on comorbidity issues in this demographic.

Conclusions

In this paper, we presented a regional study in Southern China focusing on the comorbidity and risk association between chronic physical illnesses and mental health disorders. We modeled patients' disease trajectories and analyzed the risk of comorbidity between mental health disorders and chronic physical illnesses. Through ML-based predictive modeling, we evaluated chronic physical illnesses that exhibited a higher risk of comorbidity with mental disorders. Additionally, we analyzed the risk of comorbidities, considering age and gender differences in comorbidity patterns. The findings revealed that in the male patient population aged 45‐60 years, there was a stronger interaction and higher risk of comorbidities between chronic physical illnesses and mental health disorders. Our research findings support the need for implementing "tailored" disease prevention and management measures based on patient age and gender in clinical prevention and care management. Our study particularly highlights the significance of age and gender in comorbidity research between chronic physical illnesses and mental disorders in a Chinese population.

Data Availability

Due to ethical limitations and the potential risk of exposing patient privacy, the dataset used for this study has not been fully disclosed. The author can be contacted for any needs, and all relevant data can be provided upon request and after appropriate ethical review. The processed, anonymized data are provided with the article. The key algorithms have been described in the literature.

Authors' Contributions

LL organized and cleaned disease diagnosis datasets, conceptualized and designed work, and drafted the manuscript. TL performed the literature investigation, experiments and data analysis, and writing. WO contributed to the analysis of experimental results and writing. YP contributed to the research methods, results analysis, and writing. CC designed the research and improved the methods and manuscript. YL reviewed drafts of the paper and drafted and improved the manuscript. All authors have revised and approved the final manuscript.

YL is co-corresponding author and can be reached out at luyao23@mail.sysu.edu.cn

Abstract

Background: Magnetic resonance imaging (MRI) reports are challenging for patients to interpret and may subject patients to unnecessary anxiety. The advent of advanced artificial intelligence (AI) large language models (LLMs), such as GPT-4o, hold promise for translating complex medical information into layman terms.

Objective: This paper aims to evaluate the accuracy, helpfulness, and readability of GPT-4o in explaining MRI reports of patients with thoracolumbar fractures.

Methods: MRI reports of 20 patients presenting with thoracic or lumbar vertebral body fractures were obtained. GPT-4o was prompted to explain the MRI report in layman's terms. The generated explanations were then presented to 7 board-certified spine surgeons for evaluation on the reports' helpfulness and accuracy. The MRI report text and GPT-4o explanations were then analyzed to grade the readability of the texts using the Flesch Readability Ease Score (FRES) and Flesch-Kincaid Grade Level (FKGL) Scale.

Results: The layman explanations provided by GPT-4o were found to be helpful by all surgeons in 17 cases, with 6 of 7 surgeons finding the information helpful in the remaining 3 cases. ChatGPT-generated layman reports were rated as "accurate" by all 7 surgeons in 11/20 cases (55%). In an additional 5/20 cases (25%), 6 out of 7 surgeons agreed on their accuracy. In the remaining 4/20 cases (20%), accuracy ratings varied, with 4 or 5 surgeons considering them accurate. Review of surgeon feedback on inaccuracies revealed that the radiology reports were often insufficiently detailed. The mean FRES score of the MRI reports was significantly lower than the GPT-4o explanations (32.15, SD 15.89 vs 53.9, SD 7.86; $P<.001$). The mean FKGL score of the MRI reports trended higher compared to the GPT-4o explanations (11th-12th grade vs 10th-11th grade level; $P=.11$).

Conclusions: Overall helpfulness and readability ratings for AI-generated summaries of MRI reports were high, with few inaccuracies recorded. This study demonstrates the potential of GPT-4o to serve as a valuable tool for enhancing patient comprehension of MRI report findings.

KEYWORDS

ChatGPT; AI; artificial intelligence; LLM; large language model; patient education; orthopedic surgery; MRI; magnetic resonance imaging; thoracolumbar fracture; spine surgery; trauma

Introduction

The 21st Century Cures Act has recently mandated that medical imaging exam results be made immediately available to patients after the radiologist report is finalized [1]. In many situations, patients will review their imaging reports without guidance from a medical professional, leading to confusion and anxiety [2]. Ideally, an ordering physician would be able to review the imaging results with their patients in a timely fashion, but this is often not the case. There is, therefore, a need for patients to be able to more easily and efficiently interpret the text of their imaging reports.

As large language models (LLMs) rapidly become more sophisticated and powerful, the premise of using artificial intelligence (AI)–generated summaries of imaging reports as a tool that may assist clinicians in improving communication with patients has been gaining support. Recent analyses of ChatGPT-4o (OpenAI) have demonstrated its effectiveness and

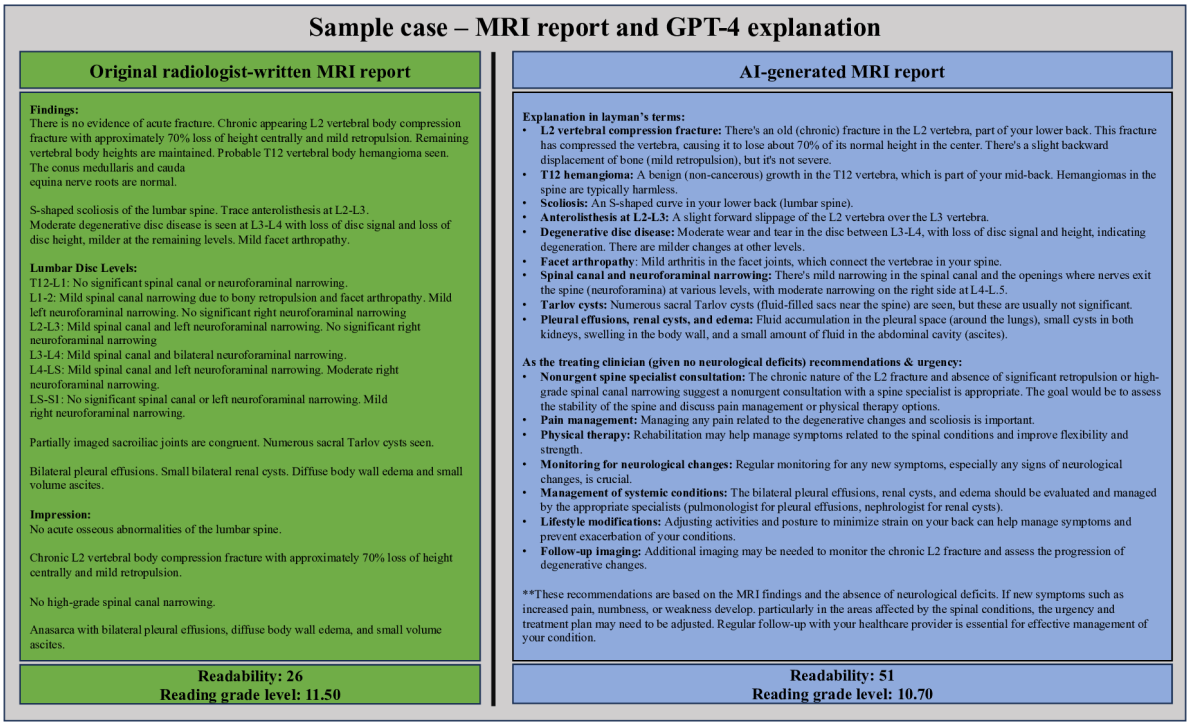
XSL•FO
RenderX

accuracy in summarizing diagnostic radiology reports, with the ability to translate medical terminology to an 8th-grade reading level [3]. When prompted to explain medical imaging reports to a child using simplified and basic language, ChatGPT-4o generated 15 different reports, which were evaluated by 15 radiologists. The overall consensus was that the reports were factually correct, complete, and did not pose any harm for misinformation [4].

Management of thoracolumbar fractures is a particularly challenging aspect of patient care for spine surgeons. Regional variation in treatment approach methodology contributes to a larger widespread inconsistency in the standard of care [5,6]. Therefore, management of vertebral body fractures is heavily influenced by an individual surgeon's experience and comfort level. The heterogeneity of spinal fracture morphology also results in more complex terminology in magnetic resonance imaging (MRI) reports.

Recent analyses have demonstrated that high quality educational content is available for patients, offering appropriate counseling on osteoporosis and bone health, diagnosing and treating cervical radiculopathy, as well as answering commonly asked questions about spinal cord injury [7-9]. However, thus far, no reports have been published on the accuracy and helpfulness of ChatGPT-generated explanations of spinal trauma MRI reports, specifically thoracolumbar fractures, in the emergency department. Therefore, the objective of our study was to evaluate the readability of ChatGPT-generated layperson summaries of radiology reports for 20 patient cases of thoracolumbar fractures. We hypothesized that ChatGPT-generated summaries would help provide clearer and more understandable MRI report findings that contain accurate explanations of imaging findings without any "hallucinated" or fabricated content—a flaw observed in earlier LLM versions where the AI program would often invent facts or cite nonexistent literature without clearly acknowledging the fabricated content.

Methods



Study Design

Searching our institutional Picture Archiving and Communications System (PACS), we identified 20 patients who presented to the emergency department at a level 1 trauma center and underwent MRI for evaluation of an acute thoracolumbar vertebral body fracture. Each patient was evaluated urgently through consultation with 1 of 7 board-certified spine surgeons providing on-call coverage. These 20 consecutive encounters all occurred between 2023 and 2024. A total of 20 patient cases were chosen in order to sufficiently include a variety of different clinical scenarios with varying types of fracture morphology and severity. MRI was chosen in favor of other imaging modalities as MRI reports are generally more challenging to interpret, as they often contain varying complex descriptors of combined ligamentous and bony injuries, making each case unique and nuanced. Reports were deidentified by excluding the patient's name, date of study, and radiologist's name from the reports. These deidentified reports were then submitted to ChatGPT-4o with the prompt, "Explain in layman terms with as much detail as possible." This prompt was selected over others, as it concise, yet specific with regards to the desired output as a patient education tool (see Figure 1).

The GPT-4o–generated layman summaries of the MRI reports were formatted into an electronic survey for evaluation by the same 7 on-call board-certified spine surgeons at the level 1 trauma center emergency department. The surgeons were asked to grade each prompt as "helpful" or "not helpful" and "accurate" or "not accurate." Descriptive statistics were used to summarize surgeon ratings of helpfulness and accuracy, with results reported as frequencies and percentages.

XSL•FO
RenderX

Figure 1. This diagram showcases how deidentified magnetic resonance imaging (MRI) reports were processed through ChatGPT-4o with a prompt that asked to explain the imaging findings in layman's terms for patient education purposes. The MRI report completed by the radiologist can be seen on the left in green, while a GPT-4o–generated, simplified version of the MRI report can be seen on the right in blue. Readability scores (Flesch Readability Ease Score) and reading grade levels (Flesch-Kincaid Grade Level) were determined for each version of the MRI report. AI: artificial intelligence.

Statistical Analysis

Readability of the original MRI report written by the radiologist, as well as the GPT-4o layman report, was analyzed using an internet-based readability scoring system [10]. The first measure of readability calculated was the Flesch Reading Ease Score (FRES; 1 to 100, with 100 being the highest readability score; see Equation 1). The second measure of readability assessed was the Flesch-Kincaid Grade Level (FKGL) scale (approximating the reading grade level of a text; see Equation 2). Readability scores were then statistically analyzed using a paired *t* test to compare readability scores between the original MRI reports written by the radiologist and GPT-4o–generated layman explanations in order to assess whether there was a significant difference in FRES and FKGL scores. Paired *t* tests were performed on the exact FKGL and FKRE values (not ranges) to assess statistical significance. A *P* value of<.05 was considered statistically significant.

$$(1) 206.835 - 1.015(\text{total words}/\text{total sentences}) - 84.6(\text{total syllables}/\text{total words})$$

$$(2) 0.39(\text{total words}/\text{total sentences}) + 11.8(\text{total syllables}/\text{total words}) - 15.59$$

In addition, interrater reliability among the 7 surgeons evaluating MRI reports was assessed using Cohen kappa statistic in an effort to quantify agreement beyond chance.

Ethical Considerations

The Scripps Health Institutional Review Board approved this study with a waiver for deidentified use of patient records. This study was conducted in accordance with the ethical standards of the Declaration of Helsinki and was approved by the Department of Orthopaedic Surgery at Scripps Health and the San Diego Spine Foundation.

Results

Surgeon Evaluation of Helpfulness and Accuracy

A total of 20 noncontrast MRI reports of the lumbar spine were included in this study. In total, 17 of the 20 layman reports (85%) were unanimously determined to be "helpful" by all 7 surgeons, while the remaining 3 reports were considered "helpful" by 6 of the 7 surgeons (see Table 1). In terms of accuracy, surgeons unanimously rated 11 of the 20 layman reports (55%) as "accurate." An additional 5 reports (25%) were rated as "accurate" by 6 of 7 surgeons, while the remaining 4 reports (20%) received mixed ratings, with 4 or 5 surgeons agreeing on their accuracy. Notably, however, at least half of all surgeons surveyed rated every layman MRI report as "accurate." In the 4 cases where only 2 or 3 surgeons rated the layman reports as "inaccurate," the original radiology reports lacked sufficient detail (see Table 2). In these instances, surgeons indicated they would prefer to personally review the imaging studies before determining the accuracy of the explanations. Interrater reliability was high among surgeons (κ=0.80), as well as between surgeon consensus and GPT-4o (κ=0.90).

XSL•FO
RenderX

Table . Surgeon ratings of helpfulness for GPT-4o layman reports.

Helpfulness rating	Reports, n	Surgeon agreement, n/N	Percentage
Unanimously helpful	17	7/7	85
Majority considered helpful	3	6/7	15

Table . Surgeon ratings of accuracy for GPT-4o layman reports.

Accuracy rating	Cases (N=20), n (%)
All 7 surgeons agreed (accurate)	11 (55)
6 of 7 surgeons agreed (accurate)	5 (25)
4 or 5 of 7 surgeons agreed (mixed ratings)	4 (20)

FKGL and FRES Readability Analysis

The readability of the MRI reports and their GPT-4-generated layman explanations was evaluated using the FRES and FKGL metrics.

The MRI reports had FRES scores ranging from 7 to 61, with a mean of 32.15 (SD 15.89), indicating that the text was classified as “difficult to read” by standard readability metrics (see Table 3). In contrast, the GPT-4 explanations had FRES scores ranging from 40 to 72, with a mean of 53.9 (SD 7.86), demonstrating a substantial improvement in readability. The average increase in FRES score between the original MRI report and GPT-4o report was +21.75 points, which was statistically significant (P<.001). This result confirms that GPT-4 effectively enhanced the readability of MRI report findings, making them considerably easier for patients to understand.

Table . Reading ease and reading grade scoring comparing magnetic resonance imaging (MRI) reports and GPT-4o explanations.

Case	FRES[a] score			FKGL[b] score		
	Original MRI report	GPT-4o report	Difference	Original MRI report	GPT-4o report	Difference
Case 1	29	55	26	11.63	10.58	−1.05
Case 2	19	72	53	13.61	7.62	−5.99
Case 3	15	56	41	13.72	11.26	−2.46
Case 4	59	68	9	8.43	8.93	0.5
Case 5	36	52	16	11.42	11.44	0.02
Case 6	39	56	17	9.48	10	0.52
Case 7	24	57	33	13.19	9.44	−3.75
Case 8	7	55	48	14.76	9.97	−4.79
Case 9	26	59	33	12.55	9.61	−2.94
Case 10	61	58	−3	9.02	10.8	1.78
Case 11	45	40	−5	8.90	12.2	3.3
Case 12	8	40	32	15.55	13.02	−2.53
Case 13	46	46	0	10.54	12.56	2.02
Case 14	20	53	33	13.32	11.44	−1.88
Case 15	46	56	10	9.67	10.36	0.69
Case 16	32	46	14	11.28	10.77	−0.51
Case 17	20	45	25	13.5	11.95	−1.55
Case 18	26	53	27	10.92	10.70	−0.22
Case 19	59	60	1	8.43	10.16	1.73
Case 20	26	51	25	11.45	10.69	−0.76

[a]FRES: Flesch Reading Ease Score; scale of 1 to 100, with 100 being the highest readability score.

[b]FKGL: Flesch-Kincaid Grade Level; assess the approximate reading grade level of a text.

XSL•FO
RenderX

The original MRI reports had an FKGL score ranging from 8.43 to 15.55, with a mean of 11.57 (SD 2.10), indicating that a high school to early college-level reading proficiency was required for full comprehension (see Table 3). In comparison, the GPT-4o–generated explanations had FKGL scores ranging from 7.62 to 13.02, with a mean of 10.67 (SD 1.24), representing a reduction in the required reading level for full comprehension. On average, the GPT-4o summaries lowered the FKGL score by 0.89 grade levels; however, this reduction did not reach statistical significance (P=.11). This suggests that while GPT-4o was effective in simplifying the reports as seen by the significant improvement in FKRE scores, some medical complexity still remained, as seen by the nonsignificant improvement in FKGL scores. This could still pose comprehension challenges for patients with lower health literacy.

Incidental Findings

8 out of 20 MRI reports (40%) reported incidental findings unrelated to spinal trauma in the MRI report. These findings included hemangiomas, renal cysts, thick-walled esophagus, epidural lipomatosis, bile duct ectasia, perineural root sleeve cysts, dorsal epidural lipomatosis, and Tarlov cysts. These incidental findings were all appropriately comprehended by LLM and explained in the GPT-4o–generated report to be likely benign, with recommendation for monitoring with follow-up.

Discussion

Principal Findings

This study demonstrates that AI, specifically GPT-4o, has the immense potential to produce accurate and helpful explanations that improve patient comprehension of MRI report findings. All 7 board-certified spine surgeons surveyed in this study reached consensus that the tool was both useful and lacked any major inaccuracies. Only 3 GPT-4o–generated reports contained potential inaccuracies, but this was determined to be due to a lack of detail in the original radiologist-written report. Furthermore, incidental findings that often cause anxiety, including common benign tumors such as hemangiomas or renal cysts, were accurately explained by GPT-4o to be unrelated to the present injury and likely benign, with recommendation for appropriate follow-up.

The improvements seen in FRES scores suggest that GPT-4o–generated explanations significantly enhance text clarity and patient accessibility. The lack of statistical significance in FKGL score reduction suggests that while GPT-4o lowers the reading grade level, some complex medical terminology and sentence structure remains–addressing this gap will require further refinement of LLMs for optimal patient comprehension. Given that MRI reports are often written at a high school or college reading level, the ability of GPT-4o to improve readability while maintaining accuracy is particularly relevant for patient education. Patients with lower health literacy may benefit from structured AI-generated summaries, potentially reducing anxiety and misunderstandings regarding their diagnosis. However, given the residual complexity in some explanations provided by GPT-4o, integrating human oversight in AI-assisted patient education remains crucial until further improvement in LLMs is seen in the future.

Addressing the Communication Gap in Medical Imaging

While medical imaging is often relied upon significantly in the decision-making process for cases that may require surgery, the complexity of the reports, which are now mandated to be made immediately available to the patient, can cause undue stress to patients who lack the means to interpret unfamiliar medical jargon [11,12]. These MRI studies are also commonly ordered by primary care and emergency department providers, who often rely on spine surgeon consultation to educate patients. The value of a resource like GPT-4o lies primarily in bridging the communication gap between spine surgeons, other members of the patient care team, and the patient [13]. For example, surgeons may often be unavailable or delayed when a patient or an emergency department clinician seeks help reviewing a study. Incorporating GPT-4o generated MRI reports, in these situations, can allow for more efficient and precise care, which results in better patient-reported outcomes in the long term. Although further input from surgeons is necessary before formal adoption, it is conceivable that nurses, physician assistants, and emergency department providers may be able to enhance their understanding and interpretation of MRI report findings with the use of GPT-4o–generated reports, allowing them to counsel patients with confidence and prevent them from making detrimental clinical decisions for patients.

Existing Literature in This Field

While ChatGPT's use as a patient education tool has been examined in previous studies, limited literature exists on application of LLMs like ChatGPT in summarizing radiology reports [14,15]. Other assessments of ChatGPT in deciphering MRI reports of knee and shoulder injuries demonstrated similar usefulness and relevant explanations [16]. A review of ChatGPT-generated explanations of 20 MRI shoulder, 20 MRI knee, and 20 MRI lumbar spine reports showed high overall ratings for accuracy and completeness, as only 3 explanations out of the 60 reviewed reports were deemed confusing or inaccurate [17]. ChatGPT also performed well in explaining chest CT and brain MRI reports, as Lyu et al. concluded that the AI-generated explanations efficiently and effectively translated complex information into plain language without direct involvement from a human expert [18].

Limitations

A so-called "hallucination" refers to any AI-generated output that contains completely fabricated content that is both factually incorrect and unrelated to content from the original MRI report written by the Radiologist. In agreement with many other previous studies cited above, our research found no "hallucinations." This may be due to our use of intentionally crafted, highly specific prompts. Nonetheless, the possibility of an LLM generating inaccurate information is certainly plausible, though it was overwhelmingly rare in this specific use case, with no instances of gross inaccuracy or fabrication found in our study. For this reason, GPT-4o has the potential to be used as a supplementary resource with oversight and contextual judgment by clinicians at this point in time. Other limitations include the diversity of possible end-users who are tasked with interpreting reports. Though the output was reviewed

XSL•FO
RenderX

by spine surgeons in this study, Radiologists and emergency department clinicians would also need to feel comfortable with the appropriateness and accuracy of the tool. Further interdisciplinary surveys to examine their assessment of the GPT-4o–generated reports would be valuable in addition to this study. Ultimately, the surgeon, along with any end-users who make clinical decisions based on MRI studies, should oversee the appropriate use of ChatGPT-generated layman explanations. There may be unforeseen risks with regards to providing inadequate clinical care or counseling without surgeon oversight, especially in the emergency department setting where patients may present with life-altering injuries. Further limitations include a limited sample size of 20 cases with a narrow, focused cohort of patients presenting with thoracolumbar fractures only. Counseling for incidental findings often recommended specialist visits; however, these cases would be more appropriately addressed with an initial evaluation by a primary care provider first.

Expanding Capabilities: Multimodal and Multilingual Applications

Although these limitations affect the current clinical usage of LLMs, ongoing advancements in their development continue to expand their potential in the medical sphere. Recent progress has demonstrated that LLMs can now analyze digital images alongside text, further enhancing their applicability in medical imaging analysis and presentation to patients. This multimodal capacity will enhance the usability of ChatGPT as a patient education tool. In the future, image recognition and analysis capabilities may allow ChatGPT to conduct its own analysis of imaging studies, and complementing or correlating to the radiologist's report. Significant advances have been demonstrated with foreign language translation, additionally aiding non-English speaking patients with high accuracy, consistency, fluency, and contextual awareness in translating text [19]. This feature would allow GPT-4o and even more advanced version of the model to analyze radiology reports that are currently being outsourced to Radiologists to read in different countries, and provide accurately translated layman reports for patients to read almost instantaneously. As LLMs continue to improve, the translation of medical jargon to layman's terms will inevitably become increasingly accurate and effective.

Addressing the Inherent Variability of Radiology Reports

A persistent limitation for AI-generated explanations, specifically in the medical field and radiology space, has been the inherent variability and occasional insufficiency of details in radiology reports [20]. As reported in this study, spine surgeons at times noted the lack of detail in ChatGPT-generated reports and cited this topic as an issue that needs to be addressed. The problem of insufficient data in reports will always be a limiting factor, as more or less detail may be required in certain reports based on the patient's particular unique presentation. Improving AI accuracy may require mimicking how clinicians approach image review, incorporating both pattern recognition and contextual judgment rather than relying only on textual descriptions written in reports [21]. Developing AI models that align more closely with how doctors synthesize image findings with clinical context could enhance the accuracy and usefulness in real-world applications.

Future Directions, Considerations, and Implications

A potential next step to enhance accuracy would be fine-tuning or retraining the model on a larger dataset of past radiology reports and corresponding expert-reviewed layperson explanations. This would allow the LLM to recognize complex fracture patterns from a particular report more reliably and improve consistency in terminology use [22]. In addition, integrating contextual memory, whereby the model retains past patient-specific information across reports, could improve continuity and personalization in explanations. Future research should be centered around using specialized medical fine-tuning techniques and human-in-the-loop verification to optimize AI-generated patient education tools [23]. Improvements in AI-generated patient education tools should focus on model retraining with expert annotated datasets to enhance accuracy and consistency. Furthermore, implemented adaptive learning mechanisms–where the AI refines its outputs based on clinician feedback–could further improve the reliability of the reports generated.

From a clinical perspective, a significant predictor of fracture instability is the competency of the posterior ligamentous complex (PLC), which is often not described in radiology reports [24]. Despite GPT-4o having an incomplete description of the fracture pattern, it was still able to describe and make the right interpretation from what was included in Radiologist's report without making inaccurate assumptions. It is well known that LLMs like ChatGPT have intrinsic biases based on the initial training data used to create the model [25]. Reproducing of the quality or accuracy of the reports in future analyses may be difficult to achieve as prompting the LLM with the same prompt may result in different, but semantically similar responses. Metastatic or infection-related fractures were deemed outside the scope of this study, as interpretation of MRI reports describing less frequently occurring "edge cases" may also require future in-depth analysis. From an ethical standpoint, the sharing deidentified patient information with ChatGPT or other AI programs may also raise ethical concerns that could hinder future improvement and optimization of LLM capabilities.

Despite these challenges, all 7 on-call spine surgeons all acknowledged the significant potential of ChatGPT to enable patient-centered care by providing simplified and more comprehensible explanations of advanced imaging reports. Patients are often discharged from the emergency department without complete understanding on the extent of their injury or whether or not they may need surgery [26]. When patients are instructed to follow-up with a spine surgeon, they often feel stress and anxiety, as the consultation may imply the need for surgical intervention [27]. In situations where surgical treatment of thoracolumbar fractures involves shared decision-making with the patient, providing layman explanations can offer additional context, helping patients better prepare for surgical discussions and be more active participants in the clinical-decision making process. There may eventually be a

XSL•FO
RenderX

role for ChatGPT to assess MRI reports and determine the urgency of clinical follow-up with a spine surgeon.

In contrast, there are considerable downsides for patients who may become overconfident in using ChatGPT and ultimately make poorly informed clinical decisions on their own without an expert opinion. Thus, smooth integration of LLMs, like GPT-4o, into the existing clinical infrastructure would be ideal, rather than having patients use it on their own offline and outside of their electronic health record. For example, automated layman explanations could be sent along with the original MRI report when it is released to the patient in their medical portal. In this scenario, ideally both the Radiologist and the spine surgeon would have the opportunity to proofread the ChatGPT-generated layman explanations before the reports are released to the patient, allowing patients to have an easy to understand report that has been approved by a specialized healthcare provider.

Conclusions

While further quantitative studies are necessary, the initial insights from this study demonstrate that ChatGPT-generated layman explanations of MRI reports for thoracolumbar spine trauma are both accurate and helpful. Patient self-directed internet research often leads to clinicians having to spend extra time correcting misconceptions about their conditions. However, more structured prompting of modern LLMs, such as ChatGPT, can improve patients' understanding of medical terminology and their conditions in an efficient and easily accessible manner. As AI tools continue to advance, surgeon oversight and evaluation will become increasingly necessary to safely integrate generative AI assistance into patient care.

Data Availability

The data that support the findings of this study are available from the corresponding author upon reasonable request and with permission from Scripps Health and the San Diego Spine Foundation.

Authors' Contributions

DCS, PHY, AB, SRS, RKE, and GMM Jr conceived of the project idea and designed the study. DCS, KSS, MP, CV, AB, SRS, RKE, and GMM Jr performed the data collection and executed the study. DCS and KSS performed the analytic calculations and analyses once the data were collected. All authors discussed the results and agreed on final conclusions and takeaways from the study. DCS and KSS wrote the final manuscript and generated all tables and figures.

Abstract

Background: People who use drugs (PWUD) are at heightened risk of severe injection–related infections. Current research relies on billing codes to identify PWUD—a methodology with suboptimal accuracy that may underestimate the economic, racial, and ethnic diversity of hospitalized PWUD.

Objective: The goal of this study is to examine the impact of natural language processing (NLP) on enhancing identification of PWUD in electronic medical records, with a specific focus on determining improved systems of identifying populations who may previously been missed, including people who have low income or those from racially and ethnically minoritized populations.

Methods: Health informatics specialists assisted in querying a cohort of likely PWUD hospital admissions at Tufts Medical Center between 2020 - 2022 using the following criteria: (1) *ICD-10* codes indicative of drug use, (2) positive drug toxicology results, (3) prescriptions for medications for opioid use disorder, and (4) applying NLP-detected presence of "token" keywords in the electronic medical records likely indicative of the patient being a PWUD. Hospital admissions were split into two groups: highly documented (all four criteria present) and minimally documented (NLP-only). These groups were examined to assess the impact of race, ethnicity, and social vulnerability index. With chart review as the "gold standard," the positive predictive value was calculated.

Results: The cohort included 4548 hospitalization admissions, with broad heterogeneity in how people entered the cohort and subcohorts; a total of 288 hospital admissions entered the cohort through NLP token presence alone. NLP demonstrated a 54% positive predictive value, outperforming biomarkers, prescription for medications for opioid use disorder, and *ICD* codes in identifying hospitalizations of PWUD. Additionally, NLP significantly enhanced these methods when integrated into the identification algorithm. The study also found that people from racially and ethnically minoritized communities and those with lower social vulnerability index were significantly more likely to have lower rates of PWUD-related documentation.

Conclusions: NLP proved effective in identifying hospitalizations of PWUD, surpassing traditional methods. While further refinement is needed, NLP shows promising potential in minimizing health care disparities.

Introduction

In the absence of harm reduction tools, people who use drugs (PWUD) are at increased risk of disease, hospitalization, and death [1-3]. Gaps in the provision of guideline-concordant care to hospitalized PWUD occur, especially among individuals from racially and ethnically minoritized communities [4-6]. Barriers to optimization of health care for hospitalized PWUD include undertreatment of pain and substance use disorders, which have been linked to discharges before medical optimization and higher rates of readmission and mortality [7-9]. Best practices for managing PWUD in a hospitalized setting include addiction care itself as well as treatment and prevention of life-threatening infections [10].

Effective identification of hospitalized PWUD is essential for epidemiological tracking, resource allocation, and evaluating interventions. However, current methodologies often fail to accurately capture this population. The "gold standard" for identifying PWUD hospitalizations is human-guided chart review, a highly regulated and time-intensive process with

XSL•FO
RenderX

potential consequences for breach of confidentiality [11,12]. Administrative billing codes (also known as International Classification of Disease codes, ICD codes) have been used for PWUD identification. Unlike several other common conditions such as cardiovascular diseases for which *ICD-10* codes are highly accurate [13,14], a systematic review found that for identification of PWUD, *ICD-9/10* codes had high specificity but limited sensitivity ranging from 47% - 83% [15,16]. Indicators for substance use tend to be noted in the social history section of the electronic medical record (EMR) rather than a formal diagnosis. Some researchers have used the hepatitis C virus (HCV) codes as a marker of drug use, although there are a substantial number of people with HCV who do not currently use drugs or have ever used drugs [16,17].

The barrier to identifying PWUD can potentially be addressed with natural language processing (NLP), to leverage artificial intelligence (AI) algorithms for interpretation of the written text in a context-relevant manner [18]. NLP has been effectively applied to medical examiners' reports to increase the accuracy of identifying substance use disorder-related deaths [19], identify substance use disorders in outpatients with HIV [20], and enhance preventive care for hospitalized patients with HIV [17]. In particular, regular expression (RegEx), a rule-based text-matching framework, has been used to identify text patterns [21]. RegEx has recently been used as a tool for identification of encounters with people with opioid use disorder (OUD) [22]. A few studies have examined the application of NLP to identify hospitalized PWUD admitted for bloodstream infections; however, these efforts were single-center evaluations, focused only on injection drug use [23-26]. Despite its innovative capacity to identify PWUD, the field of NLP methodology is nascent. The goal of this study was to evaluate the impact of NLP on the creation of a cohort of hospitalized PWUD and to evaluate disparities in documentation.

Methods

Definition of PWUD

As "drug use" is a broad term, it is worth emphasizing that "PWUD" in this study includes the use of cocaine, methamphetamine, fentanyl, and heroin. We use the term PWUD to describe people in the cohort, rather than "people who inject drugs"—another term used to describe this population—because these drugs can be consumed intravenously, smoked, or snorted. We do not use the term substance use disorder (SUD), as some PWUD do not meet diagnostic criteria for SUD and may not identify as having an SUD. Although drug use can also include cannabis and alcohol, we did not include these substances in the definition of drug use.

Overview of Cohort Creation

Tufts Medical Center (TuftsMC) is a tertiary health care center located in Boston, Massachusetts, with a strong history of clinician-researcher partnerships to improve care for PWUD [5,27,28]. A health informatics specialist (RM) queried hospitalizations likely involving PWUD at TuftsMC between January 1, 2020, and April 1, 2022, guided by specific criteria (see below). The unit of measurement was hospitalization encounters, not individual patients, even if from the same patients, which requires separate clinical considerations and presents a distinct opportunity for the implementation of evidence-based practices such as introducing medications for OUD.

The presence of any of the following criteria (ie, abbreviated with the letters B, D, M, and N) were used to qualify the hospitalizations for inclusion in the PWUD cohort:

- B (Biomarkers): In line with a previous study, positive urine toxicology for drugs or medications for SUD (eg, cocaine, amphetamine, methadone, suboxone, fentanyl, opiate, oxycodone), positive HCV antibody with positive or quantifiable HCV viral load [29]
- D (Diagnostic codes): Presence of *ICD-9* and or *ICD-10* code for overdose, substance use disorders, substance-related disorders, and Hepatitis C, considering historical diagnoses and those retained in EMRs and inactivated diagnoses that did not migrate with the transition
- M (Medications for opioid use disorder): Sublingual buprenorphine (suboxone or subutex) or oral methadone listed as medications in outpatient medication reconciliation, given during hospitalization, or prescribed at discharge. We noted that methadone for OUD is not a medication prescribed at discharge, but is included via discharge reconciliation [30].
- N (Natural language processing): An iterative list of keywords that are commonly used to describe PWUD in EMR (Table 1, Textbox 1) was refined by the study team and then provided to the health informatics specialists [31]. The RegEx patterns were used to identify keywords in the EMRs, accounting for misspellings and variations in context, with incorporation of tokenizing and parsing syntax, context embedding, and approximate string matching. These features enabled context-specific word detection that accounted for minor misspellings or aggregated words. The algorithm was run on the entire EMR, including but not limited to nursing notes, physician notes, discharge summaries, and emergency room records.

Table . List of *ICD-9/10* Codes for inclusion into PWUD cohort.

Parent code	Description
F11	Opioid-related disorders
F14	Cocaine-related disorder
F15	Other stimulant–related disorders
T400-T406; T436	Poisoning by opium, heroin, other opioids, methadone, synthetic narcotics, cocaine, unspecified narcotics and psychostimulants.
0.70.41, 070.44, 070.51, 070.54, 070.70, 070.71	Hepatitis C
B18.2	Chronic viral hepatitis C

Textbox 1. List of words programmed into NLP to detect PWUD encounters.

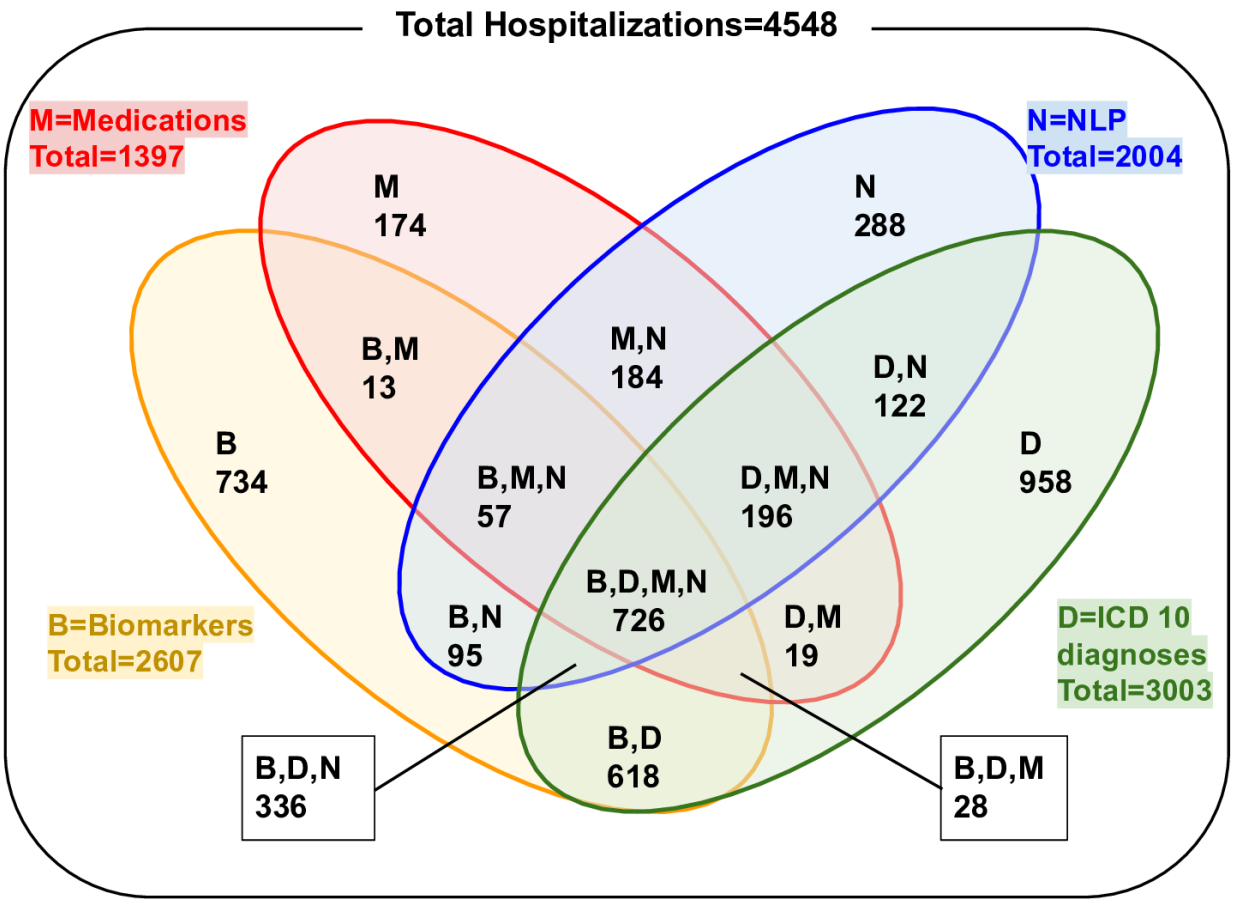
IVDU, FENTANYL, Methadone, heroin, suboxone, IVDA, drug abuse, SUD, Substance use disorder, opioid use disorder, opioid abuse, OUD, opioid overdose, illicit drugs, addicted, addict, drug addict, injection drug use, intravenous drug use, uses fentanyl, Uses heroin, PWID, abuses drugs, injects heroin, injects drugs, injects fentanyl.

In addition to the above data, each encounter also had linked demographics data (eg, age, race, ethnicity, gender), length of hospitalization, and social vulnerability index (SVI). The SVI is a tool developed by the Centers for Disease Control and Prevention, used to assess the community's susceptibility to disasters and emergencies; it uses 16 census-based data points to help assess local communities' need for aid before and after the disaster [32]. It evaluates factors such as socioeconomic status, disability, minority status, and areas that may need additional support during crises. It is a holistic way to represent the social and economic stability of neighborhoods. The SVI was provided as a quartile (eg, 1, 2, 3, 4), with 1 representing the highest level of social vulnerability. Using the Stata software (version; StataCorp), we examined the association between key indicators (ie, race and SVI) and the level of documentation for SUDs.

Data Analysis

Hospitalizations were classified based on the combination of domains (ie, B, D, M, N). A percentage of charges from the D-only and N-only group was selected for chart review by two research members (EDG, TS). The number of charts reviewed was determined by feasibility and proportion to the entire cohort. Coders reviewed each chart for information that indicated drug use (excluding alcohol and cannabis). The process for determining whether a hospitalization event occurred with PWUD included: (1) assessing three types of notes in each chart—emergency department admission note, history of present illness, and discharge summary and (2) using the Epic search bar—a tool that allows for keyword search within a person's EMR profile—for keywords (Textbox 1).. The coders conducted intercoder reliability testing after completing their first 20 chart reviews, which showed consistency. A logistic regression was performed to examine factors for drug use associated with high documentation, introduced into the cohort by the presence of all of the 4 domains (B, D, M, N) versus low documentation (NLP only).

Ethical Considerations



The study has been approved by the Health Sciences Institutional Review Board of the TuftsMC with waiver of consent granted (approval no. 2450). Identifiable data was only accessed by IRB approved study staff with approrpiate training. Identifiable data was stored on a secure file. As this was a retrospective study, there was no compensation provided to the cohort.

Results

The Venn diagram illustrates how 4548 hospitalizations involving PWUD entered the cohort based on inclusion criteria (Figure 1). The study participants' characteristics are shown in Table 2, along with results of the multivariable logistic regression. People who identified as White or non-Hispanic had higher odds of entering the cohort through NLP alone (adjusted odds ratio [aOR]=2.07; 95% CI 1.54, 2.79). Notably, individuals from the most socioeconomically disadvantaged quartiles (1st and 2nd SVI quartiles) were also significantly more likely to enter the cohort through NLP alone (aOR=1.41; 95% CI 1.06, 1.88). The subcohorts with the highest number of hospitalizations were those with ICD codes only (D-group, n=958), biomarkers only (B-group, n=734), and NLP with all four criteria (B, D, N, M group, n=726). Approximately 10% (n=93) individuals in the D-only group and 35% (n=99) in the N-only group underwent chart review. As shown in Table 3, the positive predictive value (PPV) of the NLP-only cohort was 54%, outperforming the diagnostic codes-only cohort, which had a PPV of 43%. This demonstrates NLP's ability to enhance identification of PWUD hospitalizations beyond traditional methods.

[b]ICD: International Classification of Disease codes.

[c]PWUD: people who use drugs.

Discussion

Our study augments previous work by integrating NLP with diverse identification methods, including urine toxicology and medication records, while simultaneously addressing observed demographic disparities in documentation [23]. NLP has the potential to uncover hospital encounters with PWUD that may have previously been missed. Although NLP had greater PPV than diagnostic codes, its PPV remained low. We found that PWUD from racially and ethnically minoritized communities and those who had low income were more likely to be represented in the minimally documented cohort (ie, entry with NLP-only), rather than the maximally documented cohort.

Largely a result of stigma and racism, PWUD still do not have universal access to evidence-based treatment. Black PWUD tend to enter treatment with a more severe prognosis compared to their White counterparts, partly due to economic barriers in accessing treatment earlier [33]. Black, Latino, and Native American individuals also face additional challenges in accessing treatment for SUD due to geographic barriers, health care access, and potential community characteristics or rapport with clinicians [34]. We found that such a lack of rapport may be represented at the level of documentation for SUD; lack of SUD documentation was strongly associated with racially or ethnically minoritized identity (aOR=2.07).

Identification of PWUD who access medical care is important for several reasons. Best practice guidelines for hospitalized PWUD include management of substance use disorder, pain, and acute infection, testing and management for HIV and HCV, vaccinations for hepatitis or other relevant infections, and prevention of HIV with medications [10,35]. In this study, we applied NLP retrospectively. Following previous studies that identified low HIV testing rates, we plan to use NLP to augment PWUD cohort creation in a study examining patterns of HIV testing [27,36]. NLP could indeed become a valuable tool for identifying PWUD before discharge, facilitating intervention during hospitalization if EMRs could use NLP to trigger clinical decision support tools that trigger clinicians to consider SUD treatment, prescribe overdose prevention medications at discharge, order labs to prepare for pre-exposure prophylaxis, or offer vaccine services.

As we consider this study in the larger context of improving health equity, we believe that the next step would be refining the NLP system by adding more keywords, including and excluding certain conditions and medications, and conducting analyses on false positives and false negative cases. This study should be replicated in other medical centers across the United States; its wider application across various hospitals, encapsulating diverse populations and regions, will be instrumental. This study also has multifaceted applications, spanning epidemiological tracking, optimizing hospital resource utilization, and influencing the design of specific interventional studies. This study's findings could serve as a launchpad for integrated care for PWUD with less prejudice and inequity. ReGex is a relatively fundamental AI technology, and as more advanced NLP tools become available, we envision our methodology being expanded alongside these too. Regardless of type and complexity of NLP technology, the cohorting and comparative analysis outlined in this paper can be used as a framework to assess the NLP's performance against conventional ways of locating PWUD.

This study is not without its limitations. The NLP system, despite its effectiveness, occasionally misidentifies certain keywords. The constant calibration of the algorithm and frequent addition of keywords is needed to optimize and sustain accuracy. There are potential flaws in our characterization of domains; limitations include false positives from using 'amphetamine' as a keyword, which unintentionally classified patients prescribed amphetamines for attention-deficit/hyperactivity disorder as PWUD. Similarly, methadone prescribed for pain management in conditions such as sickle cell disease was misclassified as OUD treatment. Achieving a balance between NLP's inclusivity and exclusivity presents a significant challenge for this purpose. Future steps should include evaluating the NLP system's sensitivity and specificity and iterating on the model to enhance these metrics. This will involve refining the keyword list for PWUD, enhancing the NLP algorithm to better account for common confounding variables. The field of addiction medicine is innovative and adaptive; to make NLP a meaningful clinical or research tool in this field, the NLP systems need to receive extensive training and constant input of nuanced decision-making that clinicians partake in daily. Thus, a feedback mechanism and fine-tuning to train the NLP model based on clinician feedback would be critical, fully leveraging repetitive learning, which is one of AI's biggest strengths. Furthermore, the single-cohort design of the study may limit generalizability; therefore, future studies with streamlined cross-institutional protocols, allowing simultaneous data collection from diverse locations, would improve external validity. This study had a particular focus on comparing diagnostic codes and NLP as single identifiers of PWUD. While NLP identified PWUD with higher PPV than the diagnostic codes, it must be noted that diagnostic criteria still exceeded NLP in the actual number of PWUD cases

XSL•FO
RenderX

identified. One major purpose of NLP in PWUD identification is to identify cases that are otherwise missed in conventional screenings; thus, the fact that NLP alone identified a comparable number of PWUD to diagnostic code, with a higher predictive rate, is still remarkable. Future investigation should include a more robust performance comparison between a combination of two or more PWUD clinical identification tools.

The ethics of improving identification of PWUD requires careful consideration. Medical records indicating drug use may become a source of discrimination, compromise job security, housing, and ability to care for family. To mitigate these risks, institutions should implement strict policies ensuring that NLP findings are used solely for improving patient care. Members of this research team collaborated with a broad group of experts including people with lived experience of SUD on a study outlining some of the potential pros and cons of improving systems to identify PWUD with the creation of an additional *ICD-10* code for injection drug use [37]. Future work should proactively incorporate the perspectives of individuals with lived experience of SUD. Furthermore, broader discussion regarding AI's role in health care is needed for effective, ethical, and productive clinical implementation: "Should NLP be a "wide net" or "precision tool" when locating PWUD and connecting them to the care they need?"

Despite these limitations, we believe that this study helps frame the future of systems for measuring health care delivery to PWUD. Hospitalization represents a crucial opportunity when nonjudgmental, trauma-informed, culturally competent care can be offered to PWUD. This presents many potential applications for NLP to be built into systems that track epidemiology and inform quality improvement and implementation science. By integrating NLP, we can advance equitable PWUD care.

Abstract

Background: Efficient allocation of health care resources is essential for long-term hospital operation. Effective intensive care unit (ICU) management is essential for alleviating the financial strain on health care systems. Accurate prediction of length-of-stay in ICUs is vital for optimizing capacity planning and resource allocation, with the challenge of achieving early, real-time predictions.

Objective: This study aimed to develop a predictive model, namely wavelet long short-term memory model (WT-LSTM), for ICU length-of-stay using only real-time vital sign data. The model is designed for urgent care settings where demographic and historical patient data or laboratory results may be unavailable; the model leverages real-time inputs to deliver early and accurate ICU length-of-stay predictions.

Methods: The proposed model integrates discrete wavelet transformation and long short-term memory (LSTM) neural networks to filter noise from patients' vital sign series and improve length-of-stay prediction accuracy. Model performance was evaluated using the electronic ICU database, focusing on 10 common ICU admission diagnoses in the database.

Results: The results demonstrate that WT-LSTM consistently outperforms baseline models, including linear regression, LSTM, and bidirectional long short-term memory, in predicting ICU length-of-stay using vital sign data, achieving significant improvements in mean square error. Specifically, the wavelet transformation component of the model enhances the overall performance of WT-LSTM. Removing this component results in an average decrease of 3.3% in mean square error; such a phenomenon is particularly pronounced in specific patient cohorts. The model's adaptability is highlighted through real-time predictions using only 3-hour, 6-hour, 12-hour, and 24-hour input data. Using only 3 hours of input data, the WT-LSTM model delivers competitive results across the 10 most common ICU admission diagnoses, often outperforming Acute Physiology and Chronic Health Evaluation IV, the leading ICU outcome prediction system currently implemented in clinical practice. WT-LSTM effectively captures patterns from vital signs recorded during the initial hours of a patient's ICU stay, making it a promising tool for early prediction and resource optimization in the ICU.

Conclusions: Our proposed WT-LSTM model, based on real-time vital sign data, offers a promising solution for ICU length-of-stay prediction. Its high accuracy and early prediction capabilities hold significant potential for enhancing clinical practice, optimizing resource allocation, and supporting critical clinical and administrative decisions in ICU management.

Introduction

Background and Significance

Efficient allocation of resources has emerged as a critical concern within the health care domain, with a specific focus on cost management. The effective administration of the intensive care unit (ICU) plays a pivotal role in attaining this objective [1]. ICUs have been reported to contribute significantly to a hospital's financial allocation, ranging from 22% to 34% of the overall budget [2,3]. Hence, implementing improved

XSL•FO
RenderX

management strategies for ICUs can effectively alleviate the financial burdens faced by the health care system.

Predicting patient outcomes in the ICUs has multifaceted implications, providing valuable supplementary information for medical professionals as they make critical clinical and administrative decisions (it is important to note that these predictions are intended to complement, not replace, the judgment of health care providers). First, the prediction of length of stay aids clinicians in strategizing ICU capacity planning [4]. Such predictions enable health care institutions to adeptly manage patient flow, thereby curtailing waiting durations for critically ill patients. This facilitates optimal bed turnover and efficient allocation of pivotal resources, including ventilators and staffing [5]. Second, the quantification and optimization of length-of-stay in critical care units are pivotal for enhancing patient outcomes and clinical quality [6]. An extended length of stay can potentially compromise the clinical quality within the ICU. Extended length of stay can exert undue pressure on ICU capacity, potentially resulting in the deferment of elective surgeries, which is both financially burdensome and detrimental to patient health [7]. Furthermore, it could escalate the urgency to refuse or postpone emergency admissions, potentially jeopardizing patient outcomes. Such scenarios could also inadvertently shift focus away from the gravely ill [7]. Accurate length-of-stay predictions empower intensivists to refine treatment strategies, enhancing patient outcomes while minimizing unwarranted interventions. Third, economic considerations are intricately linked with length-of-stay predictions. ICUs, by their inherent nature, are financially demanding, administering intricate interventions and mandating intensive clinician involvement for a niche patient cohort. An augmented length of stay inevitably monopolizes more ICU resources, thereby inflating costs. In a milieu where ICUs grapple with mounting pressures and financial resources are increasingly limited, the urgency to enhance the expediency and efficiency of critical care is paramount [8].

In an optimal setting, a patient outcome prediction model for intensive care would be deployed before any intervention [9]. However, in current clinical paradigms, the prediction is typically executed within the first 24 hours following ICU admission. This is primarily due to the necessity of integrating various patient-specific risk factors, including demographic information, diagnostic codes, and laboratory test results to accurately predict the outcome for individual patients [9]. The imperative to collate data from diverse sources poses challenges to the adaptability of existing methods for real-time predictions. The process is further complicated by the frequent occurrence of unidentified or “unknown” patients in the ICU, whose identities cannot be ascertained upon arrival at the hospital. As a result, demographic information, medical history, and related data remain undisclosed [10,11]. The absence of such vital information restricts the available input, compelling the model to rely solely on readily accessible data. In response to this challenge, researchers and practitioners advocate for the development of models that rely solely on real-time vital sign data, enabling predictive capabilities at any point during a patient’s stay in the ICU.

Objectives

To address the critical need for efficient ICU length-of-stay prediction with limited patient information that can be updated in real time, this research aims to develop a predictive model for ICU length-of-stay based exclusively on real-time vital sign data. By leveraging real-time vital sign data, the study enables early and accurate length-of-stay predictions, facilitating improved ICU capacity planning, resource optimization, and enhanced patient care outcomes.

Related Work

ICU Length-of-Stay Prediction

The importance of predicting the length of stay in the ICU has long been acknowledged, with numerous studies addressing this topic (Table 1). Predominantly, extant research tends to reduce the complexity of length-of-stay prediction into a binary classification problem, categorizing patients’ stays as either prolonged or nonprolonged. Nevertheless, such binary classifications lack the granularity necessary for medical practitioners to devise comprehensive care plans. Furthermore, while some regression models have been developed to predict the actual length of stay for patients in the ICU, these models are typically limited to predictive horizons of only the first 24 or 48 hours following ICU admission [12-16].

Given the critical condition of ICU patients, accurately assessing their health status—such as predicting their length of stay—is crucial, especially at time points specified by physicians rather than being limited to standardized intervals like 24 or 48 hours.

One of the principal challenges that existing models face is their reliance on multiple data sources, including domain-specific knowledge, demographic and pre-ICU condition data, vital signs, and laboratory results. Laboratory results, in particular, are often subject to processing delays, while domain knowledge relies on the interpretation of medical professionals, which can lack flexibility. In addition, demographic data may sometimes be unavailable, particularly in cases where patients' identities are unknown. In contrast, bedside-monitored vital signs represent a readily available, real-time data source. However, current research uses vital sign series in a relatively superficial manner, typically using basic statistics such as mean, maximum, and minimum values [16], or categorizing them [26]. Nonetheless, vital sign time series data often exhibit highly complex patterns, which can vary significantly across different patient cohorts. Simplifying these series using basic statistics for categorical data severely limits downstream models' ability to uncover valuable patterns and effectively leverage them for predicting ICU patients' length of stay.

To address these limitations, our research endeavors to design a model that exclusively harnesses the power of 3 vital sign series to make real-time predictions, thereby offering a more granular and timely approach to ICU length-of-stay prediction with both decent accuracy and good generalizability.

Models Dealing With Time Series

The use of time series data for prediction has been a central focus in various domains, leading to the exploration and development of diverse models [27]. Traditional statistical models, particularly regression techniques, have historically played a crucial role in time series prediction [28]. These models leverage historical data patterns to make forecasts, providing a foundational framework for subsequent advancements in predictive modeling. However, their performance is constrained by their underlying hypothesis, as most datasets struggle to fulfill these assumptions.

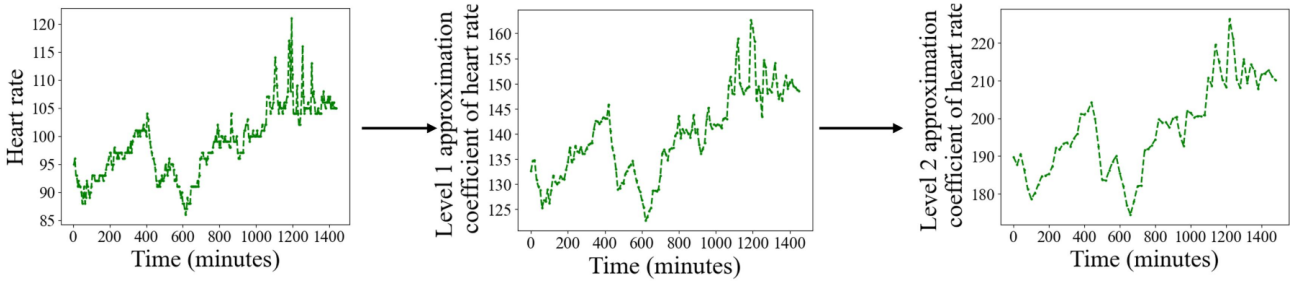
The emergence of neural networks has revolutionized time series prediction. Recurrent neural networks are specifically designed to capture sequential dependencies within data [29]. Recurrent neural networks excel in modeling temporal relationships, making them well-suited for time series forecasting tasks [30]. However, they may face challenges when dealing with long-term dependencies due to the vanishing gradient problem [31]. The introduction of the long short-term memory (LSTM) model addresses this issue by incorporating memory cells that can retain information over extended sequences [32]. LSTMs have shown remarkable success in capturing complex temporal dependencies, making them popular for time series prediction tasks. However, they are not immune to challenges, particularly when the data is affected by noise [33]. The transformer architecture, originally designed for natural language processing tasks, has also found applications in time series prediction [34]. However, a notable challenge lies in the substantial amount of data often required for effective training [35]. In addition, for task-specific small datasets, transformers have demonstrated less competitiveness compared with LSTMs, as evidenced by research in the medical field [36]. Therefore, it appears that LSTM remains the preferred choice, notwithstanding its susceptibility to noise in time series data.

To address the susceptibility of LSTMs to noise, we propose using wavelet transform techniques as a preprocessing step and introduce the Wavelet-LSTM model. This approach aims to denoise time series data before feeding it into LSTM models, with the overarching goal of enhancing the robustness of LSTM models and improving their performance in the presence of noisy signals.

Wavelet Transformation in ICU Mortality Prediction

The application of wavelet transformation remains limited in ICU outcome prediction. A previous study by Wang et al [37] demonstrated that features extracted via wavelet transformation can be among the most informative compared with those derived from other signal processing techniques. However, their approach applied wavelet features in a handcrafted and static manner, rather than integrating them into an end-to-end learning framework. In addition, much of the existing literature does not fully use the rich, high-frequency information embedded in continuous vital sign data. The proposal of a wavelet LSTM model (WT-LSTM) addresses this gap by incorporating wavelet-transformed vital signs directly into the model architecture, enabling both noise reduction and multi-resolution pattern extraction in a fully data-driven way. This represents a key contribution of our work, as it combines advanced signal processing with deep learning to enhance predictive performance while maintaining practical applicability for real-time clinical decision support.

Methods



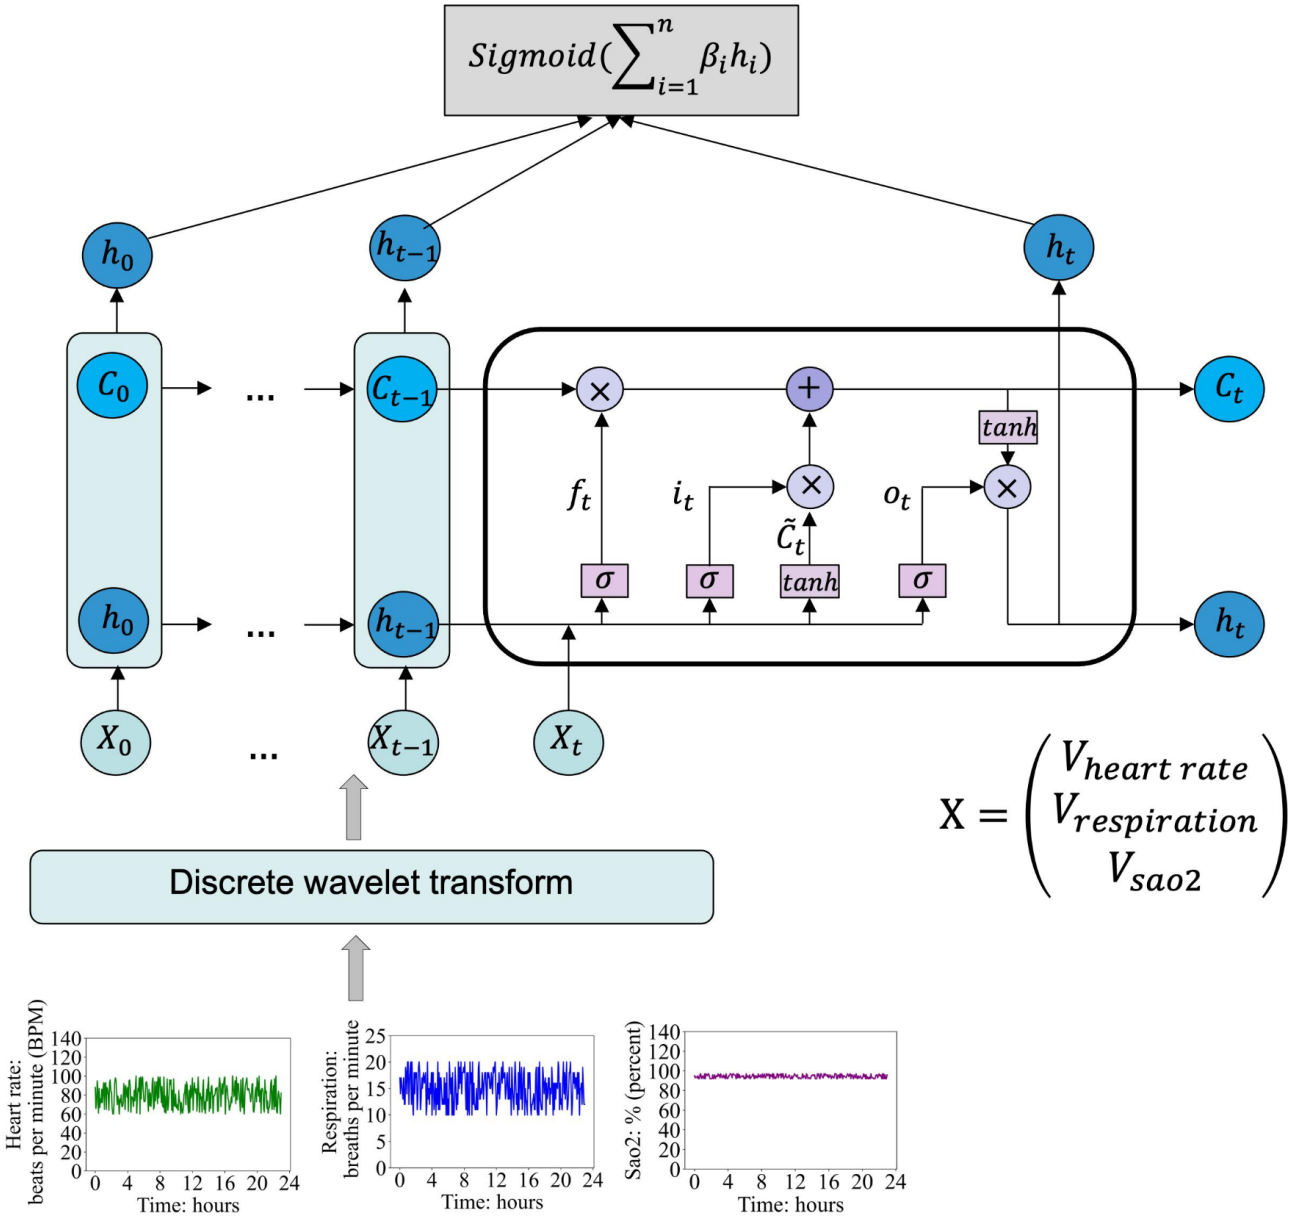
Model Structure

The WT-LSTM model introduced in this study is primarily composed of 3 key components: a wavelet transform layer, an LSTM layer, and a linear fully connected layer. Using the vital sign series denoted by Vi(t)∈ 2N, where i=1,...,m,t=1,...,n,N∈ N+, we use a discrete wavelet transform (DWT) filter bank to discern the trends therein. The trends of the vital signs are encapsulated in the low-frequency component of the signal, while the high-frequency component is predominantly noise. Given a mother wavelet ψ(t), we can construct g(t)=12jψ(-t2j) sampled

XSL•FO
RenderX

at the points 1, 2j, 22j,...,2N, where j denotes the level of the DWT. In this investigation, we select j=2, thereby using a level 2 DWT filter bank. The coefficients of this filter bank align precisely with a wavelet coefficient of a discrete set of child wavelets for a given mother wavelet ψ(t). The Vi,t series are channeled through a low-pass filter twice, culminating in the approximation coefficient Xi(t) of the original signal (Figure 1).

Figure 1. Alterations in vital sign series during level 2 discrete wavelet transform filter bank application.



By using DWT, high-frequency noise is filtered out, significantly enhancing the clarity of time series patterns in patients' vital signs. These denoised sequences, Xi(t) serve as the input for the LSTM network. At each time point, there are 3 input features: the values of heart rate, respiration, and oxygen saturation (SaO2), forming the input vector X at a specific moment, represented as VheartrateVrespirationVsao2.

The LSTM architecture efficiently uses temporal information from time series data by allowing past information to persist. For input Xi at time stamp i, Vheartrate,iVrespiration,iVsao2,i, an LSTM cell processes it as ft=σ(Xt*Uf+Ht-1*Wf) , C~t=tanh (Xt*Uc+Ht-1*Wc), it=σ(Xt*Ui+Ht-1*Wi), Ot=σ(Xt*Uo+Ht-1*Wo), Ct=ft*Ct-1+it*C~t, Ht=Ot*tanh (Ct), where W, U are the weight vectors for forget gate f, candidate c, i/p gate i and o/p gate O. Ht-1, Ht, Ct-1 and Ct are the previous and current cell output and memories respectively (Figure 2). A linear layer is then applied to the LSTM cell outputs, akin to performing regression on these outputs. The final result of the model constitutes the predicted length-of-stay value.

RenderX

Figure 2. Wavelet long short-term memory model network structure.

The WT-LSTM model effectively combines the strengths of signal processing techniques, which excel at filtering noise from patients' vital sign time series, with the robust pattern recognition capabilities of the LSTM model structure. Time series data of patients' vital signs often contain significant noise due to varying disease pathologies, medical interventions, and device errors. The synergy of wavelet and LSTM components in the proposed model effectively mitigates the adverse effects of noise on LSTM performance, thereby enhancing its robustness and overall effectiveness.

Data Description

The experiments were carried out using the electronic intensive care unit (eICU) database [38]. We extracted datasets encompassing patient records associated with the top 10 most prevalent diagnoses at ICU admission (Table 2). This selection allows for more reliable comparisons across clinically meaningful and commonly observed patient cohorts. The sole input to the model consisted of vital sign series, which constituted readily accessible real-time data from ICU bedside monitoring. These vital signs were typically interfaced as 1-minute averages and archived as 5-minute median values [37]. The vital signs used in this study presented themselves as periodic time-series data. Specifically, our analysis focused on 3 key vital signs: heart rate, respiration rate, and SaO2, recognized as the most pertinent indicators for ICU outcome prediction.

Table . Patient records with the top 10 most frequent diagnoses at intensive care unit admission.

Abbreviation	Diagnosis	Records, n
SP[a]	Sepsis, pulmonary	8862
MI[b]	Infarction, acute myocardial (MI)	7228
CVA[c]	CVA, cerebrovascular accident or stroke	6647
HF[d]	CHF[e], congestive heart failure	6617
SR[f]	Sepsis, renal/UTI[g] (including bladder)	5273
RD[h]	Rhythm disturbance (atrial, supraventricular)	4827
DK[i]	Diabetic ketoacidosis	4825
CA[j]	Cardiac arrest (with or without respiratory arrest; for respiratory arrest see Respiratory System)	4580
CABG[k]	CABG alone, coronary artery bypass grafting	4543
EB[l]	Emphysema or bronchitis	4494

[a]SP: sepsis, pulmonary.
[b]MI: myocardial infarction.
[c]CVA: cerebrovascular accident or stroke.
[d]HF: heart failure.
[e]CHF: congestive heart failure.
[f]SR: sepsis, renal.
[g]UTI: urinary tract infection.
[h]RD: rhythm disturbance.
[i]DK: diabetic ketoacidosis.
[j]CA: cardiac arrest.
[k]CABG: coronary artery bypass grafting.
[l]EB: emphysema or bronchitis.

For each experiment, the same patient cohort was used across all input time windows (eg, 3 h, 6 h, 12 h, and 24 h). To ensure temporal consistency and real-time applicability, only vital sign data recorded before the specified time point were used for model input. Patients with a length of stay shorter than the input window (eg, less than 24 h in the 24 h experiment) contributed their complete available data. For patients with longer stays, only the data from the specified time window were included. This approach preserved the real-world distribution of ICU lengths of stay while maintaining consistency in patient inclusion and ensuring that the model relied exclusively on data that would be available at the corresponding prediction time. The target variable, length of stay, was modeled and evaluated in units of days.

Ethical Considerations

The eICU databases were deidentified, anonymized, and approved for sharing by the institutional review boards of both Beth Israel Deaconess Medical Center and the Massachusetts Institute of Technology. Data access was granted to an investigator after the completion of a National Institutes of Health course and successful passing of the associated human research participant protection examination. Given that the data are accessible to the public through the eICU database, the need for ethical approval and informed consent was waived. The contributing author, YJ, obtained the necessary authorization to access the anonymized dataset and oversaw the meticulous data extraction process.

Training Details

The training, validation, and testing of our method follow the widely adopted hold-out validation procedure. Specifically, for each experiment, patient records were randomly split using stratified sampling based on the prediction target (mortality or length of stay). The data were partitioned into training (56.25%), validation (18.75%), and test (25%) sets. Each experiment was repeated 30 times with different random seeds to ensure robustness.

The specific training procedure and parameter settings of our method are summarized below. Our method was developed using PyTorch. We trained the WT-LSTM model for up to 100 epochs with early stopping based on validation loss. The optimizer used was Adam with learning rates tuned over 0.08, 0.1, 0.12, and 0.15. A batch size of 16 was used consistently across all runs. The best-performing model checkpoint (based on validation loss) was saved for evaluation on the test set. We have set torch.manual_seed(1) for reproducibility.

Results

Overview

In this section, we primarily present the outcomes of 3 key experiments. To commence, we juxtapose the results of the WT-LSTM model using mean square error (MSE), a commonly used metric for evaluating the performance of regression models, against benchmark methods used by existing research, including linear regression, LSTM, bidirectional long short-term memory (BiLSTM) using 24-hour vital sign data. Subsequently, we extend our analysis to experiments involving 3-hour, 6-hour, and 12-hour prediction intervals, thus showcasing the model's real-time and early prediction capabilities. The results are compared with the best-performing ICU outcome prediction method currently used in ICUs, that is, the Acute Physiology and Chronic Health Evaluation (APACHE) IV system [16]. In addition, we present the length-of-stay prediction distributions for each patient cohort generated by our proposed model and draw comparisons with the predictions generated by the APACHE IV model.

Comparison With Baselines

Previous studies on length-of-stay prediction have employed linear regression, LSTM, and BiLSTM models, which are adopted as baselines in our research, using vital sign series as inputs. This study conducts a comparative analysis between the performance of the WT-LSTM model, using 24-hour vital sign data, and the baselines to validate the effectiveness of our model (Table 3).

Table . Comparisons between wavelet long short-term memory model and benchmarks using 24 h vital signs as inputs.

Disease	Linear regression	BiLSTM[a]	LSTM[b]	WT-LSTM[c]	Improvement compared with LSTM, n (%)
HF[d]	17.61	14.75	13.84	13.24	0.6 (4.34)
CVA[e]	15.16	12.33	11.59	11.45	0.14 (1.21)
MI[f]	8.15	6.03	5.54	5.53	0.01 (0.18)
SP[g]	38.77	29.41	24.29	24.31	–0.02 (0.08)
SR[h]	15.24	9.99	9.08	8.84	0.24 (2.64)
RD[i]	10.69	7.71	6.66	6.02	0.64 (9.61)
DK[j]	4.08	2.38	2.39	2.37	0.02 (0.84)
CA[k]	38.77	22	20.04	19.22	0.82 (4.09)
CABG[l]	14.08	11.95	9.47	8.78	0.69 (7.29)
EB[m]	19.1	12.3	11.58	11.25	0.33 (2.85)

[a]BiLSTM: bidirectional long short-term memory.
[b]LSTM: long short-term memory.
[c]WT-LSTM: wavelet long short-term memory.
[d]HF: heart failure.
[e]CVA: cerebrovascular accident or stroke.
[f]MI: myocardial infarction.
[g]SP: sepsis, pulmonary.
[h]SR: sepsis, renal.
[i]RD: rhythm disturbance.
[j]DK: diabetic ketoacidosis.
[k]CA: cardiac arrest.
[l]CABG: coronary artery bypass grafting.
[m]EB: emphysema or bronchitis.

WT-LSTM outperforms all the baselines in 9 out of the 10 patient cohorts. In the remaining patient cohort (sepsis, pulmonary [SP]), while the WT-LSTM model did not achieve the best performance, its performance was very close to that of the best baseline in terms of MSE (24.29 for LSTM vs 24.31 for WT-LSTM) and outperformed the other 2 baselines. It is evident that when handling patients' time series of vital sign data, WT-LSTM demonstrates its strengths compared with the baselines.

Furthermore, the performance disparity between the LSTM model and the WT-LSTM model serves as an evaluation of the denoising impact of wavelet transformation on vital sign series and its subsequent contribution to model performance. The inclusion of the wavelet transformation component in the WT-LSTM model results in an average improvement of 3.3%

XSL•FO
RenderX

in prediction performance, measured through MSE. Notably, the most substantial enhancement is observed in the patient cohort with rhythm disturbance (RD), where performance improves by 9.61%.

These experimental results signify that, among all the models addressing vital sign data for the regression prediction task of ICU length-of-stay, WT-LSTM emerges as the superior choice. This aligns with our intuitive design of the model structure.

Real-Time Prediction

The WT-LSTM model, by exclusively using vital sign series as its input, exhibits remarkable adaptability in facilitating real-time predictive capabilities. To illustrate this, a series of experiments is conducted to evaluate the model's performance with varying lengths of patient time series data as input. In these experiments, we compare the WT-LSTM model with the widely used APACHE IV model, known for its credibility in predicting ICU outcomes, which relies on 24-hour data and includes demographic information, vital sign values, and laboratory results as inputs.

In comparisons using 24-hour data inputs across 10 distinct patient cohorts with various diagnoses, the WT-LSTM model outperforms the APACHE IV model in 9 out of the 10 cases (Table 4). Particularly noteworthy is the fact that, for 8 out of the 10 cohorts, the WT-LSTM model exhibits a significant performance enhancement, reducing the MSE by more than 10% compared with the APACHE IV model. In over half of the cohorts, the improvement surpasses the 20% mark.

Table . Real-time prediction comparison between wavelet long short-term memory and Acute Physiology and Chronic Health Evaluation IV.

Disease	APACHE[a] IV (24 h)	3 h	WT-LSTM[b] 3 h improvement compared with APACHE IV, n (%)	6 h	12 h	24 h	WT-LSTM 24 h improvement compared with APACHE IV, n (%)

[l]EB: emphysema or bronchitis.

The results also demonstrate that the initial 3-hour vital sign data provides the most significant insights for the prediction of ICU length of stay. The early-phase vital sign patterns of patients carry substantial implications for the assessment of their clinical condition, and the extension of the input time series yields relatively marginal improvements in the model's performance. Particularly, in the transition from 3-hour to 12-hour input intervals, the results demonstrate a noteworthy degree of similarity. However, when a 24-hour input interval is used, the model's performance exhibits a more pronounced enhancement.

It is imperative to highlight that, for over half of the patient cohorts, the 3-hour results surpass those of the APACHE IV model. This observation underscores the model's significant potential for early prediction.

XSL•FO
RenderX

Prediction Distribution Comparison Between WT-LSTM and APACHE IV

To gain deeper insights into the distinctions in prediction results between WT-LSTM and APACHE IV, we generated plots that depict the predicted length-of-stay by both methods, in conjunction with the true values of the length-of-stay for the 10 distinct patient cohorts.

Observations gleaned underscore significant disparities in the patterns of length-of-stay predictions and actual values (Figure 3). Notably, the true values of length of stay exhibit a pronounced right-skewed distribution, whereas the predictions generated by APACHE IV tend to be more conservative in their estimates. WT-LSTM, on the other hand, positions itself between these 2 extremes, manifesting a propensity to predict values that gravitate toward the statistical average. The possible reason is that our method is based on deep learning, trained in a supervised manner using the true length of stay and optimized with a MSE loss function. Deep learning models optimized for MSE are often biased toward conservative predictions due to the bias-variance trade-off, which leads them to underpredict extreme values. For example, when a model trained with MSE makes an incorrect prediction on an extreme value, the squared error amplifies the loss significantly, discouraging the model from making such predictions.

Figure 3. Predicted distribution of wavelet long short-term memory model with 3 h of vital signs versus Acute Physiology and Chronic Health Evaluation IV. CA: cardiac arrest; CABG: coronary artery bypass grafting; CVA: cerebrovascular accident or stroke; DK: diabetic ketoacidosis; EB: emphysema or bronchitis; HF: heart failure; MI: myocardial infarction; RD: rhythm disturbance; SR: sepsis, renal; SP: sepsis, pulmonary.

XSL•FO
RenderX

We also compared the prediction distributions between the WT-LSTM model using the full 24-hour input series and APACHE IV (Figure 4). The results show that the distribution of predicted length-of-stay becomes more dispersed when 24 hours of data are used, with improved alignment to the true length-of-stay distribution. This suggests that increased input duration enhances the model's sensitivity to patient-specific variation. However, the corresponding improvement in predictive accuracy, as measured by MSE, is relatively modest, as discussed previously—highlighting the strength of WT-LSTM's early prediction capability, even when only short-term data are available.

These findings highlight that WT-LSTM, which relies solely on 3 hours of vital sign data, provides predictions that are highly competitive when compared with those generated by APACHE IV, which uses 24 hours of data. Furthermore, it has the potential to serve as an early warning system for monitoring the health conditions of patients.

Discussion

Limitations and Performance Interpretation

WT-LSTM has demonstrated its advantages in predicting ICU patients' length of stay by using only real-time data that are readily accessible, achieving performance comparable with or better than most benchmark methods, including the best-performing method currently used in ICUs (ie, APACHE IV). However, it is essential to acknowledge its limitations. From the distribution comparisons presented in the results, it becomes evident that in certain patient cohorts, WT-LSTM tends to predict length-of-stay toward the mean, indicative of potential insufficient information.

One limitation of this study is the restriction to the top 10 ICU admission diagnoses in the eICU database. While this selection was made to ensure adequate sample sizes and manageable computational requirements, it may limit the generalizability of our findings to less common diagnoses or more heterogeneous ICU populations. Future work could extend the model to a broader patient population as resources permit.

The prediction results exhibit greater reliability and accuracy in patient cohorts with cardiac arrest (CA), RD, and diabetic ketoacidosis (DK), while showing relatively weaker predictions in cohorts with heart failure (HF), SP, and coronary artery bypass grafting (CABG). The primary reason for this discrepancy could be the diverse impacts that diseases have on the 3 vital signs. In disease cohorts where patient conditions significantly impact vital signs, distinguishing patients' risk levels becomes challenging. For example, patients with HF often present with a rapid or irregular heartbeat, shortness of breath, and decreased SaO2 [39]. Similarly, patients with SP exhibit shortness of breath, an elevated heart rate, and decreased SaO2 [40]. Predicting outcomes using only these 3 vital signs proves challenging. In patient cohorts with diseases that have a limited impact on the 3 vital signs, such as CABG, which lacks clear signals from these vital signs, the performance of WT-LSTM is also limited. Conversely, for certain patient cohorts, the 3 adopted vital sign time series exhibit diverse patterns, and patient conditions have certain impacts on these vital signs; such variability can enhance the prediction capabilities of the WT-LSTM. For instance, patients with RD show varied patterns on respiration and SaO2 based on the type and severity of rhythm disturbance [41]. Similarly, DK and CA impact SaO2 differently based on the severity of acidosis and the involvement of respiratory arrest, respectively. This suggests that the predictive capability of WT-LSTM is influenced by the nature of the diseases and their respective impacts on vital signs. Recognizing these nuances is crucial for refining the model and improving its predictive performance across diverse patient cohorts. Furthermore, exploring additional vital signs specific to certain disease groups provides an opportunity to adapt the model to different conditions, potentially further improving its performance.

Besides, WT-LSTM's exclusive reliance on vital sign data may lead to not fully capturing the complexity of certain clinical scenarios. For instance, critically ill patients undergoing prolonged interventions, such as mechanical ventilation, may exhibit relatively stable or normalized vital signs while still requiring extended ICU care. In such cases, the model may underestimate length of stay due to the absence of contextual clinical information. While the use of vital signs alone enhances the model's applicability in real-time and data-limited settings, future work could explore the integration of additional variables such as medication use, intervention records, or clinical documentation to better account for factors not directly observable through vital sign patterns.

In addition, WT-LSTM's exclusive reliance on vital sign data inherently limits its utility for individual-level prediction. The model performance at the individual scale is constrained by relatively low R^2 values (<10%) and wider prediction variance (higher root-mean-square error; Multimedia Appendix 1), as well as imperfect calibration. This is reflected in both the sharp distributional peaks seen in predicted length-of-stay. These patterns suggest that the model performs best when estimating average outcomes across a population but may struggle with edge cases or highly personalized clinical contexts. While this limitation does not preclude its use for operational or cohort-level applications, it is important to exercise caution in interpreting WT-LSTM predictions for individual patient decision-making. Future enhancements, such as incorporating auxiliary features or using distribution-aware loss functions, could help address this gap.

In Table 3, the BiLSTM model demonstrated worse performance than the unidirectional LSTM across most patient cohorts. This finding may be attributed to the temporal nature of ICU data, where the most predictive information is often concentrated in the initial hours following admission. Unlike LSTM, which processes data in a forward-looking manner aligned with real-time clinical decision-making, BiLSTM leverages both past and future time steps—an assumption that may not hold in real-world ICU settings where future observations are unavailable. In addition, BiLSTM's bidirectional architecture increases model complexity and may lead to overfitting when training data is relatively limited, especially when early vital signs dominate the input. These factors suggest that BiLSTM's backward temporal dependency may dilute the predictive strength of early signals, thereby reducing its overall effectiveness in this context. This further supports the design choice of WT-LSTM, which retains a unidirectional structure while enhancing temporal feature extraction through wavelet transformation.

Beyond individual-level predictions, the WT-LSTM model also has potential applications in ICU benchmarking and operational assessment. Early and accurate predictions of ICU length of stay can inform capacity planning, staffing allocation, and overall resource usage—key metrics in evaluating ICU efficiency. Previous works [42-45] have demonstrated the value of data-driven approaches in benchmarking ICU performance across institutions. By relying solely on real-time vital signs, our model offers a lightweight and scalable solution that could support these benchmarking efforts, particularly in settings with limited access to comprehensive electronic health record data. Integrating such predictive tools into ICU management workflows may help improve institutional comparisons, optimize throughput, and enhance system-level decision-making.

XSL•FO
RenderX

Conclusions

This study introduces a novel model, WT-LSTM, which incorporates signal processing techniques to augment the performance of LSTM cells, specifically for the purpose of predicting ICU length-of-stay. WT-LSTM operates exclusively on readily available vital sign data, which effectively addresses 2 significant challenges in current research for ICU outcome prediction: real-time prediction capabilities and the lack of important information for unidentified patients.

The model's performance is rigorously evaluated using the eICU database, focusing on patient records related to the top 10 most frequently diagnosed conditions. It is benchmarked against existing methods, including APACHE IV, which is a widely recognized and best-performing method currently used for ICU outcome prediction. Remarkably, when using 24-hour heart rate, respiration, and SaO2 time series as input, WT-LSTM significantly outperforms APACHE IV across most patient cohorts. Strikingly, even with just 3-hour vital sign series, WT-LSTM surpasses APACHE IV—despite the latter using 24 hours of data—in more than half of the patient cohorts.

The predictive distribution generated by WT-LSTM exhibits a tendency to predict values closer to the statistical average, offering a meaningful indicator for the early detection of changes in patients' health conditions. This capacity to predict ICU length-of-stay both early and accurately not only provides valuable insights into patients' health statuses, thereby benefiting health care providers in their clinical practice, but also offers guidance for optimizing the allocation of ICU resources. Ultimately, these advancements hold the potential to contribute significantly to healthcare management.

Abstract

Background: Ultrasound examinations, while valuable, are time-consuming and often limited in availability. Consequently, many hospitals implement reservation systems; however, these systems typically lack prioritization for examination purposes. Hence, our hospital uses a waitlist system that prioritizes examination requests based on their clinical value when slots become available due to cancellations. This system, however, requires a manual review of examination purposes, which are recorded in free-form text. We hypothesized that artificial intelligence language models could preliminarily estimate the priority of requests before manual reviews.

Objective: This study aimed to investigate potential challenges associated with using language models for estimating the priority of medical examination requests and to evaluate the performance of language models in processing Japanese medical texts.

Methods: We retrospectively collected ultrasound examination requests from the waitlist system at Keio University Hospital, spanning January 2020 to March 2023. Each request comprised an examination purpose documented by the requesting physician and a 6-tier priority level assigned by a radiologist during the clinical workflow. We fine-tuned JMedRoBERTa, Luke, OpenCalm, and LLaMA2 under two conditions: (1) tuning only the final layer and (2) tuning all layers using either standard backpropagation or low-rank adaptation.

Results: We had 2335 and 204 requests in the training and test datasets post cleaning. When only the final layers were tuned, JMedRoBERTa outperformed the other models (Kendall coefficient=0.225). With full fine-tuning, JMedRoBERTa continued to perform best (Kendall coefficient=0.254), though with reduced margins compared with the other models. The radiologist's retrospective re-evaluation yielded a Kendall coefficient of 0.221.

Conclusions: Language models can estimate the priority of examination requests with accuracy comparable with that of human radiologists. The fine-tuning results indicate that general-purpose language models can be adapted to domain-specific texts (ie, Japanese medical texts) with sufficient fine-tuning. Further research is required to address priority rank ambiguity, expand the dataset across multiple institutions, and explore more recent language models with potentially higher performance or better suitability for this task.

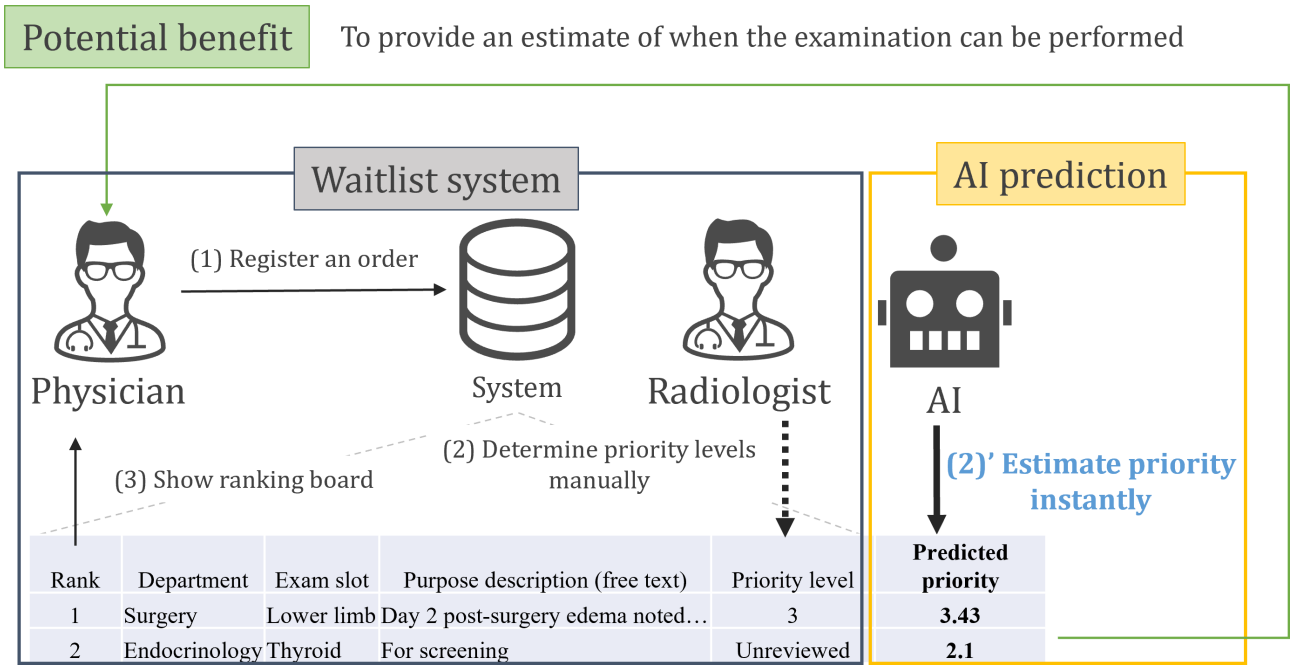
natural language processing; clinical informatics; large language model; machine learning; health resources; ultrasonography; hospital information systems.

Introduction

Waitlist System

Ultrasound, a noninvasive imaging modality, enables real-time visualization of organs and blood flow and can be performed safely in pediatric and obstetric populations. However, imaging quality depends on the proficiency of the technician. Most hospitals implement reservation systems that allocate available slots to physicians due to a shortage of ultrasound technologists. Frequently, slots for the immediate future are fully booked, and these systems typically lack mechanisms for automatic urgency assessment.



Our hospital has implemented a waitlist system in case an appointment is canceled, and a slot becomes vacant. The system

XSL•FO
RenderX

prioritizes examination requests based on urgency and clinical value. This approach facilitates more efficient use of canceled slots, reducing patient wait times, minimizing hospital stays, and improving overall care quality.

Our waitlist system organizes examination requests into 6 priority tiers, determined by board-certified radiologists based on the examination purpose, which is recorded as a brief free-text entry by the requesting physician (Figure 1). The waitlist is accessible to all physicians, enabling them to anticipate when their orders might be processed. However, the delay in updating until radiologists complete their reviews has led to difficulties in providing real-time wait time estimates. Therefore, we investigated the potential of artificial intelligence (AI) language models to provide preliminary priority estimations.

Figure 1. Artificial intelligence-predicted priority levels will allow physicians to estimate waiting time before the official priority is determined by radiologists. AI: artificial intelligence.

Use of Language Models in Medicine

To perform this task, the AI models must process free-form text through natural language processing (NLP). NLP presents challenges due to the inherent ambiguity and complexity of natural languages. Historically, NLP approaches have used simplistic models, such as the bag-of-words method, which analyzes text as a mere collection of words without considering their order or contextual relationship. While this approach suffices for basic tasks, it does not adequately capture the intricacies of human language. Consequently, researchers have worked to incorporate linguistic insights into computational models to enhance their ability to process and understand natural language.

The advent of transformer architecture, particularly with bidirectional encoder representations from transformers (BERT), has revolutionized NLP [1]. The ability of BERT to efficiently learn from extensive text corpora has significantly enhanced its contextual understanding and performance across various NLP tasks, minimizing strong inductive biases. BERT has also inspired the development of several transformer-based models tailored to specific domains, including medicine. Examples include BioBERT, ClinicalBERT, PubMedBERT, and BlueBERT [2-5]. Hence, we used JMedRoBERTa, a model specifically trained on a substantial corpus of Japanese medical research papers [6].

Large language models (LLMs), which often use architectures similar to BERT but with increased parameters and capabilities, particularly in text generation, have gained prominence. Empirical evidence from GPT-3 has demonstrated that scaling models improve performance, adhering to the scaling law in NLP [7]. The term “large” is ambiguous, as BERT can also be considered an LLM. The introduction of ChatGPT [8] and subsequent models, such as GPT-4 and PaLM (Pathways Language Model), has shown the success of LLMs across various fields, including medicine [9-11]. Despite the proprietary nature of leading models due to high training costs and safety concerns, publicly available LLMs such as LLaMA2 and OpenCalm offer opportunities for research and evaluation of their potential and limitations [12-14].

Research Gap

The application of AI for priority estimation has been predominantly investigated in the context of emergency department (ED) triage [15,16]. Several AI models use NLP techniques to analyze medical texts [17-19], aiming to rank patients or requests to optimize the allocation of limited medical resources to those in urgent need. While these models have shown promise in improving resource allocation within ED, extending research into medical priority estimation beyond ED could further enhance patients’ quality of life, reduce hospital stay durations, and lower medical costs. Therefore, additional research is required to explore AI applications in medical priority estimation across various clinical settings.

XSL•FO
RenderX

This study provides valuable insights into both priority estimation and the broader field of medical NLP and LLM applications. Although LLMs have primarily been used for generative tasks, demonstrating innovative applications, these models underperform in scenarios requiring structured and predictable outputs. Such challenges are evident in health care settings, where integrating AI into hospital systems necessitates a high degree of precision and reliability that generative models do not consistently provide. Furthermore, current research on medical LLMs predominantly focuses on question-answering (QA) metrics [9], overshadowing the exploration of LLM potential for non-QA tasks. Emphasizing LLM applications beyond QA could reveal new practical uses in medicine.

A significant challenge in applying LLMs to our context arises from the linguistic and contextual differences between the pretraining datasets, primarily in general English, and our specific use cases involving Japanese medical terminology. This mismatch impairs the model's understanding of specialized terms and complicates tokenization. Tokenizers, though less studied than model size and datasets, can significantly influence the performance of LLMs in non-English contexts [20]. Our study addresses this issue by evaluating and enhancing LLMs' linguistic and contextual adaptability for diverse clinical applications.

Methods

Dataset

We retrospectively collected ultrasound examination requests from the waitlist system at Keio University Hospital (Figure 1) from January 2020 to March 2023. Each record comprised the requesting department, the examination slot, and the examination purpose documented by the requesting physician. In addition, records included a 6-tier priority level assigned by a board-certified radiologist during the clinical workflow, which served as the ground truth for the AI models. The criteria for determining priority levels are outlined in Textbox 1. Priority level 6 was excluded from the dataset due to its rarity (only a few records), and physicians typically communicated directly with radiologists in such cases.

Textbox 1. Criteria for priority levels

1) Desired before discharge if possible.

2) Required for treatment decisions.

3) Preferred early.

4) Urgently required.

5) Immediately required.

6) Emergency (excluded).

The dataset underwent 3 main preprocessing steps to ensure data quality and consistency: aggregation, cleaning, and text normalization.

Aggregation

Initially, records with similar request texts were aggregated using the Levenshtein distance metric, and the majority priority level was assigned to the representative record within each cluster. This aggregation was essential because the dataset contained approximately identical waitlist records for common ultrasound scenarios, such as postoperative monitoring or specific clinical pathways. Duplicates could skew sample weights during model training, and inconsistencies in priority levels could adversely affect accuracy. We aimed to reduce these risks and create a more uniform and reliable dataset for model training by aggregating similar records.

Cleaning

This phase involved eliminating records unsuitable for analysis. Specifically, we excluded entries with zero or invalid priority levels because these could not contribute to meaningful priority estimation. In addition, we removed records with date-specific requests (eg, "Can we schedule an ultrasound examination by May 3?") because temporal references could bias priority estimations and present challenges for AI models during prediction. This meticulous pruning ensured the remaining dataset was relevant and suitable for accurate modeling.

Text Normalization

The final preprocessing step aimed to enhance textual consistency. We removed extraneous spaces and corrected punctuation errors by standardizing the text format across the dataset. This normalization was crucial for minimizing variability in model input and ensuring accurate text interpretation by AI.

After preprocessing, approximately 10% of the dataset was reserved for testing, with the remaining portion allocated for training. The dataset was divided based on referring doctors to ensure that requests from a single physician appeared exclusively in the training or test subset.

Models

We used several pretrained models: JMedRoBERTa, Luke, OpenCalm 7B, and LLaMA2 7B [6,13,14,21], all of which are accessible via Hugging Face (Table 1) [22]. Both OpenCalm and LLaMA2 offer multiple variants with different model sizes; however, we selected the 7B model due to computational resource limitations. These 4 models were chosen based on their size and the semantic alignment between their pretraining datasets and our downstream task. Ideally, the optimal model should possess a large number of parameters and be trained on a dataset that aligns semantically and linguistically with the downstream task. However, there is often a trade-off between model size and dataset alignment. In this study, we experimented with models positioned at different points along this trade-off,

XSL•FO
RenderX

providing valuable insights into how this balance can be managed for medical text classification tasks using LLMs.

Table . Model details.

Model	Number of Parameters	Language of training dataset	Category of training dataset
JMedRoBERTa	124 million	Japanese	Medical paper
Luke	562 million	Japanese	Wikipedia
OpenCalm	7 billion	Japanese	Mixed[a]
LLaMA2	7 billion	English (mainly)[b]	Mixed[a]

[a]Large language models are generally pretrained on diverse text data to maximize the use of their extensive parameters.

[b]LLaMA2 was primarily designed for English, but its training dataset included some Japanese data.

To establish a performance baseline, we also tested conventional NLP methods: support vector machine, random forest, and XGBoost (eXtreme Gradient Boosting) [23]. The same input text used for the LLMs was processed into a list of words with MeCab [24], using the mecab-ipadic-NEologd dictionary [25]. This list of words was then converted into a vector using the term frequency-inverse document frequency.

The model input adhered to the template provided in Textbox 2. We experimented with various prompts, ranging from simpler to more complex ones (such as role prompting or few-shot). Ultimately, we found that this simple prompting worked best for our task. We trained the models to predict the correct priority levels using continuous numbers (ie, regression). Training was conducted under 2 conditions: fine-tuning only the final layer and fine-tuning all layers. However, fine-tuning all layers was impractical due to the large number of parameters in OpenCalm and LLaMA2. Therefore, we used low-rank adaptation (LoRA) with parameter-efficient fine-tuning using r=32 [26,27]. The models were optimized using the AdamW optimizer with β_1 =0.9, β_2 =0.999, and a weight decay of 0.0001. The loss function used was mean squared error. Learning rates were set to 1e-5 for final-layer fine-tuning and 1e-7 for full-layer or LoRA-based tuning. Training was performed over 100 epochs, using the NVIDIA RTX A6000 GPU.

Textbox 2. Record was fed into the models using the simple prompt.

Input (translated): Department: General and gastrointestinal surgery; Examination Item: (bilateral) veins of lower extremities; Purpose: After hepatocellular carcinoma surgery, D-dimer elevated. Needs further inspection.

Priority level: 2

Evaluation

Kendall tau-b, the rank correlation coefficient, was used as the primary evaluation metric. While root-mean-squared error is a common metric for regression tasks, measuring the distance between predicted and actual values, our focus on accurately estimating the priority order for medical examinations made the alignment between predicted and actual rankings crucial. Therefore, Kendall tau-b was preferred, emphasizing the significance of ordinal relationships over quantitative discrepancies. In addition, we created the confusion matrices by rounding the continuous prediction values to the nearest integers.

In addition, we assessed the ability of the model to identify low priority (priority level=1) and high priority (priority level>=4) requests. Performance in this classification task was quantitatively assessed using the area under the receiver operating characteristic curve (ROC-AUC) and the F_1-score. The thresholds were optimized individually for each classification task.

Finally, we compared the accuracy of the language models with a retrospective re-evaluation performed by a radiologist. A board-certified radiologist (MH) assigned priority levels to all records in the test dataset based solely on the same text presented to the AI models. This comparison served as a benchmark for our model's predictions and provided valuable insights into the challenges and consistency involved in priority assignment.

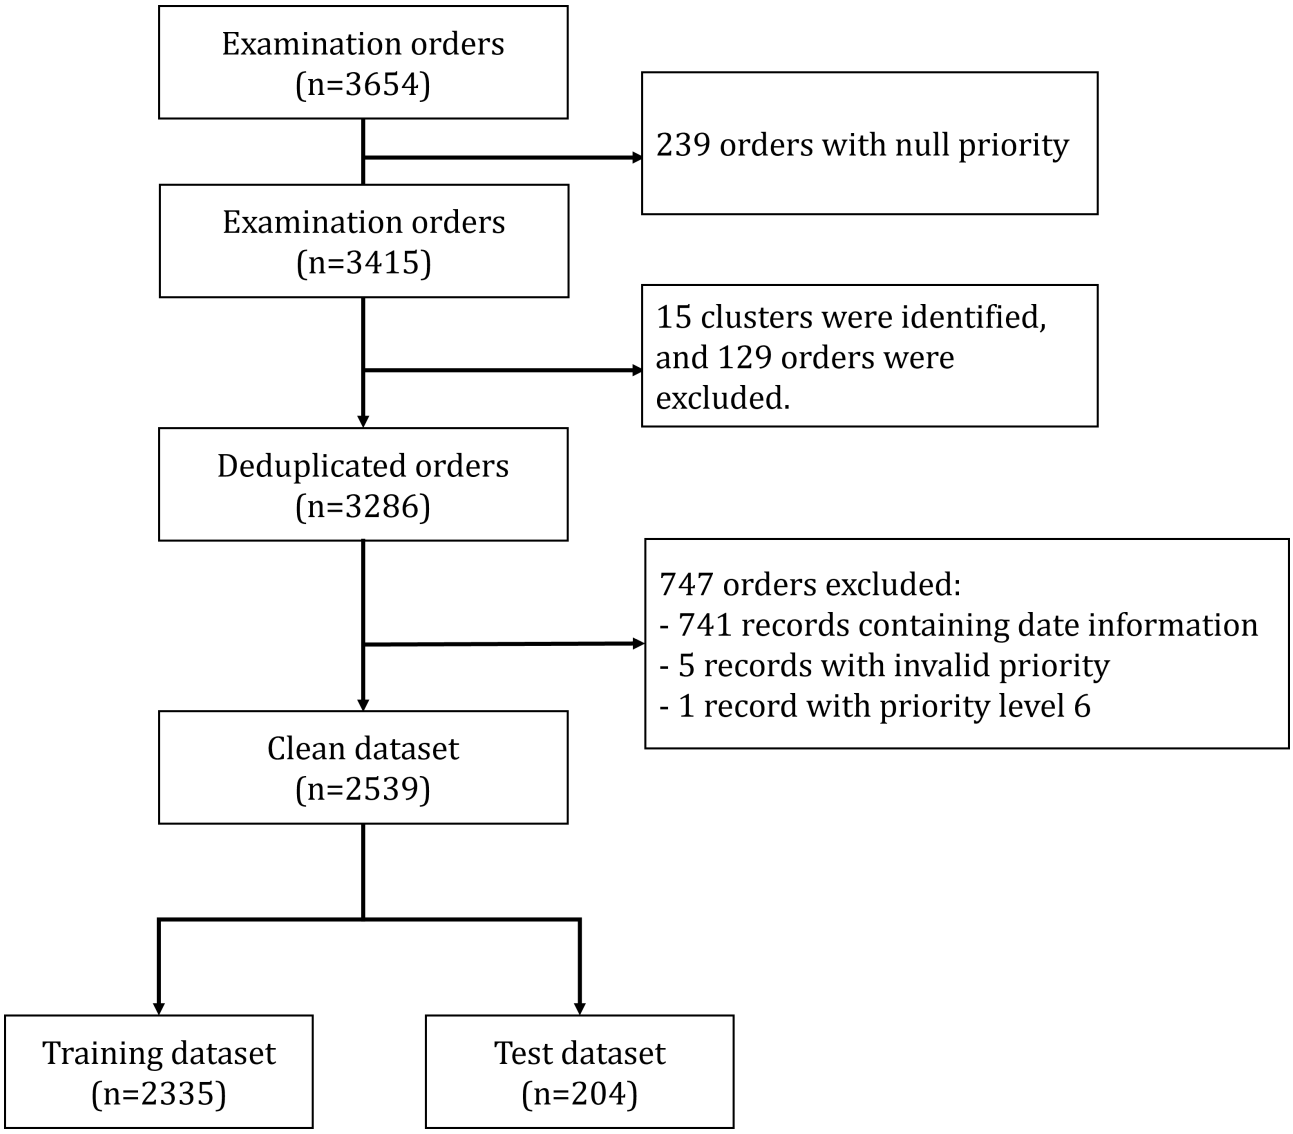
Error Analysis

We analyzed instances where the model's predictions deviated from the actual priority levels to identify potential biases and causes of errors. The error analysis was conducted on the model that achieved the best performance, as indicated by the highest Kendall score. We extracted all samples from the test dataset with an absolute error of >1. These errors were classified as either overestimations or underestimations. Each mispredicted sample was reviewed to determine the underlying patterns or

XSL•FO
RenderX

common characteristics contributing to the discrepancies. Discrepancies between the original and re-evaluation radiologist ratings were also investigated to assess the difficulty and consistency of priority estimation. In addition, we used the Shapley Additive Explanation (SHAP) [28] method to visualize the importance scores of each token in the input.

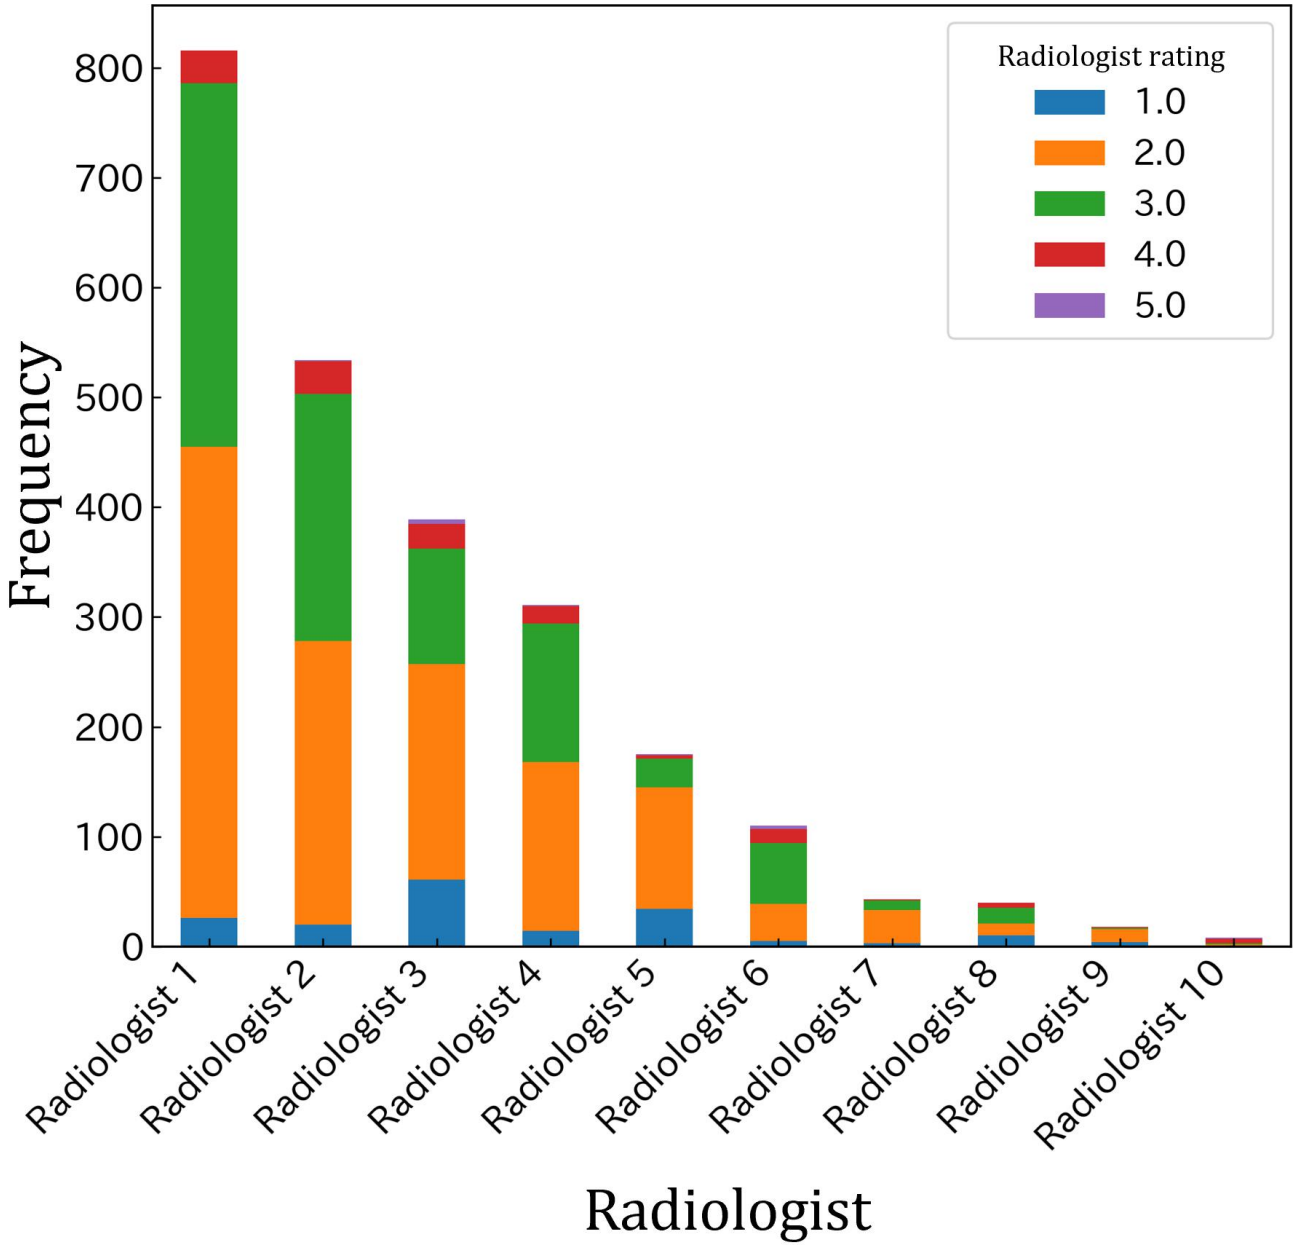
Ethical Considerations



This study received approval from the Research Ethics Committee of Keio University Hospital (approval number: 20170018) and adhered to the Declaration of Helsinki and other pertinent ethical guidelines. All patient data were processed on the machine located inside the hospital's secure intranet, isolated from the public internet, thereby ensuring participant privacy and confidentiality. The requirement for written informed consent was waived due to the retrospective observational nature of the study. The output of the AI models did not influence actual clinical practice.

Results

Dataset



The initial dataset comprised 3654 ultrasound examination requests. After text similarity aggregation and data cleaning, the final dataset consisted of 2539 records (Figure 2). These were further divided into training and test datasets of 2335 and 204 records, respectively, ensuring that requests from each referring doctor appeared exclusively in either training or test subset to prevent data leakage and maintain evaluation integrity. The distribution of assigned priority levels is depicted in Figure 3. Most requests were assigned priority levels 2 or 3, while requests at priority level 5 were extremely rare. The distribution of priority levels did not exhibit significant skewness despite variability in the number of requests reviewed by each radiologist.

Figure 2. Dataset flowchart.

XSL•FO
RenderX

Figure 3. The majority of orders are assigned to priority levels 2 or 3 with little skewness between radiologists.

Evaluation

Table 2 and Figure 4 show the performance of each model across different metrics. As expected, fully fine-tuned models outperformed the final-layer fine-tuned models. In particular, the fully fine-tuned JMedRoBERTa achieved the highest Kendall tau-b of 0.254. All the fully fine-tuned LLMs surpassed the baseline of conventional models, and notably, they also outperformed the radiologist re-evaluation in terms of Kendall tau-b. However, this result should be interpreted with caution, as it may reflect the inherent ambiguity of the priority estimation task, a topic that will be further discussed later. We observed that training all layers or using LoRA not only improved accuracy across all models but also narrowed the performance disparity between JMedRoBERTa and the other models. Regarding the classification tasks, JMedRoBERTa and Luke performed well, with ROC-AUC ranging from approximately 0.75 to 0.8.

For model-specific prediction trends, the JMedRoBERTa predictions (Figures 5A and B) revealed a trend where the distribution of AI-predicted values shifted upward as the actual priority level increased, indicating a positive correlation between AI predictions and the radiologists' assessments.

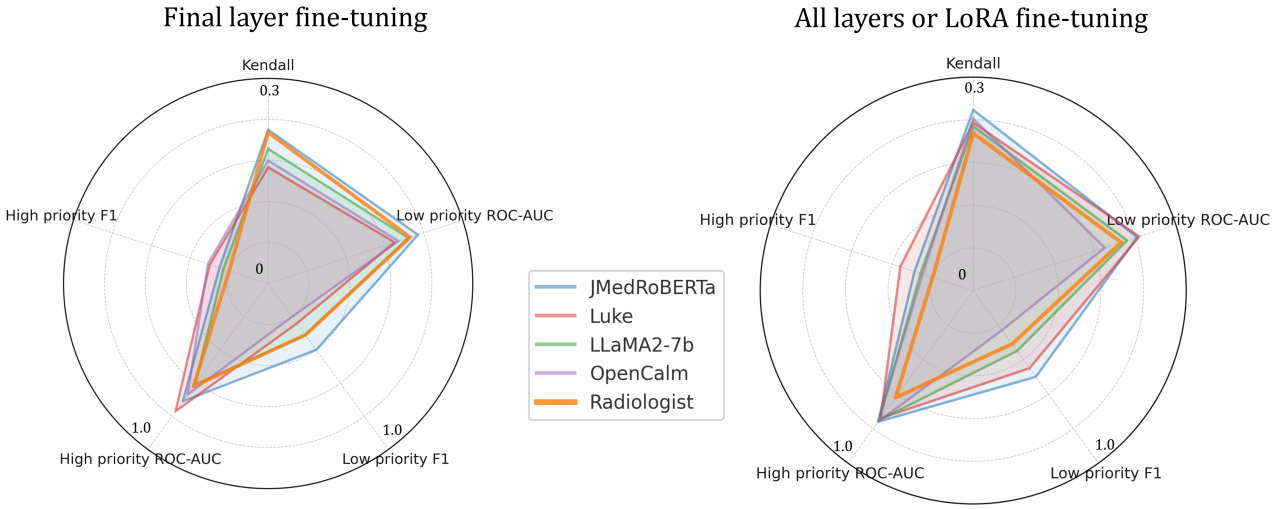
Radiologist re-evaluation	0.221	0.73	0.31	0.62	0.20

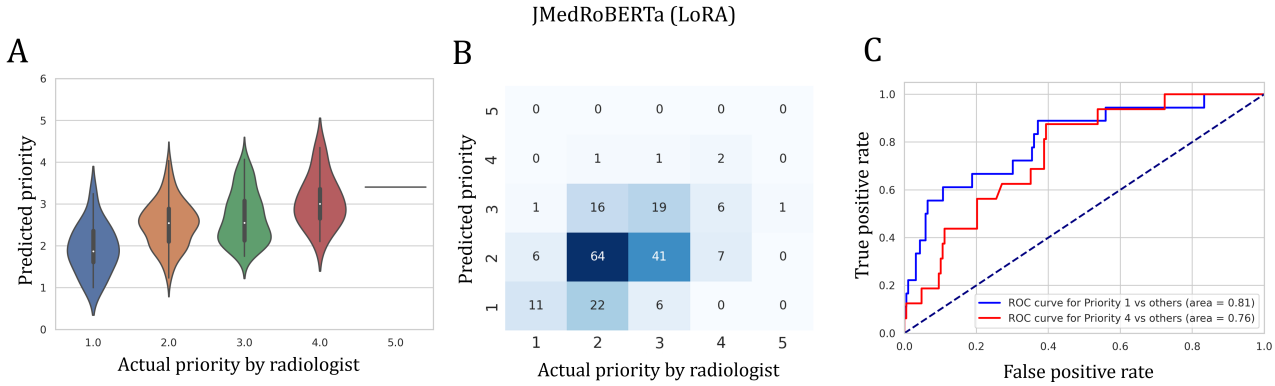
[a]ROC-AUC: area under the receiver operating characteristic curve.



[b]It should be noted that these were highly imbalanced classification tasks, and therefore, F_1-score tends to be lower. (A completely random classifier would yield an F_1-score of around 0.1).

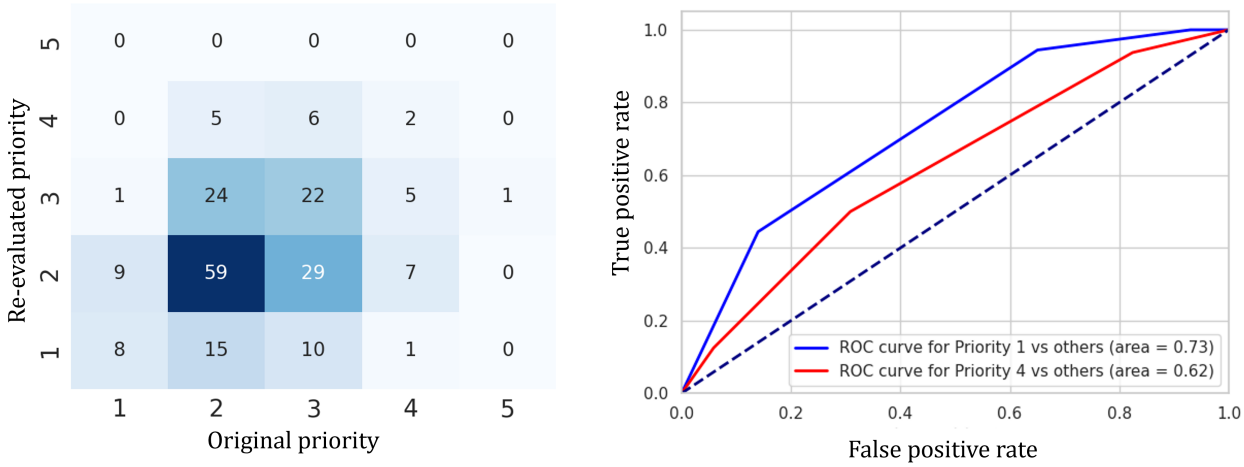
[c]Low-rank adaptation (r=32).

[d]SVM: support vector machine.



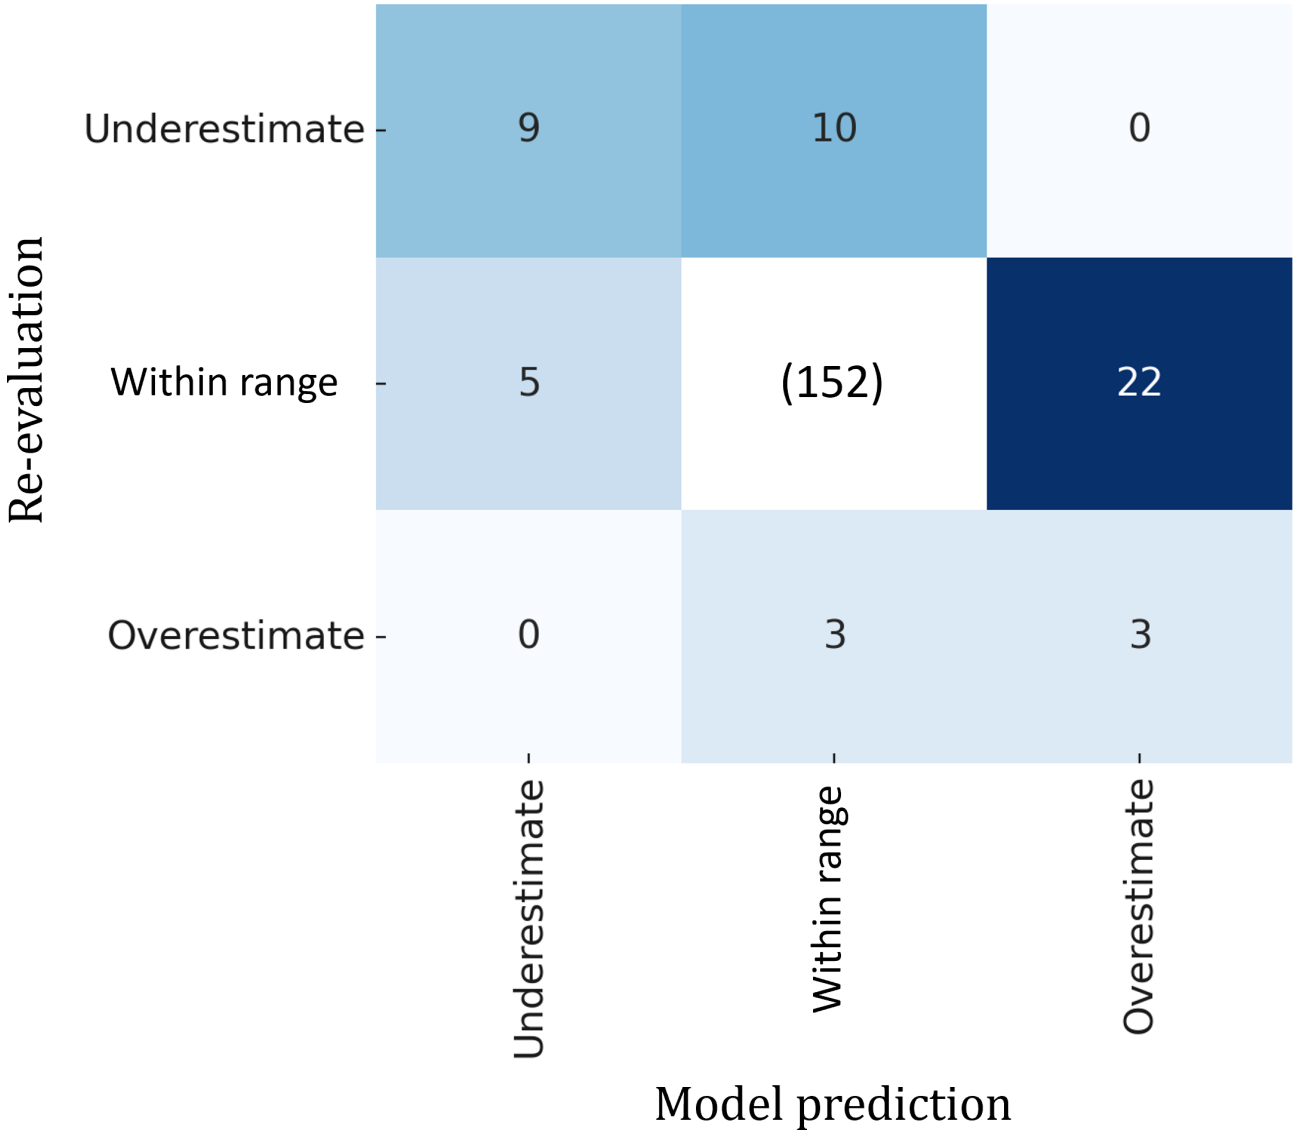
[e]XGBoost: extreme gradient boosting.

Figure 4. All layers or low-rank adaptation fine-tuning improves accuracy in all models, narrowing the performance gap between the medical language model and other general-purpose language models. LoRA: low-rank adaptation; ROC-AUC: area under the receiver operating characteristic curve.



XSL•FO
RenderX

Figure 5. JMedRoBERTa performance. (A) The distribution of priority levels predicted by the fine-tuned JMedRoBERTa model was mostly consistent with the radiologist rating except for confusion between priority levels 2 and 3. (B) Confusion matrix also shows that the model was primarily confused by priority levels 2 and 3. (C) The model detected low (<=1) or high (>=4) priority orders at an ROC-AUC of around 0.8. LoRA: low-rank adaptation; ROC-AUC: area under the receiver operating characteristic curve.



A total of 39 error cases (absolute error>1.0) were identified, including 25 overestimated and 14 underestimated cases. The most common misclassification was confusion between priority levels 2 and 3, which was also observed in the radiologist re-evaluation (Figure 6). The tendency of errors made by radiologists and AI was similar (Figure 7). A more detailed analysis of these errors follows in the “Discussion” section.

Figure 6. Radiologist re-evaluation performance. Even a radiologist struggled in replicating priority level 2 and 3. ROC: receiver operating characteristic.

XSL•FO
RenderX

Figure 7. The model and radiologist tend to make similar types of errors, as seen in the upper left and lower right cells. Underestimation and overestimation are defined as a deviation of more than one level from the original radiologist rating.

Discussion

Principal Findings

This study used language models to predict priority levels for an ultrasound examination waitlist system. JMedRoBERTa, pretrained on a Japanese medical paper dataset, demonstrated the highest performance. Other models also performed comparably when fully fine-tuned or adjusted with LoRA. This section discusses a comparison of the performance of different models, focusing on domain and language adaptations. After that, the challenges of prioritizing tasks due to the variability of priority levels are addressed. Subsequently, the nature of the error samples is discussed, followed by the ethical and social implications. Finally, the limitations of the study and its conclusions are presented.

Domain and Language Adaptation

Comparing the performances of the models provides insights into the influence of model size, pretraining datasets, and fine-tuning methods on the cross-domain and cross-language adaptation capabilities of LLMs. The critical factor influencing performance in this experiment was the alignment between the pretraining dataset and the downstream task. JMedRoBERTa, pretrained on a Japanese medical paper dataset, achieved superior performance despite having the smallest model size. JMedRoBERTa could focus exclusively on learning the priority assignment rules, while other models had to contend with both unfamiliar vocabulary and priority assignment rules.

However, this observation may change as the number of model parameters increases. Models pretrained on nonmedical and non-Japanese data may benefit relatively more from a larger number of training samples. In particular, as the dataset size grows, a model's representational capacity (roughly reflected by the number of parameters) may become a more dominant factor than the similarity of its pretraining dataset, as sufficient data would enable such models to adapt to the downstream task domain.

Meanwhile, LoRA reduced the performance gap between domain-specific and general language models. Final-layer fine-tuning can be viewed as similar to zero-shot learning, as it only updates the final layer, which primarily serves to format

XSL•FO
RenderX

the output from internal representations rather than contributing to text comprehension. In contrast, fine-tuning all layers, rather than just the final one, allowed the models to better adapt to the specific domain and language of the downstream task. Although full-parameter fine-tuning theoretically offers superior performance than LoRA [29], it often remains impractical due to constraints in computational resources (primarily memory capacity). Consequently, parameter-efficient tuning remains crucial for applying LLMs to medical tasks.

While our study used LoRA for fine-tuning all layers, there are other parameter-efficient tuning methods. For example, Sukeda et al [30] highlighted LoRA instruction tuning as a promising approach for adapting LLMs to Japanese medical QA tasks [30]. In addition, quantization is a popular technique that significantly reduces memory requirements while maintaining performance [31]. Our findings support the effectiveness of parameter-efficient fine-tuning, demonstrating that general-purpose LLMs can achieve capabilities comparable to those of fully fine-tuned domain-specific models.

The influence of tokenization on task performance was minimal. Only the JMedRoBRETa tokenizer could accurately recognize medical terms. Conversely, the Luke tokenizer recognized only nonmedical Japanese words, often splitting medical terms into multiple tokens. The other 2 tokenizers failed to process most Japanese characters correctly, resorting to byte fallback, where single characters were segmented into multiple tokens based on their Unicode representation. However, all models delivered comparable performances when fine-tuned. Since LoRA tuning does not change the tokenizer, it is suggested that the tokenization quality minimally affects the performance of this specific downstream task.

Challenges in Reproducing Priority Assignments

Although the AI model outperformed the radiologist re-evaluation, this result does not necessarily indicate the superiority of LLMs in priority estimation. Instead, it highlights the inherent ambiguity of the task itself. The priority levels were originally assigned by board-certified radiologists with sufficient clinical experience; however, the relatively low interrater agreement suggests that the process is inherently subjective.

Priority assignments are influenced by various factors, some of which are only available in the real-time clinical setting, leading to discrepancies between the original and re-evaluation ratings. For instance, the number of pending orders, the availability of examination equipment, and seasonal variations such as holidays can impact decision-making. In addition, in urgent cases, physicians may directly consult radiologists or the examination department, a factor that will not be captured in the dataset used for AI training or the radiologist re-evaluation. Consequently, even experienced radiologists may find it challenging to precisely reproduce the original priority levels in a retrospective setting, and AI models face similar challenges.

To mitigate this, cases influenced by external factors should be excluded from the training dataset, with radiologists allowed to flag them. Also, enhancing request records with supplementary information would improve reproducibility. For instance, radiologists could annotate the reasons behind priority decisions, enabling AI models to learn their decision-making processes. Providing AI with comprehensive clinical notes could enrich the contextual information. While reviewing all patient charts to determine priority is impractical for humans, AI language models can process extensive text rapidly. This capability might enable AI models to exceed human performance in priority estimation.

Error Analysis

There were 25 overestimated cases and 14 underestimated cases. The model errors can stem from 2 main sources, which are the inherent difficulty of replicating the assignment and the limitations of the model. As described previously, replicating radiologists' priority assignments made in the clinical setting is inherently challenging, and both AI models and radiologists are affected by this uncertainty. In fact, as demonstrated in Figure 7, the model and the radiologist re-evaluation exhibited similar patterns of misclassification, with no instances where the model greatly overestimated while the radiologist greatly underestimated, or vice versa. This observation suggests that certain underlying factors (ie, inherent difficulty) may be causing both the model and the radiologist to make similar errors.

To investigate the error cases further, we examined which parts of the input text contributed most to the model's predictions using SHAP. However, interpreting SHAP values in transformer-based models presents certain challenges. Since these models capture contextual relationships more holistically than conventional approaches, SHAP values do not always highlight clinically meaningful tokens. The same word can have highly varying SHAP values in different inputs, and common tokens appearing in all samples may absorb baseline importance, leading to misleading attributions. To partly mitigate this, we adjusted SHAP calculations to reduce the influence of shared tokens and improve interpretability. Despite these limitations of SHAP in our context, some cases yielded meaningful insights. We present the representative cases in Textbox 3, and we will discuss each case below.

Despite these limitations of SHAP in our context, some cases yielded meaningful insights. We present the representative cases in Textbox 3, and we will discuss each case below.

Textbox 3. High-Shapley Additive Explanation tokens are shown in bold and underlined. Some cases exhibited insightful Shapley Additive Explanation values, demonstrating the model's focus on key terms or revealing sources of misprediction.

[Sample 1 (Original: 3, Re-evaluation: 4, AI prediction: 3.784)]

[Input (Japanese)] 診療科 : 整形外科; 検査項目 : 腹部上腹部; 依頼目的 : 胆嚢炎疑い

[Translated] Department: Orthopedics; Examination Item: abdomen, **upper abdomen**; Purpose: **Cholecystitis** is suspected.

[Sample 2 (Original: 4, Re-evaluation: 3, AI prediction: 3.634)]

[Input (Japanese)] 診療科 : 産婦人科; 検査項目 : 腹部 上腹部; 依頼目的 : 妊娠 15 週交通事故シートベルト痕あり肝機能微増しており, 肝損傷疑っております FAST は陰性ですが, 右側胸部の自発痛あります御高診お願いします

[Translated] Department: **OBGYN**; Examination Item: abdomen, upper abdomen; Purpose: A 15-week **pregnant** traffic accident with a seatbelt mark. Liver enzymes are mildly elevated, **and liver injury** is suspected. FAST is negative, but she complains of spontaneous pain in the right side of her chest.

[Sample 3 (Original: 3, Re-evaluation: 2, AI prediction: 4.070)]

[Input (Japanese)] 診療科 : 心臓血管外科; 検査項目 : 頸部 甲状腺 陰嚢 その他表在 頚動脈ドップラー; 依頼目的 : 下行大動脈瘤破裂後, 仮性瘤疑い。術前評価です。

[Translated] Department: Cardiovascular surgery; Examination Item: Thyroid, Scrotum, and Other Superficial Structures / Carotid Doppler; Purpose: **Suspected pseudoaneurysm** following a **ruptured** descending aortic aneurysm. **Preoperative evaluation**.

Sample 1: Acute Cholecystitis Suspicion

The AI model correctly assigned a high priority to a case of suspected acute cholecystitis, focusing on the keyword "cholecystitis." Given that ultrasound is the effective diagnostic tool for this condition and that surgical intervention may be required promptly, this prioritization aligns well with clinical expectations. This example demonstrates that when a request contains an explicit keyword suggesting a critical condition, the model can effectively capture its importance.

Sample 2: Traumatic Liver Injury in a Pregnant Person

For a pregnant patient involved in a motor vehicle accident with concerns of hepatic injury, the model was also assigned a high priority. SHAP analysis revealed that the model placed significant weight on the terms "pregnancy" and "liver injury," suggesting that it successfully incorporated both the trauma and the patient's physiological condition into its decision-making. The model's ability to recognize such contextual factors is encouraging.

Sample 3: Preoperative Evaluation for Aortic Aneurysm

In this case, a carotid Doppler was requested for the preoperative evaluation of a pseudoaneurysm following a ruptured aortic aneurysm. While "aneurysm" and "rupture" typically indicate urgency, this patient appears to be stable, and the surgery is scheduled rather than urgent. If this were an urgent surgical case, it would be unlikely for the doctor to request an ultrasound examination from the radiology department. In fact, radiologists assigned a midrange priority of 2 and 3, reflecting the nonemergent nature of the request. However, the model assigned a priority of 4, overestimating the urgency. This suggests that the model may sometimes overprioritize cases based on emergency-associated keywords without fully considering the clinical context.

Overall, SHAP analysis indicates that the model performs well in straightforward cases where the primary pathology is explicitly mentioned but struggles with nuanced clinical scenarios requiring deeper contextual understanding.

Clinical Implementation—Benefits

The current waitlist system already provides several clinical and operational advantages. Integrating AI could further enhance its efficiency by addressing the key limitations of ensuring rapid, fair, and consistent priority assignment. This section examines the benefits of the waitlist system and the role of AI in priority estimation separately.

A priority-based waitlist system offers multiple benefits. First, it improves clinical outcomes by facilitating faster ultrasound examinations for urgent cases, enabling timely clinical decisions. In addition, it can shorten hospitalization durations, especially when ultrasound examinations are critical for determining discharge eligibility. By increasing the transparency of the examination scheduling process, this system helps physicians estimate examination dates more accurately, thereby improving planning. Furthermore, effective prioritization supports better bed management and overall hospital efficiency, allowing for higher patient turnover and boosting institutional revenue.

Despite these advantages, the existing manual priority assignment process presents several challenges. Radiologists face an increased workload due to the need for subjective prioritization, leading to delays in determining priority levels. Furthermore, inconsistencies may arise from variations in clinical judgment, making prioritization less reliable.

AI offers a promising solution by automating the priority assignment process. AI models can deliver consistent, real-time estimations, improving the accuracy and objectivity of the waitlist system. By streamlining this process, AI can reduce the burden on radiologists and enhance both efficiency and standardization.

Clinical Implementation—Challenges

However, implementing AI alone does not address all challenges. Several critical factors must be considered to ensure the successful clinical adoption of AI-assisted waitlist systems.

For AI-driven prioritization to be effectively integrated into clinical workflows, health care providers must be well-informed

XSL•FO
RenderX

about its benefits and limitations to foster trust in the technology. While existing research shows a generally positive attitude toward AI in medicine [32,33], perceptions vary depending on the underlying technology, medical specialty, and cultural background [34,35]. For instance, the term "AI" encompasses a broad spectrum of technologies, from simple symptom checkers [36,37] to sophisticated LLMs [38,39]. Case studies that highlight the potential and challenges of medical AI applications will facilitate dialogue among stakeholders and accelerate the acceptance of AI in clinical practice [40].

The potential for clinically significant misclassifications remains a concern. If an urgent case is mistakenly assigned a lower priority, it could result in adverse patient outcomes. Even in situations where human evaluators might also struggle with classification, unclear responsibility could raise legal and ethical concerns regarding liability in medical decision-making.

AI models are trained on historical data, which may contain biases related to patient demographics, socioeconomic status, or institutional practices. If these biases are not addressed, they could lead to disparities in priority assignment. However, AI also offers the potential to mitigate human biases by providing consistent, data-driven prioritization. Identifying and minimizing biases through rigorous model evaluation is crucial to ensuring fairness and equity.

Integrating AI into existing hospital information systems, such as electronic medical records and order management platforms, requires substantial technical modifications. Furthermore, the costs associated with implementing, maintaining, and updating AI models may pose financial constraints for health care institutions. Assessing the cost-effectiveness and feasibility of AI adoption is critical to ensuring widespread integration.

In summary, incorporating AI into priority-based waitlist systems can enhance clinical efficiency, reduce physician workload, and improve patient care. However, addressing concerns related to user acceptance, legal and ethical responsibility, potential biases, and system integration is essential for successful implementation. Future research should focus on strategies to overcome these challenges while maximizing AI's clinical use in resource allocation.

Limitations

The primary limitation of this study is its focus on a single institution, which limits the external validity of the findings. Applying our model to other institutions or medical contexts would likely require retraining, as hospitals vary in specialty composition, resource allocation, and priority assessment criteria, all of which could influence model predictions. In addition, the dataset is restricted to Japanese text. Future research should aim to incorporate datasets from multiple institutions and languages. While this may present challenges due to variations in clinical practices and priority criteria, addressing these issues is crucial for evaluating the model's robustness and generalizability. Pretraining on a sufficiently large and diverse dataset could facilitate adaptation to new institutions with minimal effort.

Conclusions

This study demonstrates that language models can estimate examination request priorities with accuracy comparable to human radiologists and better than conventional NLP methods. Nevertheless, improvements in the reproducibility of priority rankings are required. The research also highlights the potential for adapting general-purpose models to domain-specific text through adequate fine-tuning, underscoring the flexibility and applicability of these models in specialized contexts. Further research should explore methods to address the ambiguity in priority assignment and validate the model's performance across multiple institutions.

Abstract

Background: Recent progress has demonstrated the potential of deep learning models in analyzing electrocardiogram (ECG) pathologies. However, this method is intricate, expensive to develop, and designed for specific purposes. Large language models show promise in medical image interpretation, and yet their effectiveness in ECG analysis remains understudied. Generative Pretrained Transformer 4 Omni (GPT-4o), a multimodal artificial intelligence model, capable of processing images and text without task-specific training, may offer an accessible alternative.

Objective: This study aimed to evaluate GPT-4o's effectiveness in interpreting 12-lead ECGs, assessing classification accuracy, and exploring methods to enhance its performance.

Methods: A total of 6 common ECG diagnoses were evaluated: normal ECG, ST-segment elevation myocardial infarction, atrial fibrillation, right bundle branch block, left bundle branch block, and paced rhythm, with 30 normal ECGs and 10 of each abnormal pattern, totaling 80 cases. Deidentified ECGs were analyzed using OpenAI's GPT-4o. Our study used both zero-shot and few-shot learning methodologies to investigate three main scenarios: (1) ECG image recognition, (2) binary classification of normal versus abnormal ECGs, and (3) multiclass classification into 6 categories.

Results: The model excelled in recognizing ECG images, achieving an accuracy of 100%. In the classification of normal or abnormal ECG cases, the few-shot learning approach improved GPT-4o's accuracy by 30% from the baseline, reaching 83% (95% CI 81.8%-84.6%). However, multiclass classification for a specific pathology remained limited, achieving only 41% accuracy.

Conclusions: GPT-4o effectively differentiates normal from abnormal ECGs, suggesting its potential as an accessible artificial intelligence–assisted triage tool. Although limited in diagnosing specific cardiac conditions, GPT-4o's capability to interpret ECG images without specialized training highlights its potential for preliminary ECG interpretation in clinical and remote settings.

KEYWORDS

artificial intelligence; cardiology; decision support systems; electrocardiogram; large language models; LLMs

Introduction

Artificial intelligence (AI) in the realm of medicine, including cardiology, has been consistently evolving. A significant recent AI milestone was achieved when a model, specifically ChatGPT by OpenAI, successfully passed the European Exam in Core Cardiology [1]. However, this evaluation focused solely on text-based multiple-choice questions, excluding those with audio

XSL•FO
RenderX

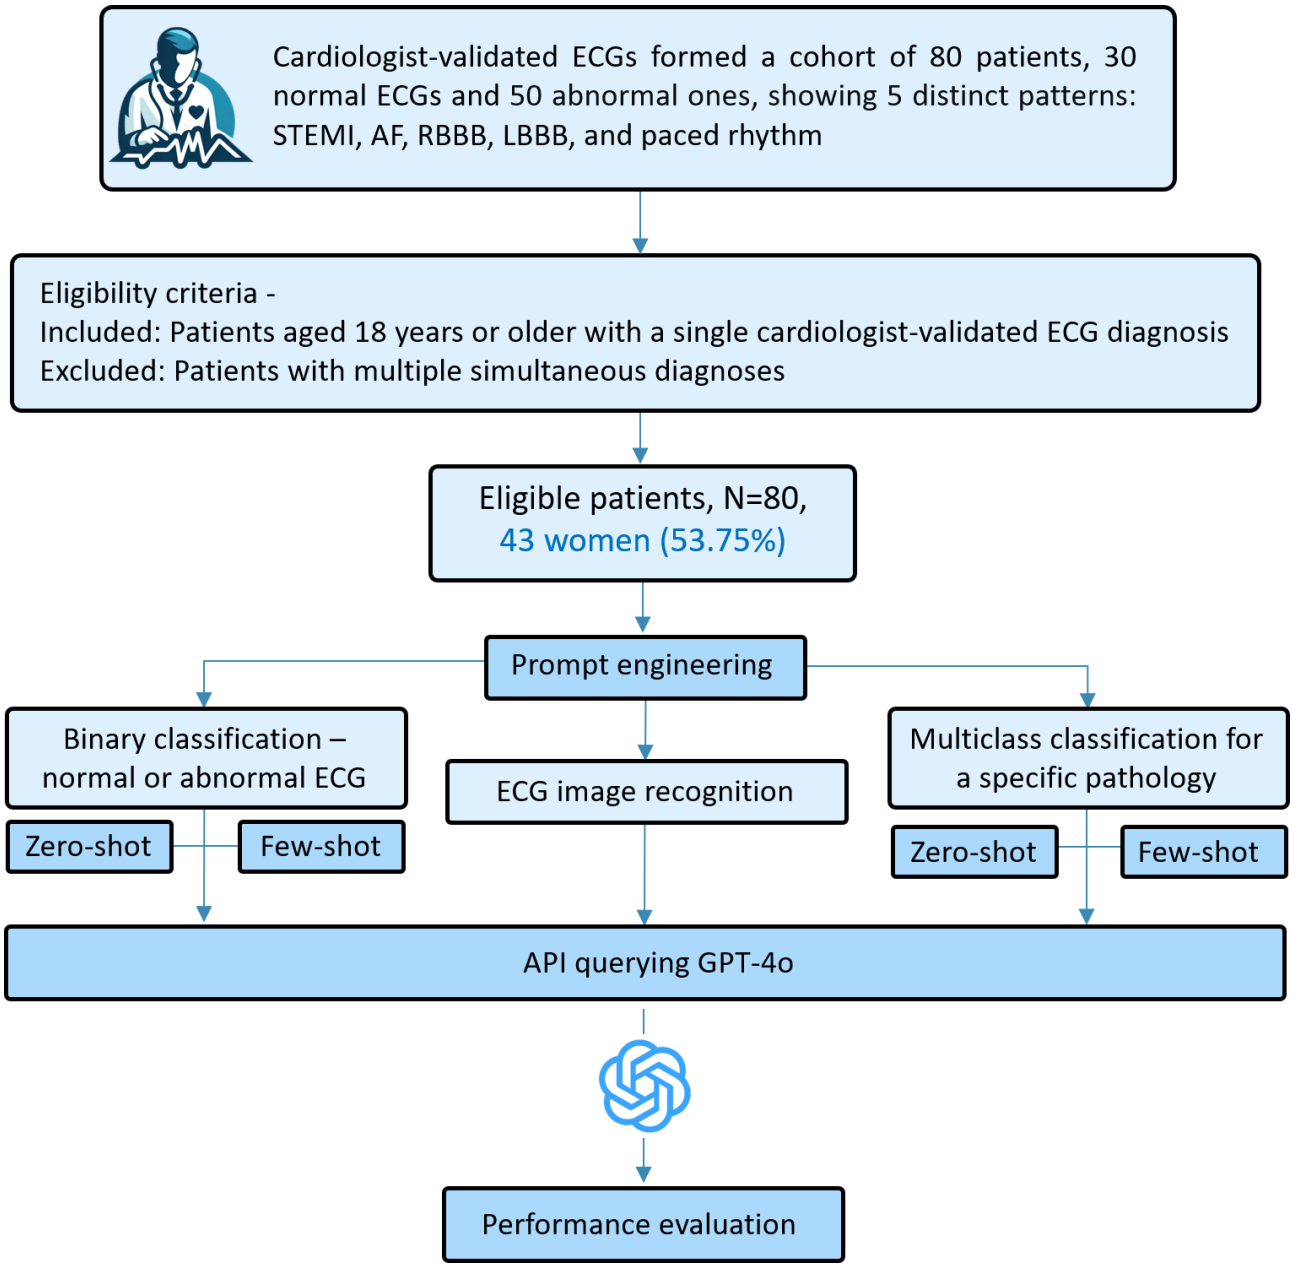
or visual elements. While this accomplishment is impressive, cardiology heavily relies on image interpretation and visual data for patient assessment [2].

Deep learning (DL), which uses neural networks for image-related tasks [3], has already demonstrated its significant impact in medical image analysis, including cardiology [4,5]. Moreover, it has been proven effective in predicting clinically significant abnormalities in electrocardiograms (ECGs), such as potassium levels and adverse reactions to medications, while also extracting valuable insights beyond human capabilities, such as estimating sex, age, and identifying specific cardiac conditions [6-10]. For example, Prifti et al [7] trained convolutional neural networks (CNNs) on short ECG recordings to accurately detect early signs of drug-induced cardiac effects and inherited rhythm disorders. In a separate study, Attia et al [9] demonstrated that deep CNNs could estimate a person's age and sex solely from the heart's electrical signals, tasks that even experienced cardiologists cannot perform reliably, highlighting AI's ability to uncover hidden insights from routine medical data. However, while DL has shown great promise, developing a DL model requires substantial efforts, including the collection of large, labeled datasets and extensive training for the specific task [11,12].

Large language models (LLMs), such as Generative Pretrained Transformer, specialize in processing human language using artificial neural networks [13]. The newly introduced multimodal LLM, GPT-4 Omni (GPT-4o) by OpenAI, advances this even further by seamlessly combining text and image data, presenting substantial potential benefits in the medical domain [14-18].

In emergency rooms, efficient patient triaging based on ECG findings is crucial. An AI model capable of distinguishing between normal and abnormal ECGs, even without offering a specific diagnosis, holds significant promise for improving patient care. The concept of "ECG triage" has the potential to transform how patients are prioritized for cardiology consultations.

This study aims to evaluate the ability of general purpose LLMs to interpret ECG images using zero-shot and few-shot learning strategies across a range of diagnostic tasks, including ECG recognition, binary classification (normal vs abnormal), and multiclass pathology classification. Our goal is to determine whether GPT-4o can perform these tasks with sufficient accuracy to support its potential role in clinical ECG triage and diagnosis.



Methods

Image Collection and Cohort Selection

The study design is depicted in Figure 1.

XSL•FO
RenderX

Figure 1. Research methodology overview illustrating the research methodology and portraying the high-level design of the method. AF: atrial fibrillation; API: application programming interface; ECG: electrocardiogram; GPT: generative pretrained transformer; LBBB: left bundle branch block; RBBB: right bundle branch block; STEMI: ST-segment elevation myocardial infarction.

The study included patients aged 18 years or older who underwent a high-quality ECG recording using the MUSE (GE HealthCare Technologies) system at our institute from August 2010 to February 2024.

A cohort of 80 arbitrarily chosen 12-lead ECG strips was assembled, covering 6 distinct electrocardiographic presentations. This included 30 records of normal ECG strips and an additional 50 ECG strips representing 5 distinct, common diagnoses (10 ECG strips of each different diagnosis): ST-segment elevation myocardial infarction (STEMI), atrial fibrillation (AF), right bundle branch block (RBBB), left bundle branch block (LBBB), and paced rhythm. These pathologies were chosen for their diverse representation of cardiac conditions, each with unique electrocardiographic features [19]. All ECG charts were anonymized, removing age and gender identifiers.

Data Validation

Each case underwent thorough validation via electronic medical record review, with ECG findings meticulously interpreted by a board-certified cardiologist. Only those patients with a singular diagnosis for each condition were included to ensure study validity; those with multiple diagnoses or low-quality images were excluded.

GPT-4o Prompt Engineering and Study Design

GPT-4o is a state-of-the-art multimodal model proficient in analyzing both image and text inputs. We used the OpenAI API to test whether it can interpret ECG images and classify them accurately into distinct categories. We tested three main scenarios: (1) Can GPT-4o recognize an ECG image? (2) Can GPT-4o classify an ECG image as normal or abnormal? (3) Can GPT-4o classify an ECG image into 1 of the 6 specific

XSL•FO
RenderX

diagnoses: normal ECG, AF, STEMI, LBBB, RBBB, and paced rhythm?

Learning Techniques

In scenarios 2 and 3, we evaluated 2 learning approaches—zero-shot and few-shot [20]. The zero-shot approach involved providing the model with only a textual instruction describing the classification task, without any previous examples. In contrast, the few-shot approach included a limited number of ECG images, each labeled with its diagnosis, to serve as training data [21,22]. These examples were intended to guide the model in recognizing diagnostic visual patterns and applying them when analyzing new ECGs. To ensure unbiased testing, the evaluation excluded images used for training. For example, if 6 images were given as examples, 54 images were evaluated. This design optimizes training efficiency.

Prompt Formats

In some scenarios, we repeated the same task using three different prompt formats to assess how varying levels of complexity and detail affect model performance. The formats were (1) a basic prompt stating only the classification task, (2) a prompt that included the task along with brief descriptions of each class, and (3) a detailed prompt that combined the task with explicit textual guidance, instructing the model on specific visual features to consider when analyzing the ECG images.

Experimental Scenarios' Processes

The following section outlines the procedures and objectives of each experimental scenario designed to evaluate GPT-4o's ability to interpret ECG images. Table 1 shows the different experiments conducted across the 3 tested scenarios, and Multimedia Appendix 1 provides the exact prompts used in each experiment.

Table . Experiments description[a].

Experiment	Scenario	Technique	Task	Total, N	Few-shot training sample	Testing sample
1.1	1	Zero-shot	Recognize ECG[b]	60	0	60
1.2	1	Zero-shot	Classify ECG or not ECG	60	0	60
2.1	2	Zero-shot	Classify normal or abnormal. No textual guidance.	60	0	60
2.2	2	Zero-shot	Classify normal or abnormal. Minimal textual guidance.	60	0	60
2.3	2	Zero-shot	Classify normal or abnormal. Textual guidance was provided.	60	0	60
4.2	2	Few-shot	Classify normal or abnormal—learn 6 examples. No textual guidance.	60	6	54
4.3	2	Few-shot	Classify normal or abnormal—learn 6 examples along with added textual guidance.	60	6	54
4.4	2	Few-shot	Classify normal or abnormal—learn 10 examples along with added textual guidance.	60	10	50
3.1	3	Zero-shot	Classify into 6 classes (normal and 5 pathologies). No textual guidance.	60	0	60
3.2	3	Zero-shot	Classify into 6 classes (normal and 5 pathologies). Textual guidance was provided.	60	0	60
5.1	3	Few-shot	Classify into 6 classes (normal and 5 pathologies). Examples were provided.	60	6	54
5.2	3	Few-shot	Classify into 6 classes (normal and 5 pathologies). Examples were provided along with added textual guidance.	60	6	54

[a]The table summarizes the experimental design, including the scenario, prompting technique, classification task, total number of images used, and the number of examples provided in few-shot learning settings.

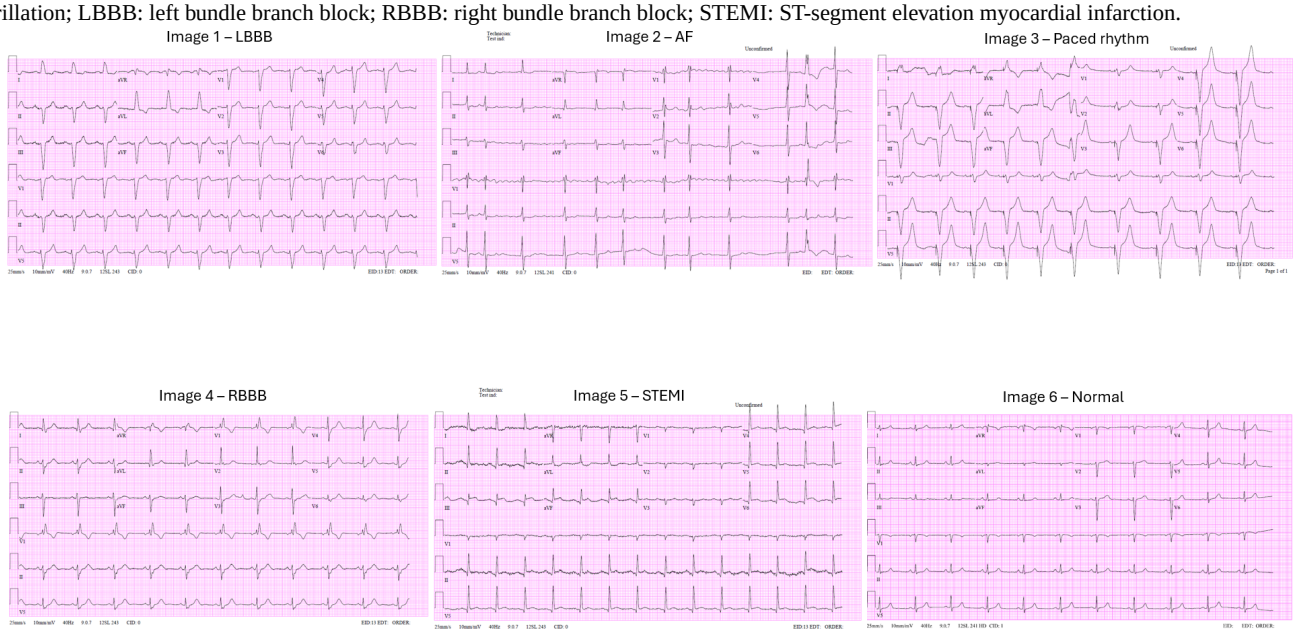
[b]ECG: electrocardiogram.

Scenario 1: ECG Image Identification

This scenario aimed to evaluate the GPT-4o model's ability to recognize ECG images. The dataset included 60 ECG images, each assessed individually by the model. Two experiments were conducted: the first (experiment 1.1) was a simple test to determine whether GPT-4o could recognize that the image presented was an ECG, using the prompt "What is this image? Output one line for the label." The second experiment

XSL•FO
RenderX

(experiment 1.2) explicitly asked the model to classify the image as either “ECG” or “not ECG.”



Scenario 2: Distinguishing ECG Images as Normal or Abnormal

This scenario aimed to evaluate the GPT-4o model’s ability to distinguish between normal and abnormal ECG images. The dataset included 30 normal and 30 abnormal ECGs (6 images from each of the 5 abnormalities). Using the zero-shot approach, ECGs were presented without previous examples or guidance. For few-shot learning, 3 experiments were conducted (4.2, 4.3, and 4.4). Two experiments used a single composite image made up of 6 examples (3 normal and 3 abnormal), with and without textual guidance. In the third experiment, 2 composite images with textual guidance were used, together containing 10 examples (5 normal and 5 abnormal). Each file contained a mix of normal and abnormal examples (Table 1 and Multimedia Appendix 1).

Scenario 3: Multiclass Classification for a Specific Pathology

This scenario aimed to assess the GPT-4o model’s ability to classify ECG images into specific abnormal categories. The dataset included 60 ECGs, with 10 images from each of 6 pathology classes. Using the zero-shot approach, ECGs were presented without previous examples or guidance (experiments 3.1 and 3.2). In the few-shot learning experiments (experiments 5.1 and 5.2), a single composite image comprising 6 examples (1 from each category) was used, with and without textual guidance. The composite image displaying the 6 pathologies is shown in Figure 2.

Figure 2. Composite image displaying the 6 electrocardiogram classes used in the multiclass classification few-shot learning approach. AF: atrial fibrillation; LBBB: left bundle branch block; RBBB: right bundle branch block; STEMI: ST-segment elevation myocardial infarction.

Study End Point

In both the binary (normal or abnormal) and multiclass classification scenarios, GPT-4o’s diagnostic output was compared with the reference assessments made by expert cardiologists who manually reviewed each ECG specifically for this study.

Evaluation Metrics

The agreement level between the GPT-4o predictions and the actual labels was evaluated using measures of accuracy, sensitivity, specificity, and F_1-score. The positive class was defined as abnormal ECG, with sensitivity representing the detection rate of abnormal ECG, and specificity indicating the detection rate of normal ECG. To ensure the robustness of the results, we repeated the best-performing experiment 5 times and reported both the average values of all evaluation metrics and their corresponding confidence intervals across runs.

Software and Statistical Analysis

Python (version 3.10; Python Software Foundation) was used to interface with the GPT-4o API and generate visualizations. Statistical analyses and performance metric calculations were conducted using R (version 4.4.2; R Foundation for Statistical Computing).

Sensitivity Analysis

To assess the robustness of GPT-4o’s performance, we conducted a sensitivity analysis using 2 additional models: a pretrained Vision Transformer (ViT) and Gemini 2.0 Flash (Google), the latest stable version of the Gemini model.

Vision Transformer

We implemented a pretrained ViT (vit_base_patch16_224, pretrained on ImageNet) using the timm library in PyTorch. The model was fine-tuned on 10 manually labeled ECG plots (classified as normal or abnormal). Only the classification head was trained, while the transformer backbone remained frozen. Training was performed over 7 epochs using the Adam optimizer (learning rate=1e-4). We also experimented with data augmentation techniques (random rotation and horizontal flipping), which did not improve performance in this small data setting. Model evaluation was performed on a held-out test set of 50 ECG images.

XSL•FO
RenderX

Gemini 2.0 Flash

We evaluated Gemini 2.0 flash (Gemini-2.0-Flash-001) using the official Vertex AI SDK (vertexai.generative_models) in Python. Each ECG image was submitted along with the same prompt used in the GPT-4o experiments (as described in the "Methods" section) except for the few-shot learning experiments, which were adapted to the structured format supported by the model. The model's textual output was parsed to assign a binary class label (normal or abnormal). We assessed accuracy, sensitivity, specificity, and F_1-score using the ground truth labels of the test set. We ran 1 iteration for each experiment and set the temperature parameter to 0.2 for consistency across runs.

Ethical Considerations

Ethical approval was obtained from the institutional ethics committee following standard institutional procedures (SMC-D-0522-23).

Results

Overview

The cohort consisted of 80 patients, with a median age of 69 (IQR 57.0-78.0) years, of which 53.8% (43) were females, carefully selected to ensure representativeness. Table 2 shows the number of patients in each ECG pathology group, the patients' age distribution, gender, and key ECG parameters that reflect the clinical and electrophysiological diversity of the cohort.

Table . Demographic characteristics and electrocardiogram parameters of the cohort patients.

Characteristics	Statistics
Total number of patients	80
Group, n (%)	
AF[a]	10 (12.5)
LBBB[b]	10 (12.5)
Normal	30 (37.5)
Paced	10 (12.5)
RBBB[c]	10 (12.5)
STEMI[d]	10 (12.5)
Age at ECG[e] (years), median (IQR)	69.0 (57.0-78.0)
Sex (female), n (%)	43 (53.8)
Ventricular rate, median (IQR)	72.0 (66.0-81.2)
QRS duration, median (IQR)	98.0 (84.0-138.0)
R axis, median (IQR)	4.5 (−42.8 to 46.2)
T axis, median (IQR)	44.0 (23.2-79.0)
Num QRS complexes, median (IQR)	12.0 (11.0-13.2)
Pacemaker, n (%)	10 (12.5)

[a] AF: atrial fibrillation.

[b] LBBB: left bundle branch block.

[c] RBBB: right bundle branch block.

[d] STEMI: ST-segment elevation myocardial infarction.

[e] ECG: electrocardiogram.

As part of a sensitivity analysis, we compared the performance of GPT-4o with Gemini 2.0 Flash and a pretrained ViT model. Since GPT-4o consistently outperformed the alternative models, we report the full sensitivity analysis results in Multimedia Appendix 2. The following sections present the classification results for each scenario using GPT-4o.

Scenario 1: ECG Image Identification

This scenario assessed the GPT-4o model's ability to recognize whether an image depicted an ECG. In both simple experiments (experiments 1.1 and 1.2), the model demonstrated excellent recognition ability, correctly classifying 100% of the images as ECG. These findings are consistent with previous work showing that the earlier model, GPT-4V, achieved 100% accuracy in recognizing medical modalities such as ultrasonography, computed tomography, and radiography [23], further supporting GPT-4o's reliability in fundamental image recognition tasks. However, we did not evaluate its performance in more complex scenarios, such as distinguishing electroencephalograms from ECGs.

XSL•FO
RenderX

Scenario 2: Distinguishing ECG Images as Normal or Abnormal

This scenario evaluated the GPT-4o model's ability to differentiate between normal and abnormal ECGs using both zero-shot and few-shot learning approaches. The zero-shot approach showed moderate to high success in diagnosis, with performance gradually improving with the addition of more auxiliary text: 53% without any text, 57% with minimal text, and 63% with extended text (Table 3). The sensitivity in the zero-shot experiments was very high, while the specificity was low, indicating that the model classified most cases as abnormal, including many that were normal. In the initial experiment, where no textual guidance was provided, the specificity was close to zero. Following this, we added the sentence "Normal ECG: Look for regular P waves, QRS complexes, and T waves with consistent intervals between them. Absence of significant abnormalities." to the prompt, thereby clarifying the definition of a normal ECG. As a result, specificity improved by 26%.

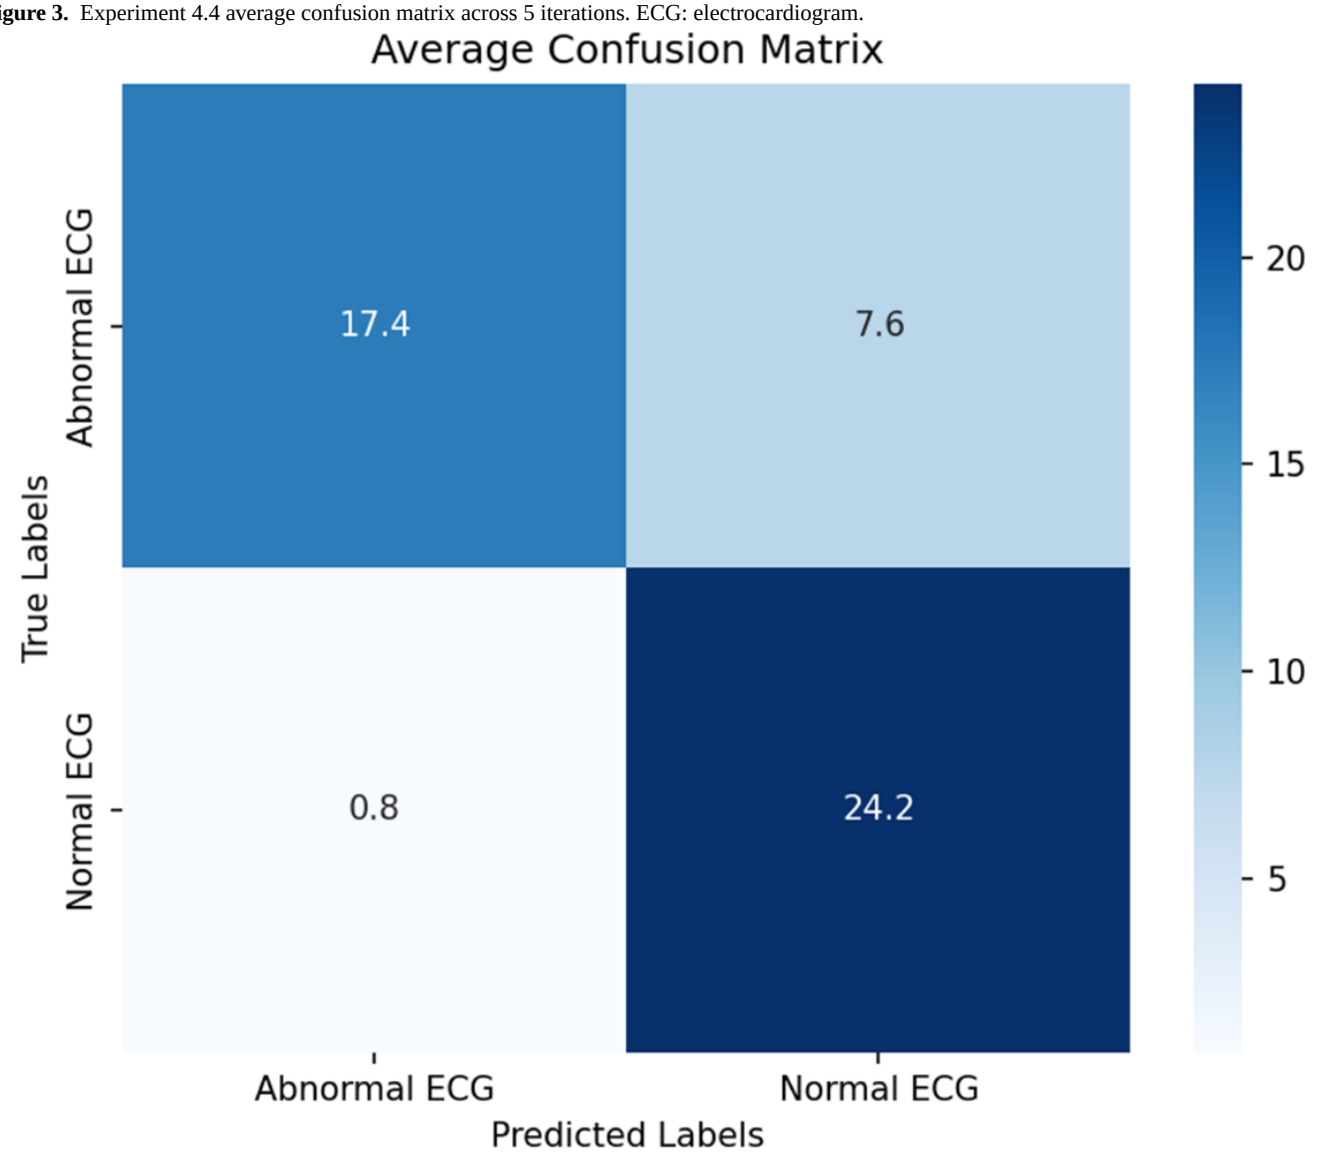


Table . Scenario 2 results.

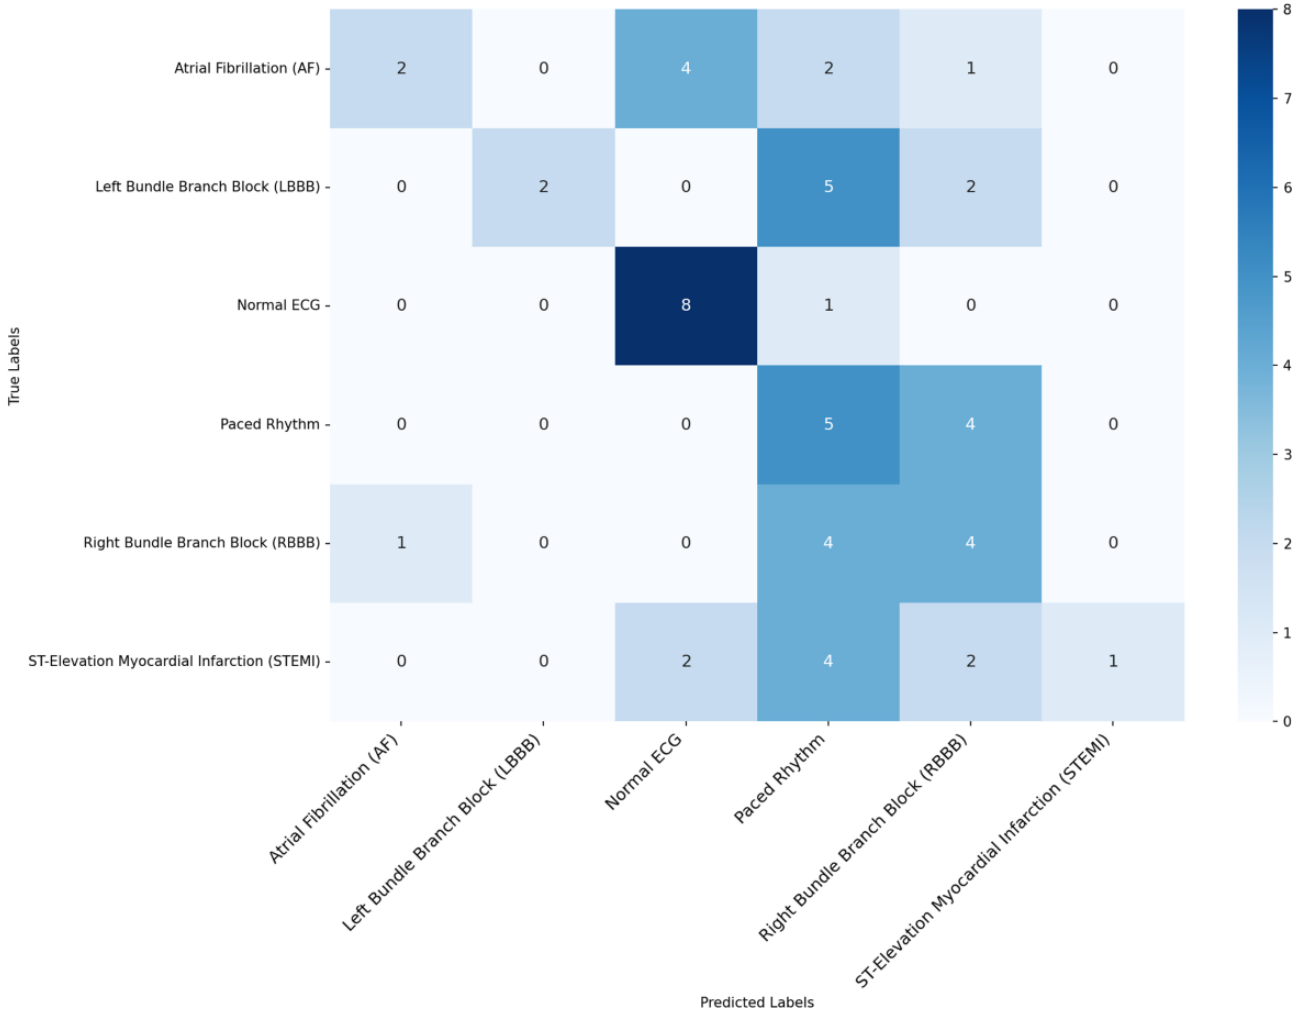
Experiment	Technique	Prompt type	Testing size	Accuracy	Sensitivity	Specificity	F_1-score
2.1	Zero-shot	No textual guidance.	60	0.53	1.0	0.07	0.68
2.2	Zero-shot	Minimal textual guidance.	60	0.57	1.0	0.13	0.7
2.3	Zero-shot	Provide textual guidance.	60	0.63	0.93	0.33	0.72
4.2	Few-shot	Learn 6 examples. No textual guidance.	54	0.72	0.67	0.78	0.71
4.3	Few-shot	Learn 6 examples along with added textual guidance.	54	0.8	0.67	0.93	0.77
4.4	Few-shot	Learn 10 examples along with added textual guidance—average results across 5 runs.	50	0.83	0.7	0.97	0.81

In contrast, the few-shot approach demonstrated enhanced accuracy, particularly in experiment 4.4. Incorporating 10 learning examples and additional guidance led to the highest classification performance, achieving an average accuracy of 83% (95% CI 81.8% - 84.6%), sensitivity of 70% (95% CI 62.9% - 76.3%), and specificity of 97% (95% CI 92.6% - 100.0%) across 5 runs (Table 3 and Figure 3). By adding textual guidance and providing examples, we improved the accuracy by 30% compared with the baseline model (experiment 2.1), indicating a significant improvement. Multimedia Appendix 3 shows 2 examples of the GPT-4o model's reasoning when classifying an image as a normal or abnormal ECG. We see from the reason it provides that it considers the R-R intervals, P waves, QRS complex, QRS duration, and T waves. However, the accuracy of these explanations was not formally evaluated in this study.

XSL•FO
RenderX

Figure 3. Experiment 4.4 average confusion matrix across 5 iterations. ECG: electrocardiogram.

Scenario 3: Multiclass Classification for a Specific Pathology



In identifying a specific pathology, both approaches showed low success. However, few-shot outperformed zero-shot, achieving an accuracy of 41% compared with 28%. In the few-shot scenario, textual guidance also led to improved results compared with the case without it (Table 4 and Figure 4). Notably, 89% of normal ECGs were correctly classified as normal. Paced rhythm was the most accurately identified cardiac condition, with an accuracy of 55.5%.

Table . Scenario 3 results.

Experiment	Technique	Prompt type	Testing size	Accuracy
3.1	Zero-shot	No textual guidance.	60	0.28
3.2	Zero-shot	Textual guidance was provided.	60	0.28
5.1	Few-shot	Six examples were provided.	54	0.31
5.2	Few-shot	Six examples were provided along with added textual guidance.	54	0.41

RenderX

Figure 4. Experiment 5.2 confusion matrix. Multiclass classification, few-shot learning. ECG: electrocardiogram.

Discussion

Principal Findings

This study assesses the image analysis capabilities of GPT-4o for interpreting ECG tests. The main findings reveal that GPT-4o's capabilities in recognizing and understanding ECG images can be significantly improved with prompt engineering and learning examples. In our case, accuracy improved by 30%. GPT-4o effectively identified the images as ECGs and demonstrated a solid theoretical understanding of ECG components and pathologies. Its performance in distinguishing normal from abnormal ECGs was moderate to high, with an average accuracy of 83% (95% CI 81.8% - 84.6%) across 5 repeated runs on the same 50 ECG examples, reflecting consistent performance. However, the model struggled with more granular classification tasks, achieving only 41% accuracy when identifying specific diagnoses. Furthermore, the study showed that few-shot learning surpassed zero-shot learning, and combining textual instructions with image examples led to better outcomes, achieving moderate to high accuracy and high specificity improvement compared with the baseline model. As part of a sensitivity analysis to contextualize GPT-4o's performance, we also evaluated Gemini 2.0 Flash and a pretrained ViT model; however, neither outperformed GPT-4o in this task.

Previous studies [24-31] extensively investigated DL AI models' diagnostic capabilities for classifying ECGs, achieving higher accuracy rates compared with our study, which explored the performance of LLMs in zero-shot and few-shot learning contexts. While previous studies have reported superior accuracy using specialized DL models (eg, CNNs and LCNNs), these approaches require substantial computational resources and model-specific training, limiting their accessibility in routine clinical practice. In contrast, multimodal LLMs such as GPT-4o provide a low-barrier alternative that could support medical professionals without specialized AI expertise.

Our findings also align with recent research on the robustness of multimodal models to domain shifts, such as ECG images, which differ substantially from the natural images seen during model pretraining. Previous work has shown that performance under such shifts can be improved through in-context learning strategies such as few-shot learning, as demonstrated in studies evaluating GPT-4V and other vision-language models [32-35]. In our study, this was evident in the improved performance observed with few-shot learning when distinguishing normal from abnormal ECGs. However, the model continued to struggle with identifying specific pathologies, as seen in scenario 3. Several factors likely contributed to this limitation. Certain cardiac conditions are inherently difficult to detect, as their features may be masked by noise, artifacts, or subtle waveform

XSL•FO
RenderX

variations [16]. These factors can mislead the model, especially with incomplete or atypical ECGs that do not match the patterns it learned during training [36], situations in which multimodal LMMs often fail to generalize effectively. Furthermore, the absence of clinical context may further constrain performance, as incorporating patient symptoms or medical history has been shown to enhance diagnostic accuracy [37]. Together, these factors likely contributed to the model's limited ability to accurately identify specific abnormalities.

When comparing our study with those investigating AI's diagnostic performance, a distinct contrast emerges. These studies, using DL models trained on large ECG datasets for specific diagnosis tasks ranging from arrhythmia to STEMI detection, consistently report high diagnostic accuracy rates, often exceeding 90% [24-29]. Conversely, compared with the studies focusing on binary classification of ECGs (normal vs abnormal) [30,31], our study achieved a moderate to high accuracy of 83% despite minimal training, and by that, highlighting the potential of accessible AI models for cardiac diagnostics. Conversely, compared with the studies focusing on binary classification of ECGs (normal vs abnormal) [30,31], our study achieved a moderate to high accuracy of 83% despite minimal training, and by that, highlighting the potential of accessible AI models for cardiac diagnostics.

In addition to its potential in cardiology, GPT-4o's image interpretation capabilities find relevance in various medical domains, such as radiology, neurology, and ophthalmology. Research in these fields indicates that while GPT-4o can identify imaging modalities and tackle intricate diagnostic tasks, its current success rates remain modest [14-17,33].

Consistent with these findings, our results suggest that although GPT-4o shows promise in medical image interpretation, it remains best suited as a supplementary tool to support, rather than replace, clinical expertise [15,16]. This is especially important given the risk of hallucinations and overconfident misclassifications that LLMs may produce when faced with ambiguous or unfamiliar inputs [38]. As multimodal AI models continue to evolve, further research is needed to refine their integration into diagnostic workflows and optimize their clinical use.

Limitations and Future Research

The current findings rely on a small retrospective sample of 80 patients. While this limited sample size constrains the statistical robustness of the findings, it was sufficient to support a focused proof-of-concept evaluation of GPT-4o's capabilities in ECG interpretation. The sample, although small, demonstrated consistent performance across repeated runs and helped highlight key challenges and opportunities in applying multimodal LLMs to ECG analysis. Moreover, our study acknowledges the documented potential impact of prompt wording variations on GPT-4o's responses [39]. Minor changes in prompts can significantly affect language models such as GPT-4o. Finally, our study solely evaluated GPT-4o with ECG recordings, excluding the patient's medical history, a departure from typical clinical practice, where attending physicians have access to comprehensive patient information. We hypothesize that incorporating these contextual data into the model could enhance diagnostic accuracy.

Future research could assess custom GPT-4o performance when it is enhanced with specific knowledge sources, such as cardiology textbooks, rather than solely instructions. Furthermore, to address the challenges observed in multiclass classification of specific diagnoses (scenario 3, Multimedia Appendix 4), future studies should explore few-shot learning setups that include multiple examples for each diagnostic class and test on a larger sample. As demonstrated in previous work, this approach can improve performance under domain shift conditions by enabling the model to generalize more effectively across diverse pathology patterns [36,40]. Finally, future work should consider evaluating more advanced models such as Gemini 2.5, which, while not yet part of a stable public release, has demonstrated strong performance in multimodal tasks and may offer improved capabilities for clinical ECG interpretation.

Conclusions

The current version of GPT-4o exhibits moderate to high proficiency in distinguishing between normal and abnormal ECG readings. However, its ability to diagnose specific cardiac conditions remains limited. Our findings suggest that GPT-4o's performance can be enhanced through prompt engineering and few-shot learning, highlighting its potential as a supplementary decision support system in clinical practice. Future improvements to the algorithm, particularly in fine-tuning its diagnostic capabilities, could further expand its use in medical image analysis.

Abstract

Background: Generative artificial intelligence (AI) is showing great promise as a tool to optimize decision-making across various fields, including medicine. In anesthesiology, accurately calculating maximum safe doses of local anesthetics (LAs) is crucial to prevent complications such as local anesthetic systemic toxicity (LAST). Current methods for determining LA dosage are largely based on empirical guidelines and clinician experience, which can result in significant variability and dosing errors. AI models may offer a solution, by processing multiple parameters simultaneously to suggest adequate LA doses.

Objective: This study aimed to evaluate the efficacy and safety of 3 generative AI models, ChatGPT (OpenAI), Copilot (Microsoft Corporation), and Gemini (Google LLC), in calculating maximum safe LA doses, with the goal of determining their potential use in clinical practice.

Methods: A comparative analysis was conducted using a 51-item questionnaire designed to assess LA dose calculation across 10 simulated clinical vignettes. The responses generated by ChatGPT, Copilot, and Gemini were compared with reference doses calculated using a scientifically validated set of rules. Quantitative evaluations involved comparing AI-generated doses to these reference doses, while qualitative assessments were conducted by independent reviewers using a 5-point Likert scale.

Results: All 3 AI models (Gemini, ChatGPT, and Copilot) completed the questionnaire and generated responses aligned with LA dose calculation principles, but their performance in providing safe doses varied significantly. Gemini frequently avoided proposing any specific dose, instead recommending consultation with a specialist. When it did provide dose ranges, they often exceeded safe limits by 140% (SD 103%) in cases involving mixtures. ChatGPT provided unsafe doses in 90% (9/10) of cases, exceeding safe limits by 198% (SD 196%). Copilot's recommendations were unsafe in 67% (6/9) of cases, exceeding limits by 217% (SD 239%). Qualitative assessments rated Gemini as "fair" and both ChatGPT and Copilot as "poor."

Conclusions: Generative AI models like Gemini, ChatGPT, and Copilot currently lack the accuracy and reliability needed for safe LA dose calculation. Their poor performance suggests that they should not be used as decision-making tools for this purpose. Until more reliable AI-driven solutions are developed and validated, clinicians should rely on their expertise, experience, and a careful assessment of individual patient factors to guide LA dosing and ensure patient safety.

Introduction

Generative artificial intelligence (AI), powered by large language models (LLMs), has emerged as a promising tool for enhancing medical decision-making [1]. These AI models, which process vast amounts of text data to generate human-like responses, have demonstrated capabilities in drug discovery and dosing optimization [2,3].

Recent studies have extensively evaluated the performance of generative AI models in medical question-answering scenarios. These models have shown promising results in medical licensing examinations [4,5] clinical case discussions and diagnostic reasoning [6,7]. However, their performance varies significantly based on task complexity. While generative AI models demonstrate strong capabilities in tasks requiring medical knowledge recall and explanation, they show limitations in scenarios demanding precise numerical calculations or complex clinical decision-making [8]. Understanding these varying capabilities of LLMs across different medical tasks is crucial when evaluating their potential role in clinical applications that require both medical knowledge interpretation and accurate numerical computations. This is particularly relevant for local anesthetic (LA) dosing, where calculation accuracy directly impacts patient safety [9,10].

LAs represent one such challenging area in clinical practice [11]. These drugs, used to induce temporary loss of sensation in specific body areas [12], require particularly careful dosing due to their narrow therapeutic window. The optimal dosing of LAs is complex, influenced by a variety of factors including patient-specific characteristics, underlying health conditions, and potential drug interactions [13].

Current methods for LA dose calculation rely heavily on empirical guidelines and clinician expertise, with no standardized recommendations universally adopted [14]. While several mobile apps exist for LA dose calculation, most allow the computation of potentially unsafe doses. Recently, LoAD Calc (Local Anesthetics Dose Calculator) was developed as a computational tool to systematize LA dose calculation [15], but like all specialized medical tools for dose calculations, it requires extensive validation to meet medical device regulations before clinical implementation. Meanwhile, health care providers increasingly turn to readily available AI models for clinical decision support [16,17]. Given this trend and the widespread accessibility of generative AI models, understanding their capabilities and limitations in LA dose calculation becomes crucial for patient safety. Empirical approaches and unsafe calculation tools can lead to overdosing and adverse outcomes, such as local anesthetic systemic toxicity (LAST) [18]. Understanding the capabilities and limitations of AI models in LA dose calculation is therefore crucial for patient safety, particularly given their widespread accessibility in health care settings [19].

In this context, generative AI emerges as a promising tool to enhance the precision of LA dose calculation. The aim of this study was to evaluate the efficacy and safety of 3 leading generative AI models in addressing the complexities of LA dose calculation. By analyzing their responses to a dedicated questionnaire including clinical vignettes, we sought to assess the accuracy and reliability of these AI algorithms in optimizing LA dosing and calculating maximum safe LA doses.

Methods

Study Design

This study is a comparative analysis of the performance of 3 generative AI models on the knowledge of LA dosing and computation of maximum doses in 10 simulated vignettes. Three of the most popular generative AI models: ChatGPT (OpenAI), Copilot (Microsoft Corporation), and Gemini (Google LLC), were exposed to a questionnaire about LA dose calculation once in June 2024.

Questionnaire

A 51-item questionnaire, derived from a protocol developed by anesthesiologists to test LA calculation by clinicians [20], included 3 questions on model performance in answering medical questions and output accuracy, 17 questions on LA dose calculation specifics, 1 introductory question on dose determination in clinical vignettes, and 10 clinical vignettes, each followed by 2 questions on the assessed safety of model outputs. These clinical vignettes were initially created to carry out a parallel group randomized controlled trial, the protocol of which has already been published [20]. The purpose of these vignettes was to compute the maximum safe dose of 3 commonly used LAs, alone or in combination (mixture of 2 different LAs). Different clinical settings were described, and the patients' physical characteristics, comorbidities, and medications varied significantly. The complete questionnaire is available in Multimedia Appendix 1.

AI Model Data Generation

We analyzed the latest stable versions of 3 generative AI models, namely ChatGPT-4.0, Microsoft Copilot, and Google Gemini 1.0. These models were selected due to their popularity at the time of the study, their widespread accessibility in health care settings, and their representation of current state-of-the-art technology from 3 leading AI companies (OpenAI, Microsoft, and Google) [21,22]. All models were accessed through their public web interfaces using standard parameter settings between noon and 5:00 PM UTC during our data collection period (June 19 - 24, 2024). Each model was presented with the exact prompts provided in the questionnaire (Multimedia Appendix 1) in a standardized sequence. Given the stochastic nature of LLMs, which can produce varying responses across multiple runs, we opted for a single-run approach to mirror real-world clinical scenarios where practitioners typically rely on single queries. The responses were recorded in a separate Microsoft Word file for subsequent analysis.

Definition of Maximum Safe Doses

The expected maximum safe doses were determined manually using a set of scientifically grounded calculation rules previously described and used in the development of the LoAD Calc app [15]. The anticipated results were calculated using the app itself. Before the study, these results were cross-checked by 3 anesthesiologists who manually recomputed the calculations

XSL•FO
RenderX

for each vignette using the LoAD Calc calculation rules, without using the app itself.

Typically, maximum safe doses are calculated in milligrams. However, in clinical practice, anesthesiologists administer a volume of LA, the concentration of which can vary, rather than a specific quantity of LA. Thus, while toxicity correlates with the quantity (in milligrams) of LA administered, it is more clinically relevant to determine the maximum volume (in milliliters) of LA suitable for a particular patient and a specific LA concentration. Therefore, half of the vignettes required calculating volumes while the other half dealt with milligrams.

Initially, each maximum safe dose was calculated in milligrams and then converted back to milliliters based on the concentration of the LA used in the vignette. This volume was rounded down to the nearest integer. An overdose was defined as any dose exceeding this maximum volume or its corresponding quantity of LA in milligrams.

Quantitative Evaluation

For the quantitative evaluation values in milligrams or milliliters given by each AI model were compared with the values computed with the full set of rules. Briefly, the first step was to determine the calculation weight (CW). To determine the CW, the BMI and ideal body weight (IBW) using Devine formula were calculated [23]. CW was capped at 70kg to ensure safe LA doses. The CW was determined as follows:

1. If actual weight (AW) was ≤70 kg, BMI<30 kg/m², and IBW >AW, then CW=AW.
2. If AW≤70 kg, BMI<30 kg/m², and IBW≤AW, then CW=IBW.
3. If AW≤70 kg and BMI≥30 kg/m², then CW=IBW.
4. If AW>70 kg and IBW>70 kg, then CW=70 kg.
5. If AW>70 kg and IBW≤70 kg, then CW=IBW.

Next, the maximum safe dose was adjusted based on patient factors affecting LA metabolism. For patients aged 70 years or older, with renal dysfunction (glomerular filtration rate <50 mL/min), hepatic dysfunction (prothrombin time <50%), heart failure (left ventricular ejection fraction ≤30%), pregnancy, or using major cytochrome P450 1A2 or 3A inhibitors (eg, ciprofloxacin and macrolides), the maximum dose was reduced by 20%. If 2 or more of these factors were present, it was reduced by 30%. A simplified calculation relies solely on the patient's AW or IBW to compute the maximum safe dose using the following formula [24]:

$$\text{Maximum dose (mg)} = \text{Weight (AW or IBW) (kg)} \times \text{Dose limit for chosen LA (mg/kg)}$$

While patient-specific adaptations are important for safety, a simplified calculation method relying solely on patient weight is more commonly used in clinical practice [19]. This dual approach reflects the complexity of LA dosing, where multiple calculation methods coexist. While we chose the comprehensive method as our primary evaluation criteria for its rigorous safety assessment, including the simplified method as a secondary outcome helps contextualize our findings within current clinical practices.

Qualitative Evaluation

To conduct a qualitative assessment, a comprehensive list of elements crucial for reproducing the calculation rules used by LoAD Calc was predefined. From this selection, a detailed list of items was compiled and organized in a Microsoft Excel file (Multimedia Appendix 2). The 2 independent reviewers were board-certified anesthesiologists with over 5 years of clinical experience in regional anesthesia and LA dose calculation. Their familiarity with LoAD Calc in both clinical practice and research settings ensured a thorough understanding of LA dosing principles. For each element, reviewers evaluated domains by considering the accuracy of dose calculations compared with reference values, consistency between stated principles and computed doses, and relevance of provided explanations to clinical practice. These aspects were synthesized into a single rating for each domain. This balanced approach aimed to evaluate the performance of AI models beyond just numerical accuracy. The reviewers, blinded to the AI models, assessed the performance of each AI for every predefined individual item on a 5-point Likert scale (1=very poor, 2=poor, 3=fair, 4=good, and 5=very good).

Outcomes

The primary outcome was the overall overdose rate using the comprehensive set of calculation rules used in the development of LoAD Calc. The secondary outcomes included assessing the overdose rate based on the simulated patient's IBW and AW, as well as examining the overdose rate associated with each studied LA. In addition, a qualitative evaluation was conducted to gauge the AI's proficiency in considering individual elements of the calculation process.

Statistical Analysis

Data were entered in an Excel Binary File Format (.xls) file and curated using Stata (version 17.0; StataCorp LLC). If ranges were suggested by the AI model, the lowest dose advised was used. Descriptive characteristics were reported using means and SDs, as were the LA values exceeding the reference doses. The frequencies of categorical variables were calculated and reported in percentages. An overall value was computed for the qualitative evaluation of each AI model and rounded to the nearest integer to report a consistent rating. Each element was also specifically analyzed, and ratings reported accordingly. When reviewers disagreed on a rating, the median value was computed and rounded to the nearest integer. Cronbach α coefficient was computed to assess inter-rater reliability.

Results

All 3 models were able to complete the questionnaire. The complete questionnaires with the answers given by each model can be found in Multimedia Appendix 3.

Gemini only generated 3 ranges of values (3/10, 30%), one for each LA tested. In the 2 instances where mixtures were used (2/3, 67%), the values provided exceeded maximum safe doses by 140% (SD 103%) (Table 1). This model's responses contained no precise dose calculations or specific doses or volumes, and included statements about consulting medical professionals for accurate dosing guidance.

XSL•FO
RenderX

Table . Detailed values provided by Gemini, ChatGPT, and Copilot for each vignette. The maximum safe doses were computed using the full calculation rules.

Vignette	Local anesthetic	Reference value	Mixture	Gemini	ChatGPT	Copilot
1	Ropivacaine (mg)	165	No	150	165	165
2	Levobupivacaine (mL)	9	Yes	15	20.6	10
3	Lidocaine (mg)	40	Yes	—[a]	270	270
4	Levobupivacaine (mL)	18	No	—	21	28
5	Levobupivacaine (mg)	110	No	—	240	240
6	Ropivacaine (mL)	18	Yes	—	64	—
7	Levobupivacaine (mg)	82.5	No	—	120	150
8	Lidocaine (mL)	6	Yes	18.75	33.75	33.75
9	Ropivacaine (mg)	123.75	No	—	270	33.75
10	Ropivacaine (mL)	29	No	—	48	16

[a]Not available.

ChatGPT provided values for all vignettes. These values were unsafe in 9 cases (9/10, 90%). In unsafe cases, the values proposed by the AI model exceeded maximum safe doses by 198% (SD 196%; 129, SD 143 mg for lidocaine, 46, SD 58 mg for levobupivacaine, and 70, SD 67 mg for ropivacaine).

Copilot provided values for 9 cases (9/10, 90%). These values were always safe when ropivacaine was the LA tested. They were nevertheless unsafe in the 6 cases where either lidocaine or levobupivacaine were used (6/9, 67%). In these cases, the values proposed by the AI model exceeded maximum safe doses by 217% (SD 239%; 129, SD 143 mg for lidocaine and 52, SD 60 mg for levobupivacaine). When values lower than the ones used as reference were given no details on the calculation were given. Detailed values are given in Table 1.

When considering IBW, the proportion of LA overdose remained unchanged with Gemini. It was of 70% (7/10) with ChatGPT and 56% (5/9) with Copilot. When the patient's actual weight was the only parameter taken into account to determine maximum LA doses, the values provided by Gemini were still too high in the 2 instances where mixtures were used (2/3, 67%). However, the proportion of LA overdose dropped to 40% with ChatGPT, and to 33% with Copilot.

The qualitative assessments conducted by the 2 independent reviewers showed high consistency, with a Cronbach α value of 0.87 and no differences exceeding a single level on the Likert scale. A total of 5 disagreements were recorded for Gemini and Copilot (5/8, 63%), and only 1 for ChatGPT (1/8, 13%). Gemini was rated as "fair," while both ChatGPT and Copilot were rated "poor." Copilot had the highest rate of "very poor" ratings (3/8, 38%; Table 2).

Table . Qualitative analysis of Gemini, ChatGPT, and Copilot for specific local anesthetics dose calculation elements.

Criteria for dose adaptation	Gemini	ChatGPT	Copilot
Height and weight	Poor	Poor	Poor
Age	Fair	Poor	Poor
Renal dysfunction	Good	Good	Fair
Hepatic insufficiency	Fair	Poor	Fair
Heart failure	Fair	Poor	Poor
Pregnancy	Fair	Very poor	Very poor
Drugs decreasing LA[a] metabolism	Fair	Poor	Very poor
Use of LA mixtures	Poor	Poor	Very poor
Overall	Fair	Poor	Poor

[a]LA: local anesthetic.

Discussion

Principal Findings

In this study, the evaluated generative AI models generally advised unsafe LA doses when confronted with realistic clinical vignettes. The analysis showed considerable variability in the outputs from these models, with Gemini's responses containing the fewest unsafe doses but also providing the least number of specific recommendations. Importantly, most AI-generated doses were deemed unsafe when evaluated against a comprehensive set of calculation rules that prioritize the lowest,

XSL•FO
RenderX

safest dose. Even when using less stringent criteria, AI models still tended to recommend excessively high doses, raising serious safety concerns about their potential use in clinical practice.

While our study focused on general-purpose AI models, it's worth noting that specialized tools for LA dose calculation are rare. As analyzed in our previous work [15], most available tools for LA dose calculation were found to be potentially unsafe, allowing computation of excessive doses. LoAD Calc, which served as our reference standard, was specifically designed to address these safety concerns. The significant performance gap between this purpose-built medical tool and general-purpose AI models highlights the importance of domain-specific knowledge and safety constraints in clinical applications.

While the models' responses included general recommendations about dose adaptation based on patients' comorbidities or treatments, when asked to perform specific calculations in the clinical vignettes, the calculated outputs showed significant inconsistencies. The limitations in dose adaptation calculations based on patient-specific factors, such as comorbidities or drug interactions, further underscore their limitations [8]. Personalized medicine requires an approach that AI models currently cannot provide adequately [10]. Furthermore, all models underperformed when tasked with calculating doses for LA mixtures, a common practice in anesthesiology, indicating their current inadequacies in complex clinical scenarios [25].

These findings align with previous research that has questioned the reliability of AI in critical medical applications. For instance, while AI has demonstrated promise in diagnostic imaging and drug discovery, its performance in decision-making tasks like diagnosis and dose calculation, remains inconsistent [26]. When processing multiple clinical variables, these models generate errors that can compromise patient safety [27,28].

The clinical implications are especially concerning given the severe consequences that can arise from LA dosing errors. When safe dosing limits are exceeded, LAST can manifest through central nervous system toxicity (seizures and loss of consciousness) and cardiovascular collapse. This is especially alarming for the high-risk scenarios in our vignettes involving patients with organ system dysfunction (hepatic, renal, or cardiac), advanced age, or concurrent medications affecting LA metabolism, where the safety margin is already reduced. The significant overdosing we observed with LA mixtures is particularly dangerous in clinical practice, as the combined toxicity of multiple agents can potentiate adverse effects and complicate resuscitation efforts if LAST occurs.

A notable concern was the lack of transparency in how AI models like Copilot arrived at their dose recommendations, sometimes suggesting lower, safe doses without clear explanations. This "black box" nature poses significant risks, as it prevents users from understanding the AI's decision-making process, potentially leading to errors [29]. In addition, AI models are susceptible to hallucinations, generating content that is not based on real or existing data and thus misrepresenting reality [30]. Previous research has also demonstrated that generative AI can fabricate references, misleading users into believing that the information provided is scientifically grounded [31].

In the qualitative assessment, Gemini received the highest overall rating for its explanations on adjusting doses according to different patient characteristics and medications. However, its tendency to withhold exact dosage recommendations, opting for a safer approach, diminishes its usefulness for dose computation. While this conservative approach of recommending specialist consultation aligns with safety principles, it limits practicality for real-time clinical use. As noted in previous research, optimizing Gemini to provide more direct answers to medical queries could enhance its use [32].

Given these outcomes, the applicability of these 3 generative AI models in clinical practice for LA dose calculation remains limited. The AI models tested were unable to consistently provide safe and accurate dosage recommendations, which is crucial in anesthesiology to prevent complications such as LAST. Health care professionals should exercise caution when considering the use of generative AI models for LA dose calculation. The study suggests that while AI has potential in certain aspects of medical practice, its application in dose computation for LAs is potentially dangerous and therefore premature. Until AI models can reliably incorporate complex, patient-specific factors and adhere to stringent safety guidelines, their role should be limited to supplementary tools rather than primary decision-makers [33,34]. Preference should be given to AI systems that are transparent in their decision-making processes, allowing clinicians to understand and verify recommendations. AI models that integrate continuous learning capabilities and up-to-date medical guidelines would be more suitable for clinical applications. At present, clinicians should prioritize their clinical judgment and experience, carefully evaluating individual patient factors to guide LA dosing and maintain patient safety.

This study evaluated generative AI models through their default public interfaces using standardized prompting, mirroring how health care providers would typically access these tools in clinical practice. This methodological choice was deliberate, as surveys indicate most clinicians use these models through standard web interfaces rather than fine-tuned versions or specialized prompting strategies [16,19]. While fine-tuning these models with domain-specific data on LA dosing might potentially improve performance, such customization requires technical expertise, computational resources, and access to proprietary APIs, resources generally unavailable to most health care providers. In addition, even fine-tuned models would require rigorous clinical validation equivalent to medical devices before implementation in clinical practice, highlighting the gap between technological capability and clinical applicability.

Our standardized prompting approach focused on obtaining direct dosing recommendations rather than explicitly requesting step-by-step reasoning processes, aligning with our primary research objective of evaluating output safety and reliability rather than reasoning transparency. As previous studies have noted, generative AI models can demonstrate a disconnect between reasoning and output accuracy, providing seemingly sound explanations for incorrect outputs or correct answers with flawed reasoning [6].

XSL•FO
RenderX

Limitations

This study has several limitations. The evaluation was based on simulated clinical vignettes, which, while designed to mimic real-world scenarios, cannot capture the full complexity of actual clinical practice. While our set of vignettes was designed to cover major clinical variables affecting LA dosing, we recognize that real-world scenarios present an even wider range of patient characteristics and clinical contexts. In addition, the study relied on predefined calculation rules and expert evaluations, which, while rigorous, may not encompass all possible clinical scenarios or dosing variations. Furthermore, the study focused on 3 specific AI models, currently available to the public, so the findings may not be generalizable to other generative AI systems or future iterations of these models. Another limitation is the static nature of AI models, which lack the ability to update their knowledge or reasoning processes in real-time. This is particularly problematic in medicine, where new research and clinical guidelines continually evolve. Without regular updates to their training data, AI models may quickly become outdated, leading to recommendations that do not reflect current best practices. Finally, our single-run methodology, while reflecting typical clinical usage where practitioners rely on single queries, presents a limitation given the stochastic nature of LLMs. This methodological choice prevents assessment of response consistency and reliability across multiple attempts, particularly relevant for drug dosing calculations, where response variability could have safety implications. Future research could explore whether fine-tuned models specifically trained on LA dosing guidelines or alternative prompting strategies requesting step-by-step reasoning might improve calculation accuracy. In addition, multiple runs should be considered to evaluate response consistency and establish confidence intervals for dosing recommendations. Such investigations could enhance our understanding of these models' limitations while maintaining the focus on patient safety.

Conclusion

In conclusion, while generative AI models like Gemini, ChatGPT, and Copilot offer significant promise, their current capabilities fall short in the critical area of LA dose calculation. The study's findings suggest that these AI tools are not yet ready for clinical use in this context, primarily due to their inconsistent performance and the potential for recommending unsafe dosages. Future advancements in AI technology must focus on enhancing the accuracy, transparency, and adaptability of these models to ensure they can be safely integrated into medical practice. Until then, reliance on clinician expertise and established dosing tools remains essential for ensuring patient safety.

Abstract

Background: Artificial intelligence has advanced significantly in various fields, including medicine, where tools like ChatGPT (GPT) have demonstrated remarkable capabilities in interpreting and synthesizing complex medical data. Since its launch in 2019, GPT has evolved, with version 4.0 offering enhanced processing power, image interpretation, and more accurate responses. In medicine, GPT has been used for diagnosis, research, and education, achieving significant milestones like passing the United States Medical Licensing Examination. Recent studies show that GPT 4.0 outperforms earlier versions and even medical students on medical exams.

Objective: This study aimed to evaluate and compare the performance of GPT versions 3.5 and 4.0 on Brazilian Progress Tests (PT) from 2021 to 2023, analyzing their accuracy compared to medical students.

Methods: A cross-sectional observational study was conducted using 333 multiple-choice questions from the PT, excluding questions with images and those nullified or repeated. All questions were presented sequentially without modification to their structure. The performance of GPT versions was compared using statistical methods and medical students' scores were included for context.

Results: There was a statistically significant difference in total performance scores across the 2021, 2022, and 2023 exams between GPT-3.5 and GPT-4.0 (P=.03). However, this significance did not remain after Bonferroni correction. On average, GPT v3.5 scored 68.4%, whereas v4.0 achieved 87.2%, reflecting an absolute improvement of 18.8% and a relative increase of 27.4% in accuracy. When broken down by subject, the average scores for GPT-3.5 and GPT-4.0, respectively, were as follows: surgery (73.5% vs 88.0%, P=.03), basic sciences (77.5% vs 96.2%, P=.004), internal medicine (61.5% vs 75.1%, P=.14), gynecology and obstetrics (64.5% vs 94.8%, P=.002), pediatrics (58.5% vs 80.0%, P=.02), and public health (77.8% vs 89.6%, P=.02). After Bonferroni correction, only basic sciences and gynecology and obstetrics retained statistically significant differences.

Conclusions: GPT-4.0 demonstrates superior accuracy compared to its predecessor in answering medical questions on the PT. These results are similar to other studies, indicating that we are approaching a new revolution in medicine.

Introduction

Artificial intelligence (AI) is a branch of science centered on the development of systems and algorithms capable of performing complex tasks that typically require human cognition. One well-known example is ChatGPT (GPT), introduced by OpenAI in 2019 [1]. Unlike other AIs, it relies on large language models and deep learning, which means that the tool uses vast amounts of text processed through deep neural networks to analyze and generate natural language with a high degree of complexity and precision, learning and evolving from its own mistakes. Its popularity stems from its ability to synthesize and interpret complex texts and respond to users within seconds. Instead of retrieving information directly from internet data sources, its responses are generated based on the probabilistic patterns of two or more words appearing together in a sentence. Since its launch, OpenAI has been making improvements and updating the tool, releasing GPT-v4.0 in March 2023, surpassing its predecessor, v3.5. The improvements

XSL•FO
RenderX

include image interpretation, greater processing power, the ability to solve complex problems, interpretation of more words in a single query, and more accurate responses with improved understanding of the nuances of human language.

Since its development, AI has been used in various fields of medicine, with new studies focusing on medical education [2-5]. When GPT-3.0 was challenged with the United States Medical Licensing Examination (USMLE), it scored approximately 60%, enough to pass the exam, a milestone in the academic field, as the tool passed all three steps of an exam, which together contain more than 1,000 questions and are recognized worldwide for their difficulty. This performance suggested that GPT-3.0 had intelligence similar to that of a third-year medical student [6]. In addition, Liu et al [7] in 2024, conducted a meta-analysis evaluating the performance of GPT on 45 medical examinations worldwide. The study found that v4.0 achieved an overall accuracy rate of 81%, outperforming GPT-3.5, and in most cases, surpassing the average scores of medical students. In this study, 29 of the articles used v4.0, 26 tested the performance of v3.5, and 14 studies tested both GPT-4.0 and GPT-3.5. This study also found that translating the test into English significantly improved the accuracy of GPT-3.5, but not GPT-4.0. Only one Brazilian study was included in the meta-analysis, which reported 87.7% of correct answers for GPT-4.0 when exposed to the Brazilian National Examination for Medical Degree Revalidation (Revalida); however, only GPT-4.0 was evaluated in this study [8].

The present article builds upon the work of Rodrigues Alessi et al [9] in 2024, who applied GPT 3.5 to the Progress Tests (PT) of 2021, 2022, and 2023, finding an average accuracy of 68.4%, surpassing that of medical students from all years [9]. Although Brazil lacks a national medical exam for resident selection or for newly graduated doctors, the PT is a national exam in which over 50,000 medical students participated in recent editions. It consists of 120 multiple-choice questions, each with five alternatives and only a single correct answer, equally distributed across the areas of surgery, pediatrics, social sciences, internal medicine, basic sciences, and gynecology and obstetrics. In 2021, the Brazilian Association of Medical Education (ABEM) administered a single national exam, whereas in 2022 and 2023, the exams were conducted across different regions of Brazil. These last two evaluations have a regional scope, encompassing certain conglomerates of states in the country. One of these nuclei is the South II Institutional Pedagogical Support Center (NAPISUL II), which includes a total of 13 universities from Paraná and Santa Catarina. It is worth noting that this exam is administered by the same group, with the same number of questions and covering the same six topics. The difficulty and the manner in which the questions are evaluated are similar.

The exact evolution between GPT 3.5 and GPT-4.0 in answering Brazilian medical questions remains uncertain. Therefore, this study aimed to assess and compare the performance of medical students and the two GPT versions in answering questions from a Brazilian national medical exam in its native language.

Methods

Overview

The study had an observational, cross-sectional design to evaluate the performance of GPT 3.5 and GPT-4.0 on 333 questions from the 2021, 2022, and 2023 Progress Tests (PT) in its original language, excluding questions with images, nullified questions, and repeated questions. Each question was manually inputted into the AI platform, with the tool's history cleared and session restarted after each question to avoid memory bias. Responses were categorized as correct or incorrect. In addition, the mean scores of first- through sixth-year medical students were compared using appropriate statistical methods to assess accuracy and effectiveness. Although ABEM did not release the number of students per year of medical school who participated in these tests, the approximate number of all tests together surpassed 50,000 medical students. All questions and the corresponding answer keys used in this study are publicly available.

Inclusion and Exclusion Criteria

A total of 360 questions (120 from each test) from the 2021 National PT and the 2022 and 2023 Regional Tests (NAPISUL II) were included. We excluded questions that included images or figures containing graphs, questions that were repeated across the three tests evaluated, and questions that were invalidated by the test organizers (those found after the exam was administered to contain errors or issues such as ambiguous wording, incorrect answers, or flawed reasoning).

As a result, 333 multiple-choice questions were included: 109 from the 2021 PT, 117 from the 2022 NAPISUL II Test, and 107 from the 2023 NAPISUL II Test, each containing only one correct answer among five possible alternatives (A, B, C, D, or E).

Procedures

First, each question included in the study criteria was submitted to the virtual platform GPT 3.5 and GPT-4.0 separately, and the responses were categorized into two possible outcomes, correct answer or incorrect answer, based on the official answer key for each test. To avoid memory bias, the platform's history was deleted and the site was restarted after each question was presented.

In instances where the platform selected more than one answer to be correct, a follow-up question—"Which is the most correct alternative?"—was asked to obtain a single answer and improve statistical interpretation. If the new AI response matched the official answer key, it was considered correct; otherwise , it was considered incorrect.

Thus, three possible outcomes were obtained for each question for GPT: (1) correct; (2) initially incorrect but aligned with the answer key after it was presented; (3) incorrect and did not align with the answer key after it was presented.

The results were compared between GPT v3.5, v4.0, and the students, divided into overall average scores (ie, from students from the first to sixth year) and scores for only sixth-year students. The results were also analyzed into the six main subject

XSL•FO
RenderX

areas of the test. For the 2021 test, the average percentage of correct answers per subject for students from the first to sixth year was not provided by ABEM, only the percentage per subject for sixth-year students was made public. Since the data were only available in averages, a statistical significance test could not be conducted.

Data Evaluation

The data were organized in an Excel spreadsheet and analyzed using SPSS (version 29.0.0; IBM Corp) software. For descriptive analysis of quantitative variables, the mean, standard deviation, median, minimum, and maximum were presented. The Wilcoxon nonparametric test was used to compare the accuracy rates between GPT versions-3.5 and GPT-4.0, and Bonferroni corrections was performed for the comparisons. A *P* value <.05 was considered statistically significant.

Ethical Considerations

This study only used information that was already publicly available on the internet and did not involve human subjects; rather, it was limited to an analysis of the PT performance. Therefore, approval by the institutional review board of Shimane University was not required.

Results

Main Findings

Based on the questions that met the inclusion criteria, our results showed that there is a statistically significant difference between the total performance scores of the three tests (2021, 2022, and 2023) between the GPT-3.5 and GPT-4.0 (*P* value .03). However, this difference lost significance after Bonferroni correction. The average accuracy for v3.5 was 68.4%, while v4.0 achieved an outstanding 87.2% accuracy rate. This indicates an absolute difference of 18.8% between the two versions and a relative improvement of 27.4% in accuracy in the latest platform version.

The mean scores by subject areas across the three tests were as follows for v3.5 and v4.0, respectively: 73.5% versus 88% for surgery (*P* value=.03), 77.5% versus 96.2% for basic sciences (*P* value=.004), 61.5% versus 75.1% for internal medicine (*P* value=.14), 64.5% versus 94.8% for gynecology and obstetrics (*P* value=.002), 58.5% versus 80% for pediatrics (*P* value=.02), and 77.8% versus 89.6% for public health (*P* value=.02) as shown in (Table 1). After Bonferroni corrections, only basic sciences and gynecology and obstetrics retained statistical significance.

The largest absolute difference in accuracy was observed in Gynecology and obstetrics (30.3%), corresponding to a relative improvement of 46.9%. Additionally, the smallest difference was in public health, with an absolute difference of 11.8% and a relative difference of 15.1%.

Among the 333 questions selected for the study, the overall average accuracy of GPT-3.5 for the 2021, 2022, and 2023 tests was 69.7%, 68.3%, and 67.2%, respectively. On the other hand, GPT-4.0 scored 87.8%, 86.4%, and 87.7% for the same tests during that period. Conversely, medical students scored 49.7%, 45%, and 57.4%, respectively. Among the sixth-year medical students alone, the average accuracy was 66.3%, 56.5%, and 60% for the respective tests. These results are illustrated in Figures 1 and 2.

In the 2021 test, due to the unavailability of students' subject-specific accuracy data, it was not possible to compare students' accuracy by subject against GPT. However, when comparing the overall accuracy scores, the scores were 49.7% for the students, 69.7% for GPT-3.5, and 87.8% for GPT-4.0. The values for GPT-3.5 and GPT-4.0, respectively, were as follows: 94.1% versus 94.1% (basic sciences), 68.7% versus 81.2% (surgery), 66.6% versus 66.6% (internal medicine), 50% versus 100% (gynecology and obstetrics), 59.0% vs 85.0% (Pediatrics), and 90.0% vs 100% (public health), as presented in Figure 3.

In the 2022 test, the overall scores were 45.2% for the students, 68.3% for GPT-3.5, and 86.4% for GPT-4.0. When evaluating the average accuracy per subject for students and GPT-3.5 and GPT-4.0, the results were as follows: 46.1% versus 73.6% versus 94.7% (basic sciences); 44% versus 68.4% versus 94.7% (surgery); 43.3% versus 65% versus 70% (internal medicine); 50.2% versus 68.4% versus 89.4% (gynecology and obstetrics); 42.3% versus 60% versus 80% (pediatrics); and 45.1% versus 75% versus 90% (public health), summarized graphically in Figure 4.

In 2023, the overall student score was 57.4%, compared to 67.2% for GPT-3.5 and 87.7% for GPT-4.0. The scores by subject for medical students, GPT-3.5 and GPT-4.0, respectively: 56.8% versus 64.7% versus 100% (basic sciences); 57.9% versus 83.3% versus 88.8% (surgery); 56% versus 52.9% versus 88.8% (internal medicine); 62.3% versus 75% versus 95% (gynecology and obstetrics); 56.9% versus 56.2% versus 75% (pediatrics); and 54.7% versus 68.4% versus 78.9% (public health), graphically illustrated in Figure 5.

The combined score analysis for the 2022 and 2023 tests, comparing medical students versus GPT-3.5 versus GPT-4.0, respectively was: 51.3% versus 67.8% versus 87% (overall); 51.5% versus 69.2% versus 97.3% (basic sciences); 51% versus 75.9% versus 91.7% (surgery); 49.7% versus 59% versus 79.4% (internal medicine); 56.3% versus 71.7% versus 92.2% (gynecology and obstetrics); 49.6% versus 58.1% versus 77.5% (pediatrics); and 49.9% versus 71.7% versus 84.4% (public health), as presented in Figure 6.

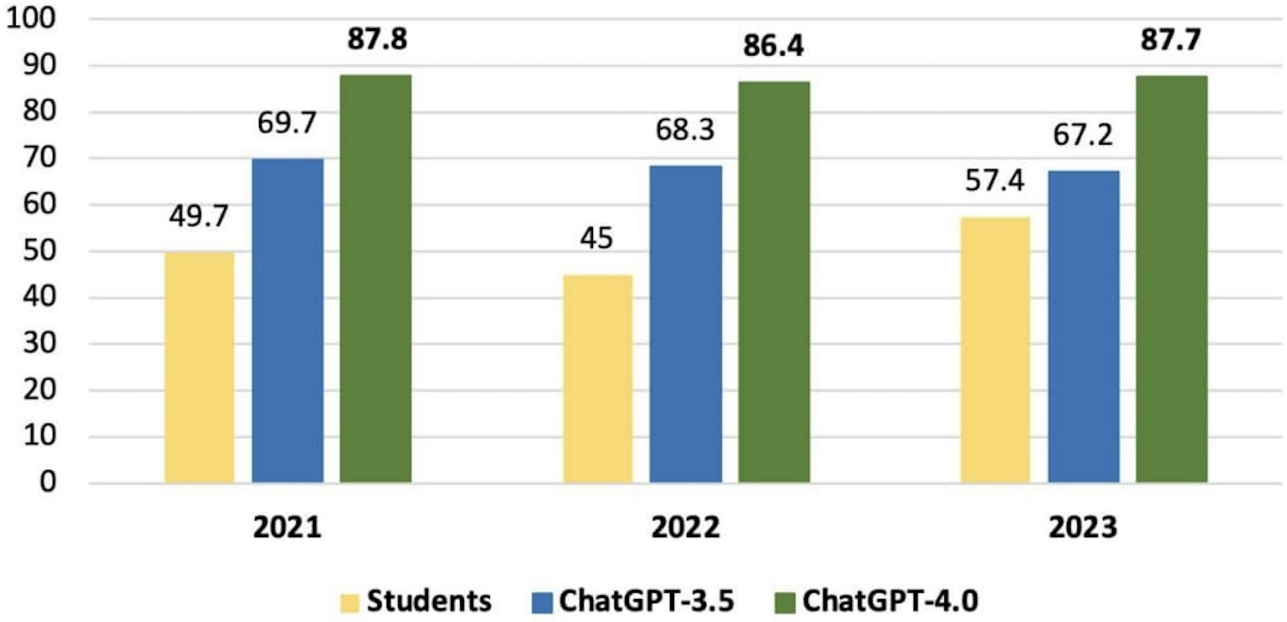
Data on average subject accuracy for sixth-year students in all three tests were made available by ABEM, which allowed to compare the accuracy of sixth-year students with GPT-3.5 and GPT-4.0. The results were as follows: 60.9% versus 68.4% versus 87.2% (overall); 54.8% versus 77.5% versus 96.2% (basic sciences); 51.2% versus 73.5% versus 88% (surgery); 53.8% versus 61.5% versus 75.1% (internal medicine); 56.7% versus 64.5% versus 94.6% (gynecology and obstetrics); 55.1% versus 58.5% versus 80% (pediatrics); and 55% versus 77.8% versus 89.3% (public health), as shown in Figures 7 and 8.

The latest AI version (ie, GPT-4.0) answered two new incorrect questions and 12 new correct ones for basic sciences; four new incorrect questions and 11 new correct ones for surgery; four new incorrect questions and 11 new correct ones for internal

XSL•FO
RenderX

medicine; two new incorrect questions and 18 new correct ones for gynecology and obstetrics; five new incorrect questions and 19 new correct ones for pediatrics; and two new incorrect questions and 10 new correct ones for public Health.

Table . Comparison of performance of GPT-3.5 versus GPT-4.0 based on the 6 test subjects and the overall score.



Subject	Version	Mean	*P* value[a]	*P* value[b]	Number of questions[c]
Surgery	v3.5	73.5	.03	.22	53
	v4.0	88.0			
Basic sciences	v3.5	77.5	.004	.03	53
	v4.0	96.2			
Internal medicine	v3.5	61.5	.14	.96	55
	v4.0	75.1			
Gynecology and obstetrics	v3.5	64.5	.002	.01	57
	v4.0	94.8			
Pediatrics	v3.5	58.5	.02	.15	56
	v4.0	80.0			
Public health	v3.5	77.8	.02	.15	59
	v4.0	89.6			
Overall	v3.5	68.4	.03	.20	333
	v4.0	87.2			

[a]Nonparametric Wilcoxon test was used and the statistical significance was defined as $P<.05$.

[b]Nonparametric Wilcoxon test with Bonferroni corrections was used and the statistical significance value was defined as $P<.05$.

[c]The number of questions from all three tests together is also present in the right column.

Questions Example and Responses

The answer key indicated that option C was the correct one, meaning GPT-4.0 selected the correct answer with a meaningful explanation, whereas GPT 3.5 made a mistake, but still tried to explain why it choose that alternative (Textbox 1).

XSL•FO
RenderX

Textbox 1. Questions Example and Responses

Questions Example

For demonstrative purposes, an example of a real question presented to GPT-3.5 and GPT-4.0 is presented below. All the text was inputted in Portuguese, and latter translated to English for better worldwide comprehension. However, it is important to highlight that all procedures in this research were conducted using the original language of the text.

Example questions: News reported that ovarian implantation technique can be successful in the field of fertility. A woman who suffered from leukemia had her ovaries removed and preserved in a laboratory; after undergoing treatment for the disease, she underwent reimplantation of the ovaries, successfully producing oocytes. After the medical-surgical procedure, it was possible to verify the growth and maturation of the oocytes. The hormones secreted by the pituitary gland and ovary, respectively, that induce ovulation are:

Response Options

A. Follicle-stimulating and estrogen; luteotrophic hormone.

B. Luteinizing and follicle-stimulating; progesterone.

C. Stimulating and luteotrophic follicle; estrogens.

D. Stimulating and luteotrophic follicle; progesterone.

GPT-3.5 answer: "The correct answer is option A: Follicle-stimulating and estrogens; luteotrophic hormone. Here is the explanation:

1. Follicle stimulating hormone (FSH): secreted by the pituitary gland, stimulates the growth and maturation of ovarian follicles, which contain oocytes. During this process, developing follicles secrete estrogens.
2. Estrogens: These are hormones produced by the ovaries (specifically by maturing follicles) and play a crucial role in regulating the menstrual cycle, promoting the growth of the endometrium, and preparing the body for a possible pregnancy.
3. Luteinizing hormone (LH) or luteotrophic hormone: It is also secreted by the pituitary gland and is responsible for triggering ovulation (the release of the mature oocyte from the follicle). After ovulation, LH promotes the formation of the corpus luteum, which secretes progesterone.

Therefore, ovulation is induced by pituitary hormones such as FSH, which stimulates the maturation of follicles and the production of estrogen and LH, which triggers ovulation."

GPT-4.0 answer: "The correct answer is option C: Stimulating and luteotrophic follicle; estrogens. The explanation is given below:

- FSH: Hormone secreted by the pituitary gland, responsible for stimulating the growth and maturation of ovarian follicles, which contain oocytes.
- LH: It is also secreted by the pituitary gland and responsible for the ovulation process, where the mature follicle releases the oocytes.
- Estrogens: These are hormones produced by the ovary, important for the development and maintenance of the female reproductive system, and in regulating the menstrual cycle. They also play a crucial role in inducing the LH surge, which results in ovulation.

Therefore, the correct sequence is FSH and LH (luteotrophic), both from the pituitary, and estrogens from the ovary."

Discussion

Principal Findings

GPT-4.0 displayed a high degree of superiority over its predecessor, improving its score by at least 10% across all subjects, with overall performance similar to those found in other studies. The average score of the three tests together was 87.2%, with a relative increase of 27.4% compared to the 3.5-version. Comparing the results obtained with those in the literature, which assessed the percentage of correct answers between the two GPT versions in various medical knowledge exams from different countries, it is noted that all studies found reported approximately 70% accuracy for GPT-4.0, with better performance by the new version and accuracy differences ranging from 5.34% to 32.1% [10-17]. A recent meta-analysis reviewing 45 studies that compared these two platforms in licensing examination tests across the globe found an accuracy rate above 80% for GPT-4.0, consistent with this study [7]. Like our results, Liu et al [7] in 2024 found many results surpassing human performance on the exams.

Reflections

However, the question remains: is this improvement aligned with expectations? Analysts, including Bill Gates, have raised concerns that AI platforms such as GPT may be approaching a performance plateau, with each successive update yielding diminishing returns [18]. While there are no direct comparisons between GPT-2.5 or GPT-3.0 on PT questions, the leap from GPT-3.5 to GPT-4.0 was substantial, as evidenced by a 27.6% relative score increase observed in our study. Although this evolution does not necessarily mean that future updates will not encounter stagnation, it suggests that the plateau has not yet been reached. As further updates and studies emerge, further comparison across applications will be crucial.

While the results were impressive, the most important takeaway from this study is that GPT can be a reliable source for learning when used in conjunction with other tools. Its potential applications in medical education include communication, knowledge retention, writing and interpreting texts and images, individualized and personalized study, creation of clinical cases, and hypothesis generation for diseases, especially the rarer or overlooked conditions [19-23].

XSL•FO
RenderX

Despite all of these, some schools are working to restrict the use of AI in classrooms, fearing that students will misuse it to complete assignments faster without learning. This view is flawed since the focus should be on educating professors and institutions on how to integrate AI into curricula effectively. If a student can easily complete an assignment using GPT, then perhaps the task itself needs re-evaluation. Time and resources should not be spent on a task that AI can perform better This technology is too new, and professors are still learning how to use it; therefore, more time will be required to train teachers on balancing the use of AI in class. Ultimately, machine learning could prove as transformative as the internet revolution in academic settings.

In medicine, AI is already being used for the creation of medical forms, assistance in diagnoses and decision-making, interpretation and reporting of exams, patient monitoring, cost reduction, education, probabilistic prognostic elaboration, identification of treatment responses, medical record creation, among other applications [2-5]. However, we cannot overlook the potential concerns involving its use. The main barriers are validation, usability, utility, and ethics [24]. More global research is still needed to generate more data on the use of AI in medicine. Only after extensive proof of superiority will its use be legalized [25]. Utility refers to the functionality of a tool being studied and improved through research and its use in various functions, while usability refers to the ability of health care professionals to use the tool to achieve satisfactory results [25]. Finally, ethical considerations are a cornerstone in integrating AI in medicine [26]. AI systems can pose risks to privacy and confidentiality, as sensitive patient data could be vulnerable to misuse or unauthorized access. Additionally, biases inherent in the algorithms, such as those resulting from biased training data or model development, can perpetuate disparities in health care, potentially leading to unfair outcomes for certain groups. Furthermore, deploying AI in areas without prior validation can raise concerns about its reliability and safety in clinical decision-making, as well as its impact on patient care. These challenges underscore the importance of addressing ethical principles such as transparency, liability, and fairness in the development and application of AI in health care, ensuring it serves all patients equitably and responsibly.

Another key issue with GPT is the phenomenon by which the tool creates fictitious and incorrect information, referred to as "hallucinations" [27]. This action is not fully understood, but it results in a plausible-sounding, yet incorrect answer for the user, without informing the user of its inaccuracy [25]. The most concerning issue is that GPT can create detailed and local explanations that are completely wrong, yet may look very convenient for the reader. This phenomenon may explain why the AI answered some questions incorrectly despite previously scoring correctly.

There remain many unsolved questions. How will AI affect the doctor-patient relationship? Will the new generation of doctors be dependent on technology or will it enhance their abilities? What will become of medical intuition? These questions will only be answered with time, but the impact of a good patient-medical relationship in treating diseases or improving medication adherence must not be overlooked [28]. Additionally, we must consider the increasing dependence on technology in current practice. A physician should be able to diagnose appendicitis through physical examination, without requiring a computer tomography. The future generations of doctors must understand how to use technology to their advantage, without forgetting the basics of medicine. Finally, medical intuition has been used for years to assist health care professionals when machines could not detect abnormalities [29]. The instinct, or "sixth sense" developed with years of medical practice cannot be taught or ignored at the expense of algorithms and probability formulas. The central challenge will be integrating AI into medicine while preserving the essential human touch in patient care.

Although we are still in a period of study and adaptation regarding the implementation of these new technologies in medicine, it is evident that AI will replace humans in certain areas. Daily, new research is published daily presenting the use of machine learning in image interpretation, clinical reasoning, laboratory test analysis, drug development, and more [2-5,23,24]. Unfortunately, those who fail to stay updated with these advancements will be at greater risk of being left behind in the job market. Most likely, individual qualities will shift drastically toward more human characteristics such as empathy, creativity, abstraction, leadership, communication, and flexibility. Professionals who learn to work alongside new technologies, forming a human-machine symbiosis to take advantage of their functions while remaining empathetic and human, will likely be the most valued in the future.

Limitations

Several limitations need consideration in this study such as the use of average student scores from the ABEM, which limits the ability to perform detailed statistical significance analyses. The AI's last data update was in 2021, which may affect performance on more recent topics. Additionally, the optional nature of the PT introduces potential selection bias, as not all students or universities participate. Finally, LLMs can generate different responses each time due to inherent stochasticity, it is important to note that this variability was not systematically assessed in the present study and should be addressed in future research. Addressing these limitations in new studies may provide even more insightful results.

Conclusions

GPT-4.0 demonstrates superior accuracy compared to its predecessor in answering medical questions on the PT. Its percentage of correct answers was higher across all subjects of the exam, even surpassing the scores of students from the first to sixth years of medical school. Although these findings are similar to previous studies, further research is required for the full implementation of AI in medicine. Nonetheless, it is evident that this technology is here to stay.

Abstract

Background: The use of artificial intelligence (AI), especially large language models (LLMs), is increasing in health care, including in dentistry. There has yet to be an assessment of the diagnostic performance of LLMs in oral medicine.

Objective: We aimed to compare the effectiveness of ChatGPT (OpenAI) and Microsoft Copilot (integrated within the Microsoft 365 suite) with oral medicine consultants in formulating accurate differential and final diagnoses for oral lesions from written clinical scenarios.

Methods: Fifty comprehensive clinical case scenarios including patient age, presenting complaint, history of the presenting complaint, medical history, allergies, intra- and extraoral findings, lesion description, and any additional information including laboratory investigations and specific clinical features were given to three oral medicine consultants, who were asked to formulate a differential diagnosis and a final diagnosis. Specific prompts for the same 50 cases were designed and input into ChatGPT and Copilot to formulate both differential and final diagnoses. The diagnostic accuracy was compared between the LLMs and oral medicine consultants.

Results: ChatGPT exhibited the highest accuracy, providing the correct differential diagnoses in 37 of 50 cases (74%). There were no significant differences in the accuracy of providing the correct differential diagnoses between AI models and oral medicine consultants. ChatGPT was as accurate as consultants in making the final diagnoses, but Copilot was significantly less accurate than ChatGPT (P=.015) and one of the oral medicine consultants (P<.001) in providing the correct final diagnosis.

Conclusions: ChatGPT and Copilot show promising performance for diagnosing oral medicine pathology in clinical case scenarios to assist dental practitioners. ChatGPT-4 and Copilot are still evolving, but even now, they might provide a significant advantage in the clinical setting as tools to help dental practitioners in their daily practice.

KEYWORDS

artificial intelligence; ChatGPT; Copilot; diagnosis; oral medicine; diagnostic performance; large language model; lesion; oral lesion

Introduction

Creating models that accurately replicate the complexity of the human brain and thinking has been a longstanding challenge for the scientific community [1]. The term “artificial intelligence” (AI) was first coined by John McCarthy in 1956, and this evolving scientific and engineering challenge focuses on computationally understanding intelligent behavior and creating applications that demonstrate such behavior [2]. AI has also emerged as a promising avenue for enhancing the precision and efficiency of diagnosing oral lesions. The diagnosis of pathological conditions within the oral cavity has traditionally relied on visual examination, histopathological analysis, and clinical expertise [3]. However, AI algorithms have the potential to analyze various data sources, including clinical images, patient records, and radiographs, to provide valuable insights

XSL•FO
RenderX

and suggestions for clinicians to facilitate the diagnosis of oral lesions [4].

ChatGPT is a recently introduced AI tool developed by OpenAI. ChatGPT is a large language model (LLM) trained with extensive data and capable of understanding and generating human-like responses accurately and consistently. ChatGPT currently operates on the GPT-4 architecture, allowing it to understand and respond to complex queries in a conversational manner [5]. ChatGPT can be used in medicine by rapidly providing appropriate answers to queries (or "prompts"), for instance, by assisting in decision-making based on up-to-date research and guidelines. There are high expectations for ChatGPT in the health sciences, including for education, research, and practice across different medical disciplines [6], and it can be embedded in various platforms.

Microsoft Copilot is another AI-driven assistant that can be accessed via a web interface or through seamless integration within the Microsoft 365 suite [5]. Leveraging LLMs and insights from Microsoft Graph, Microsoft Copilot delivers tailored support, enhancing the users' experience across Microsoft 365 applications such as Word, Excel, and PowerPoint. Copilot offers real-time suggestions and completions based on the context of the existing request. Powered by GPT-4 Turbo, it also has access to information, enhancing its utility for up-to-date coding tasks.

ChatGPT has also been used in several areas of medicine. For example, ChatGPT provided excellent responses on basic knowledge, lifestyle advice, and treatment for cirrhosis and hepatocellular carcinoma but performed less well for diagnosis and prevention [7]. In an analysis of ChatGPT responses to 284 medical questions, the results were highly accurate but incomplete [8]. AI has also been applied to dentistry [9-11]. In endodontics, AI models have been used to explore the anatomy of the root canal system, predict the health of dental pulp stem cells, detect root fractures and periapical lesions, and predict the success of retreatment procedures [12,13]. In oral medicine, ChatGPT was used to address questions about oral potentially malignant disorders. Guidelines on oral potentially malignant disorders from scientific societies were used to create questions for input into ChatGPT, which showed moderate knowledge about oral potentially malignant disorders as assessed by specialist reviewers [6]. AI also shows promise for scheduling, patient management, managing drug interactions, predictive tasks, and even robotic endodontic surgery [14], although the cost-effectiveness, reliability, and practicality of implementation still need to be assessed before widespread adoption [11].

To the best of our knowledge, no study has examined the use of AI-powered tools (ChatGPT and Copilot) in oral medicine, especially with respect to the diagnosis of oral lesions. To address this gap, herein, we compared the accuracy of ChatGPT and Copilot with oral medicine consultants in providing differential and final diagnoses from text-based clinical case scenarios.

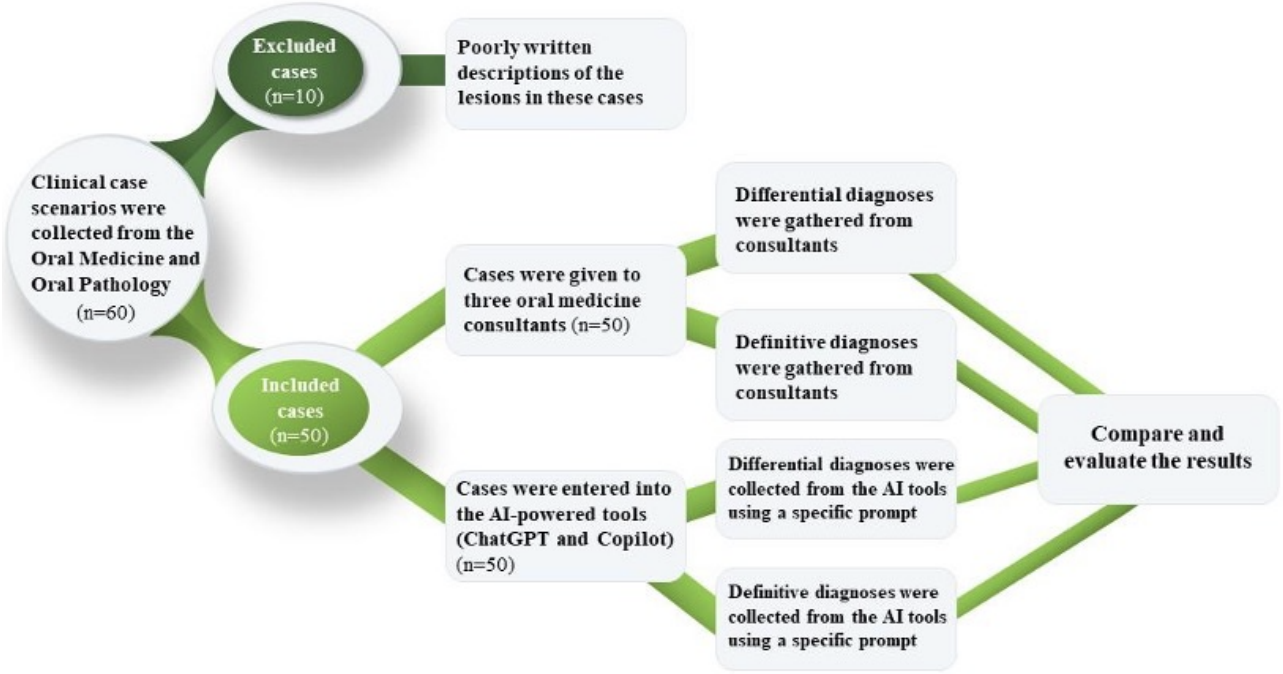
Methods

Study Design

This was a comparative analytical study conducted at the King Abdulaziz University Faculty of Dentistry in Jeddah, Saudi Arabia. The primary objective was to assess and compare the accuracy of ChatGPT and Copilot with oral medicine consultants for diagnosing oral lesions from written clinical scenarios.

Ethical Considerations

The Research Ethics Committee-Faculty of Dentistry, King Abdulaziz University granted ethical approval (no. 209-11-23).



Data Collection

Sixty clinical case scenarios were collected from the Oral Medicine and Oral Pathology Division of the Oral Diagnostic Sciences Department. The final diagnosis was determined on the basis of the results of laboratory investigations, radiographs, and histopathological examination. Ten cases were excluded by an external reviewer, as they were deemed to be poorly written. The remaining 50 cases included patient age, chief complaint, history of the chief complaint, medical history, allergies, intra- and extraoral findings, a description of the lesions, and any additional information, including laboratory investigations and specific clinical features. An example clinical scenario is shown in Multimedia Appendix 1. The LLMs and oral medicine consultants were not provided with the histopathological features.

The cases were given to 3 oral medicine consultants (with clinical experiences of 7 years, 10 years, and 5 years for consultants 1, 2, and 3, respectively), who were asked to formulate differential and final diagnoses. Two specific prompts were designed for entry into ChatGPT and Copilot to formulate differential and final diagnoses (Figure 1): the first prompt enquired about the differential diagnoses for each clinical scenario ("As an oral medicine consultant, what is your differential diagnoses of the case?"), and the second enquired about the final diagnosis ("What is your final diagnosis based on the provided information?").

XSL•FO
RenderX

Figure 1. Schematic of the study design, describing the distribution of the clinical case scenarios to the oral medicine consultants and artificial intelligence (AI)-powered tools.

Responses were reviewed and evaluated independently by two reviewers who specialized in oral pathology and medicine and who were involved in case selection. Any discrepancies were resolved by a third reviewer. Each response was assessed for accuracy and assigned a score based on the following criteria: the differential diagnoses responses by ChatGPT, Copilot, and consultants were assigned a score of 2 (correctly identified all the listed differential diagnoses), 1 (correctly identified one listed differential diagnosis), or 0 (wrongly identified all the listed differential diagnoses). For the final diagnosis, responses were categorized as 1 (correct) or 0 (incorrect).

Statical Analysis

The performances of ChatGPT, Copilot, and the oral medicine consultants in providing differential and final diagnoses for oral lesions in the clinical scenarios are presented as frequency tables. The χ^2 or Fisher exact test was used to compare the performance distributions between the AI tools and consultants. A *P* value of .05 was considered significant. All statistical analyses were performed using IBM SPSS Statistics version 29.0.0 (IBM Statistics).

Results

Comparison of Differential Diagnoses Between AI Tools and Oral Medicine Consultants

ChatGPT exhibited the highest accuracy, correctly diagnosing 74% (37/50) of the cases, partially diagnosing 24% (12/50) of the cases correctly, and making completely incorrect diagnoses in only 2% (1/50) of the cases. In contrast, Copilot provided all correct differential diagnoses for 60% (30/50) of the cases, only one correct diagnosis in 34% (17/50) of the cases, and all wrong diagnoses in 6% (3/50) of the cases. There was no significant difference in the accuracy between the two models (*P*=.32).

In comparison to these AI models, oral medicine consultant 1 correctly diagnosed 60% (30/50), partially diagnosed 34% (17/50), and incorrectly diagnosed 6% (3/50) of the cases (*P*=.32 vs ChatGPT and *P*≥.99 vs Copilot). Oral medicine consultant 2 correctly diagnosed 72% (36/50) of the cases, partially diagnosed 22% (11/50) of the cases, and incorrectly diagnosed 6% (3/50) of the cases (*P*=.75 vs ChatGPT and *P*=.41 vs Copilot). Lastly, oral medicine consultant 3 accurately diagnosed 54% (27/50) of the cases, partially diagnosed 38% (19/50) of the cases, and incorrectly diagnosed 8% (4/50) of the cases (*P*=.10 vs ChatGPT and *P*=.82 vs Copilot). The AI models had similar accuracy in providing the differential diagnoses as oral medicine consultants, as shown in Table 1.

XSL•FO

Table . Comparison of accuracy of artificial intelligence (AI) versus oral medicine consultants for differential diagnoses.

AI model or consultant	Differential diagnosis, n (%)				
	All wrong	One correct	All correct	*P* value[a]	*P* value[b]
Oral medicine consultant 1	3 (6)	17 (34)	30 (60)	.31	≥.99
Oral medicine consultant 2	3 (6)	11 (22)	36 (72)	.74	.42
Oral medicine consultant 3	4 (8)	19 (38)	27 (54)	.11	.82
ChatGPT	1 (2)	12 (24)	37 (74)	_[c]	.32
Copilot	3 (6)	17 (34)	30 (60)	.32	–

[a]*P* values in comparison to ChatGPT.

[b]*P* values in comparison to Copilot.

[c]"–": not applicable.

Comparison of Final Diagnoses Between AI Tools and Oral Medicine Consultants

With respect to the definitive diagnoses, ChatGPT again showed the highest accuracy: 70% (35/50) correct diagnoses and 30% (15/50) incorrect diagnoses. Copilot performed less well, providing 46% (23/50) correct diagnoses and 40% (27/50) incorrect diagnoses.

Oral medicine consultant 1 correctly diagnosed 66% (33/50) of the cases and incorrectly diagnosed 34% (17/50) of the cases (*P*=.66 vs ChatGPT and *P*=.04 vs Copilot). Oral medicine consultant 2 had the highest diagnostic accuracy, diagnosing 80% (40/50) of the cases correctly and 20% (10/50) incorrectly (*P*=.25 vs ChatGPT and *P*<.001 vs Copilot). Oral medicine consultant 3 correctly diagnosed 64% (32/50) of the cases and incorrectly diagnosed 36% (18/50) of the cases (*P*=.52 vs ChatGPT and *P*=.07 vs Copilot); the data are shown in Table 2.

Table . Comparison of accuracy of artificial intelligence (AI) versus oral medicine consultants for final diagnoses.

AI model or consultant	Final diagnosis, n (%)			
	Wrong	Correct	*P* value[a]	*P* value[b]
Oral medicine consultant 1	17 (34)	33 (66)	.67	.04
Oral medicine consultant 2	10 (20)	40 (80)	.25	<.001
Oral medicine consultant 3	18 (36)	32 (64)	.52	.07
ChatGPT	15 (30)	35 (70)	_[c]	.02
Copilot	27 (54)	23 (46)	.02	–

[a]*P* values in comparison to ChatGPT.

[b]*P* values in comparison to Copilot.

[c]"–": not applicable.

Discussion

In this study, we compared the diagnostic accuracy of AI language models (ChatGPT-4 and Copilot) with three oral medicine consultants in providing differential and final diagnoses for oral lesions from text-based clinical scenarios. We found that the diagnostic accuracy of the LLMs and oral medicine consultants for providing accurate differential diagnoses was similar. However, Copilot was significantly less accurate than ChatGPT (*P*=.015) and one of the oral medicine consultants (*P*<.001) in providing the correct final diagnoses. Our results suggest that advanced language models, especially ChatGPT, can provide comparable diagnostic insights to human experts in the context of oral lesion diagnosis. ChatGPT-4 and Copilot are still evolving, but even now, they might provide a significant advantage in the clinical setting as tools to help dental practitioners in their daily practice. Copilot may have underperformed in making the final diagnoses compared to ChatGPT and consultants due to differences in training, dataset variations, and algorithmic constraints. ChatGPT is exposed to a broader range of medical and dental literature, whereas Copilot is optimized for general productivity, affecting its diagnostic precision. Additionally, Copilot's customization for enterprise applications may limit its ability to provide accurate clinical diagnoses [15].

Our findings are consistent with those obtained by Altamimi et al [16], who concluded that AI tools can be useful in clinical settings to provide diagnoses for certain conditions. Friederichs et al [17] evaluated the performance of ChatGPT using 400 multiple-choice questions from the progress test administered

XSL•FO
RenderX

in German-speaking countries, reporting that ChatGPT surpassed most first- to third-year medical students by correctly answering two-thirds of the multiple-choice questions, with proficiency equivalent to the level required for the German state licensing examination in Progress Test Medicine. Several studies have reported similar accuracy and efficacy of ChatGPT. A recent study from India demonstrated that ChatGPT was a reliable tool for addressing complex problems that involved higher-level cognitive skills such as interpretation, analysis, evaluation, and evidence-based opinion or prediction, correctly answering 100 complex questions in pathology [18]. Das et al [19] reported that ChatGPT could be considered a tool for answering direct inquiries regarding microbiology, showing 80% accuracy in its responses. Furthermore, Johnson et al [8] found that ChatGPT consistently provided accurate and comprehensive responses to a variety of questions in the medical field.

Copilot showed promising performance in providing differential diagnoses compared with oral medicine consultants, albeit with higher rates of all wrong differential diagnoses. Kaftan et al [20] recently examined the accuracy of AI-powered tools for interpreting biochemical data, reporting the highest accuracy for Copilot compared with ChatGPT-3.5 and Gemini. However, ChatGPT-3.5 had fewer capabilities than ChatGPT-4, which we used here. While Copilot is based on GPT-4, as noted above, its outputs differ due to Microsoft-specific customizations, including specialized training for productivity tasks, integration with enterprise tools, and compliance filters, perhaps explaining the difference in results between the two LLMs [20]. Tepe and Emekli [21] similarly observed significant variability between LLMs for answering prompts related to breast imaging. ChatGPT-4 showed high accuracy in responding to these questions, outperforming Gemini and Copilot. Moreover, AI-powered tools tended to give more differential diagnoses for each clinical scenario, regardless of whether the answers were all correct or not, with only two answers needed for analysis. Accordingly, expert judgment, knowledge, and experience are required to evaluate these answers to construct specific differential diagnoses for each case.

Diniz-Freitas et al [6] reported that integrating ChatGPT into oral medicine could significantly accelerate decision-making for patient diagnosis, treatment, and care. We found that oral medicine consultants outperformed Copilot with respect to the final diagnosis. However, one of the oral medicine consultants outperformed Copilot in providing an accurate final diagnosis, and this was the consultant with the most experience. Clinicians accumulate subject-specific knowledge and experience. Consequently, AI tools like ChatGPT, when paired with health care practitioners' expertise, could yield even more dependable and efficient outcomes for patients requiring oral medicine treatment [6].

AI tools obtain their datasets from different sources and have different training, which influences their applications and affects their performance. Training AI tools with medical or dental datasets reviewed by specialists might be expected to improve results and transform diagnostic health care services. The clinician's experience, which is influenced by solid knowledge and experience and unaffected by dataset variability, plays a major role in their superiority over AI tools [22].

As the training and refinement of filtered datasets improve AI tools, LLMs are expected to be integrated into clinical workflows, especially in areas without access to specialized consultants in the field. During the implementation of such technologies, ethical concerns should be considered and governed. The privacy and safety of patient data are major concerns in the use of AI in health care, requiring adherence to regulations like the HIPAA (Health Insurance Portability and Accountability Act) to prevent unauthorized access [23,24]. There are also medico-legal concerns, as AI-related errors could lead to liability issues, necessitating clear regulatory frameworks. Ethically, AI should serve as an assistive tool rather than a replacement for clinical expertise to maintain fairness and reliability. Clinician reliance on AI must be balanced to ensure that decision-making remains informed by human judgment, supported by proper training.

This study has some limitations. It was a pilot study that focused solely on evaluating the application of AI-powered tools in diagnosing text-based clinical scenarios specific to oral medicine. Therefore, the findings and conclusions may not be applicable or generalizable to other subjects or domains. Depending on text-based clinical scenarios makes it more difficult to provide both differential and definitive diagnoses. Using clinical images and histopathological findings greatly improves the accuracy of diagnostics, which were not provided in this study. Moreover, we only studied a limited number of cases (50 questions), and 10 cases were excluded by an external reviewer, which may have introduced bias. The formulation of the input "prompts" when interacting with language models can greatly impact the quality and nature of the generated responses. Consequently, further studies are needed to examine the optimal prompts that provide the best and most accurate responses. Moreover, it remains uncertain whether LLMs consistently produce identical or similar responses to the same query at different times. In this study, each question was submitted only once to the AI-powered tools, which may have limited the assessment of response consistency. Additional studies are needed to overcome these limitations and explore the real-world potential of using AI-powered tools in oral medicine.

In conclusion, LLMs such as ChatGPT and Copilot showed promising performance in making diagnoses in oral medicine clinical case scenarios. ChatGPT-4 and Copilot are still evolving, but even now might provide a significant advantage in the clinical setting as tools to help dental practitioners in their daily practice. Such technologies could particularly benefit dentists in rural areas or areas with no access to oral medicine consultants, who—provided the technology is further validated—could collect medical histories, perform extra- and intraoral examinations, and provide these data to LLMs systems to provide a set of relevant differential diagnoses to help with decision-making regarding further testing, referral, or simple management.

Abstract

Background: The “fourth trimester,” or postpartum time period, remains a critical phase of pregnancy that significantly impacts parents and newborns. Care poses challenges due to complex individual needs as well as low attendance rates at routine appointments. A comprehensive technological solution could provide a holistic and equitable solution to meet care goals.

Objective: This paper describes the development of patient engagement data with a novel postpartum conversational agent that uses natural language processing to support patients post partum.

Methods: We report on the development of a postpartum conversational agent from concept to usable product as well as the patient engagement with this technology. Content for the program was developed using patient- and provider-based input and clinical algorithms. Our program offered 2-way communication to patients and details on physical recovery, lactation support, infant care, and warning signs for problems. This was iterated upon by our core clinical team and an external expert clinical panel before being tested on patients. Patients eligible for discharge around 24 hours after delivery who had delivered a singleton full-term infant vaginally were offered use of the program. Patient demographics, accuracy, and patient engagement were collected over the first 6 months of use.

Results: A total of 290 patients used our conversational agent over the first 6 months, of which 112 (38.6%) were first time parents and 162 (56%) were Black. In total, 286 (98.6%) patients interacted with the platform at least once, 271 patients (93.4%) completed at least one survey, and 151 (52%) patients asked a question. First time parents and those breastfeeding their infants had higher rates of engagement overall. Black patients were more likely to promote the program than White patients (P=.047). The overall accuracy of the conversational agent during the first 6 months was 77%.

Conclusions: It is possible to develop a comprehensive, automated postpartum conversational agent. The use of such a technology to support patients postdischarge appears to be acceptable with very high engagement and patient satisfaction.

Introduction

The "fourth trimester," or postpartum time period, is often a forgotten "trimester" of pregnancy, yet plays a critical role in parental and newborn well-being. While undergoing numerous physiologic and emotional changes following birth, patients are also susceptible to complications such as infection, thrombosis, and hypertensive disorders as well as the new onset or exacerbation of mental health disorders [1,2]. The potential for medical complications post partum is of particular concern as over one-half of pregnancy related deaths occur after the birth of the infant [3,4]. These deaths also disproportionately affect Black women with maternal mortality rates nearly 3-times that of non-Hispanic White women [5]. The American College of Obstetricians and Gynecologists (ACOG) recommends that care during the postpartum period should be an "ongoing process" rather than the traditional 1-time postpartum visit [6]. A study evaluating the clinical features of postpartum presentation for emergency care indicated that while rates are overall low around 5%, most visits occur within the first 2 weeks post partum and are more likely to occur in Black patients [7]. Yet, even when follow up is recommended, nearly 50% of patients in the United States do not attend their routine postpartum appointment and adding additional clinic visits to increase access is impractical and impossible for both patients and clinicians [8].

This gap between patient needs, clinical recommendations and reality of health care access presents a significant challenge to patients and practicing providers. Innovative methods of identifying needs and providing ongoing care for the postpartum patient are needed without added burden to already overextended providers. A wide range of SMS text messaging health care interventions have been developed and trialed with varied success [9]. Within the realm of postpartum care these innovations have largely focused on specific individual conditions regarding postpartum recovery such as breastfeeding [10-12], blood pressure monitoring [13], and weight loss [14-17]. While many of these interventions have shown great promise in improving compliance with care and reducing health care disparities [13], there are limited comprehensive technologic interventions to support patients holistically during the fourth trimester. A technology-based solution has the potential to meet ACOG's goals of continued contact and comprehensive postpartum care for patients. In this manuscript we describe the development of a novel comprehensive postpartum conversational agent, which uses natural language processing (NLP) to provide anticipatory guidance and respond to patients' questions in real time. We also describe patient engagement and satisfaction with this novel technology.

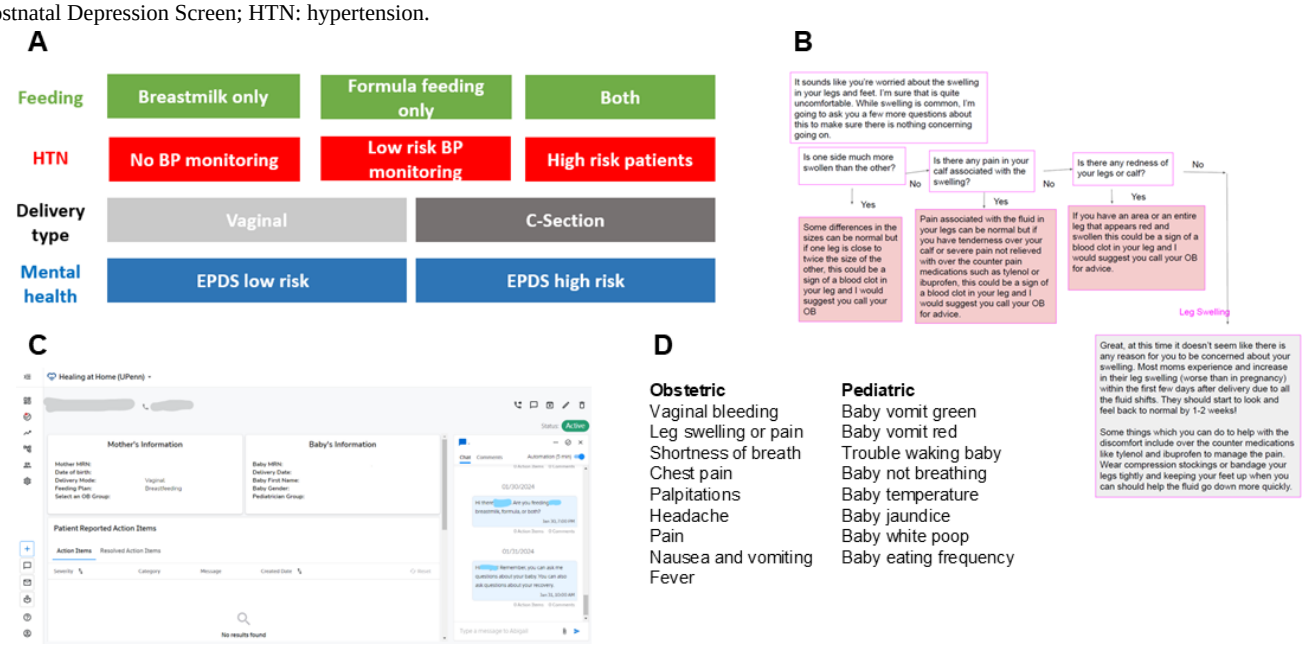
Methods

Program Design and Content Development

We sought to create a comprehensive technology-based postpartum support program, "Healing at Home," which would provide 24/7 support to individuals through the use of SMS text messages for 6 weeks post partum. Content included anticipatory guidance regarding physical recovery, infant care and feeding, clinical algorithms to respond to urgent needs and postpartum depression screening through the Edinburgh Postnatal Depression Screen (EPDS). The EPDS is a clinically validated 10-question survey that is considered the standard for screening patients for postpartum depression. We postulated that a 24/7 SMS text message—based holistic support would result in increased engagement of patients and allow providers to identify symptoms before they resulted in complications. Automation of messaging and responses, alongside the ability to focus attention efficiently on patients with demonstrated higher needs, could also minimize care team workload. Patients could be quickly connected to their care team and receive in-the-moment answers to their concerns.

We used a multipronged approach to optimize discharge planning and maintain postpartum connection for patients delivering at the Hospital of the University of Pennsylvania (HUP), described in detail by Gaulton et al [18]. We called this program of optimized discharge planning and increased postpartum support "Healing at Home." Pertinent to the innovation described here, this preintervention pilot leveraged a "fake back end" SMS text message—based support during business hours (8 AM-5 PM) for patients for the first 6 weeks post partum. During this preintervention phase described by Gaulton et al [18], 90 patients were enrolled and encouraged to text their questions to the team. Text messages were monitored by nonclinical as well as clinical staff viewing and responding to patients. The team used a clinical reference guide, which was elaborated on throughout the pilot, outlining responses to frequently asked questions. While this method was effective at connecting with patients, it required significant time monitoring messages and responding to patients. Over 2000 text messages were exchanged with this cohort of 90 patients. In addition, we identified highly complex and individual needs ranging from inquiries about physical recovery specific to delivery mode (vaginal vs cesarean) to care of newborns (diapering and umbilical cord care) and infant feeding difficulties (pain with breastfeeding, difficulty pumping, and preparing formula). This complexity led us to conclude that a "simple" algorithmic approach was unlikely to be successful in providing this population with the holistic support required.

Conversational agents are designed to simulate conversation with human users and have become nearly ubiquitous in business, but their development within health care has been slow. Given the complexity and individualized needs of the



XSL•FO
RenderX

postpartum patient we postulated that a conversational agent using NLP might be a good solution and be acceptable to this population. We envisioned a 24/7 available SMS text message—based support program that interpreted patients' postpartum concerns, responded in real sentences and could also alert clinicians in real time when appropriate.

Conversational Agent Development

We partnered with Memora Health to undertake a 4-step process to develop the conversational agent using NLP to interact with patients in a HIPAA (Health Insurance Portability and Accountability Act)-compliant manner. Unlike a basic chatbot which uses rigid decision trees to respond to people, this type of conversational agent leverages NLP to understand and interpret patient messages, providing appropriate responses, leading to a conversational experience. First, a frequently asked question bank was used to generate accurate mapping of questions to the appropriate responses. Second, surveys (standardized conversation templates designed to collect patient data) were created by patients' clinical characteristics (ie, breastmilk vs formula fed, Figure 1A). Third, creation of anticipatory guidance specific to patient clinical characteristic was planned. Finally, algorithms for potentially acute clinical concerns were designed and layered onto the program. Throughout this process we incorporated personal touches into responses, such as patients or infants' names and worked to develop a consistent and empathetic tone.

Figure 1. Layering of patient clinical characteristics (1A), example of clinical algorithm with symptom triage for lower extremity edema (1B), Memora Health patient dashboard (1C), comprehensive list of clinical symptoms for which algorithms were developed (1D). BP: blood pressure; EPDS: Edinburgh Postnatal Depression Screen; HTN: hypertension.

The frequently asked questions were generated from both patients (through our 90-patient preintervention pilot) and clinicians (obstetrics, neonatology, lactation, and social workers on our mother-baby unit). Clinicians were encouraged to "think like a patient" and ask questions they had either received or conceived as important. An example question might be whether nipple pain with feeding is normal. Topics from both patients and providers were categorized (obstetrics, neonatology, or lactation), reviewed by our team for accurate clinical content and then made available in a frequently asked question bank.

Surveys, that is, structured questions designed to collect patient data, were used and incorporated into this program including validated clinical questionnaires such as the EPDS and net promoter score (NPS). The NPS is a customer satisfaction and loyalty metric used to measure the likelihood that customers will recommend a product, service, or experience to others. People are asked to provide a score from 0 to 10. Promoters are those who score a program 9 or 10, passives score of 7 or 8, and detractors 6 or less. The NPS is calculated by subtracting the percentage of promotors from the percentage of detractors. Scores of 50 or greater indicates exceptional loyalty. The NPS was collected from patients during week two of the program.

We also developed multiple surveys with branching logic to dynamically respond to patients around topics such as infant feeding and the importance of attending scheduled appointments. Surveys were added to the program at scheduled times according to clinical needs.

Next, structured anticipatory guidance customized to patient characteristics (Figure 1) was generated by our clinical team such that patients with certain characteristics received appropriate educational materials at the right time (when they needed it and not before). Examples of customized anticipatory guidance include information on the volume of feeds by feeding method (breast vs formula).

Finally, we created a series of algorithms designed to address specific clinical scenarios outside of the conversational agent. For example, when asking about lower extremity edema, it cannot be assumed that this is normal swelling post partum, so triage regarding possible signs of venous thromboembolism is essential for providing safety (Figure 1). We also developed a "latch" algorithm, which was designed to address some common concerns in early lactation and difficulty with breastfeeding.

XSL•FO
RenderX

All content, including ad hoc content, surveys, anticipatory guidance, and clinical algorithms, was reviewed not only by our internal clinical leads but also by an expert clinical panel. This external panel, composed of a group of clinician leaders at our institution uninvolved with the design or development, provided us with insight and perspective on the content, our approach, and identification of perceived patient risks in development.

While we aimed to minimize unnecessary escalation, we erred on the side of caution with standard language and responses. For example, if the conversational agent is unable to answer a patient's concern about their infant, they would receive the following response: "It sounds like this is something that infant name's doctor can help with. Please call their office at 555-555-555." We also instructed patients to use the phrase "TEXT ME" to indicate that their concern was not addressed, alerting the team to review the conversation and intervene. This was primarily accomplished through messaging patients directly in the Memora Health dashboard. Best practices when interacting with the conversational agent, such as using single-sentence questions and rephrasing questions to improve responses, were shared with the patients through flyers and a short educational video at the time of the program start.

Conversational Agent Testing

Testing of the conversational agent required multiple phases, including internal and external testing. First, we tested this program internally by asking our own team members to ask questions that they would imagine patients might ask, attempting to cover a wide range of common clinical scenarios. Suggested scenarios included concerns around the color of infant stools, pain management, etc. Accuracy of the responses was also improved through a rapid-fire test using Mechanical Turk as described in detail by Lin et al [19]. Once these tests had been completed, we tested the program with providers external to our team and a small set of patients.

First, we recruited 23 providers from obstetrics, neonatology, nursing, and lactation who had not been involved in the design of the program to use the conversational agent as if they were a patient (they were assigned a patient characteristic such as feeding method for testing). In the second phase, we recruited 37 patients from the HUP postpartum unit to use the conversational agent in their own recovery. These patients were selected to be representative of our population with examples of demographics including race, parity, marital status, insurance, and age. During this initial patient testing phase, monitoring of the platform occurred once daily at a minimum by our clinical team.

Chatbot Enrollment and Clinical Monitoring

Clinical criteria for patient participation in Healing at Home was determined by our clinical team and expert panel at the start of this program. Program participants were patients who were planned for discharge around 24 hours of after birth who had an uncomplicated vaginal delivery at term of a singleton infant; full exclusion criteria are outlined in Textbox 1. These clinical criteria were selected as clinicians felt most comfortable with a new technology being used by a group of patients less likely to experience postpartum complications. The data presented here regarding patient engagement includes 290 patients who met these clinical characteristics. Upon discharge, patients were enrolled in the texting platform by the postpartum nurse and verbally consented. Our first nontest patient was enrolled March 6, 2020. Once the program was live, we took a data-driven approach to improve the patient experience and the conversational agent itself. For example, when we discovered that many patients were asking about their infant's umbilical cord care during the first week, we programmed a message to be proactively sent at that time.

XSL•FO
RenderX

Textbox 1. Clinical exclusion criteria to enrollment in the "Healing at Home" program (planned discharge around 24 h post birth).

Maternal exclusion criteria:

- Age<18
- Cesarean delivery
- Gestational age<37 weeks and 0 days
- Multiple gestation
- Blood loss>1000cc
- 3rd or 4th degree perineal laceration
- Preexisting diabetes mellitus or gestational diabetes on medication
- Preeclampsia with severe features
- Chronic hypertension on medication

Infant exclusion criteria:

- Intensive care nursery admission
- Birth weight<2500 g
- Direct antiglobulin test positive
- 24-hour glucose<50 mg/dL
- 24-hour bilirubin>6 mg/dL
- No void at 24 hours of life
- Elevated sepsis risk score (≥0.7)
- Weight loss >7% at 24 hours of life
- <6 feeds in first 24 hours

Other exclusion criteria:

- No access to texting
- Non-English speaking primary language
- Adoption case
- Department of Human Services involvement
- Patient opt out
- Provider opt out
- Latch score ≤6

While interactions are designed to be automated, it was assumed that unanswered questions or clinical concerns would occur. Clinical teams were assigned to respond to these escalations which were assigned an acuity level by our team as appropriate. Some alerts were received through email, while more critical alerts were sent by SMS text messages if deemed to be emergent. While patients interacted with the conversational agent by text message, monitoring of the program occurred through the Memora Health dashboard, where patients could be viewed, chat history seen, and patient characteristics could be edited as appropriate (for example, changing the feeding method from breast milk to formula). On the dashboard, clinicians could directly message with patients in addition to traditional methods of patient contact by phone (Figure 1C).

Collection of Patient Engagement Data

A complete summary of clinical outcomes regarding users of this platform is beyond the scope of this paper, but we present demographic and engagement data from the first 6 months of users. This study was approved as a Quality Improvement Project by the University of Pennsylvania Institutional Review Board. Demographic data including age, parity, race, feeding method and insurance were collected from our electronic medical record. Patient engagement metrics and chatbot accuracy were extracted from individual patient text messages reviewed manually by our investigators. Classical descriptive statistics were generated using mean and SD for continuous variables and frequency and percentage for categorical variables. To measure the differences between demographically different groups, the chi-square test was used for categorical variables, and *t* test and ANOVA for continuous variables. Spearman rank correlations were used to describe relationships between continuous variables. All statistical analysis was performed using Stata (StataCorp).

XSL•FO
RenderX

Engagement with the chatbot was measured by the number of total texts, number of questions asked, and survey response rates. Questions were classified by content category (maternal, baby, lactation, and social work) and by whether the question was prompted or unprompted. Prompted questions were defined as questions related to a previous message (ie, “Remember you can ask me questions about your health or baby”) or directly following another interaction. Messages that were unrelated or temporally distant (>3 h since last message) were defined as unprompted. Binary data (asked vs did not ask question) and the total number of questions were recorded. Reworded questions did not count towards the total number of questions asked. Interactions between patients by a pleasantry (emoji, “ok,” “thanks!”) were recorded in a binary fashion. Patient satisfaction was collected through the NPS. Chatbot accuracy was measured by the percentage of correct answers per patient, excluding ignored interactions and no content situations. No qualitative interviews were conducted.

Ethical Considerations

This study was approved as a Quality Improvement Project by the University of Pennsylvania Institutional Review Board.

Results

A total of 290 patients used our chatbot over the first 6 months of use from March to August 2020. The average patient age was 28.8 (SD 5.47) years, 112 out of 290 (38.6%) patients were first time parents, 134 (46%) had private insurance, and 163 (56%) were Black (Table 1). This distribution is representative of the population at our large urban academic medical center. Of these 290 patients, 286 (98.6%) responded to the platform at least once, with 271 (93.4%) completing at least one survey, 151 (52%) asking a question (prompted or unprompted), and 162 (55.9%) interacting by a pleasantry. All patients were sent the EPDS at least 3 times over 6 weeks with 128 (44%) patients completing at least one EPDS. In addition, 93 (32%) of patients completed an NPS with an overall NPS score of 34.

Table . Demographic characteristics of first 6 months of users (N=290).

Demographic characteristics		n (%)
Age		
	<20	14 (4.8)
	20 - 29	139 (48.1)
	30 - 39	130 (44.7)
	≥40	7 (2.4)
Parity		
	0	112 (38.6)
	1	94 (32.4)

XSL•FO
RenderX

Black patients were statistically more likely to promote the program (score 9 or 10 on a scale of 0 - 10; *P*=.047) with an NPS score of 53 compared a NPS score of 18 for White patients. Engagement through survey completion and questions asked is shown in Table 2. White patients completed more surveys than Black patients (10.64 vs 6.64; *P*<.001), but there was no significant difference in the number of questions asked. Patients with private insurance completed more surveys than those with Medicaid (9.83 vs 6.43; *P*<.001), however, again no difference in questions asked. Patients feeding their infant breastmilk were more likely to ask questions (8.92 vs 4.65; *P*<.001) and complete surveys (10 vs 4; *P*<.001). There were a total of 32 "super users" (patients who asked more than 4 questions) of which 25 (78%) were non-White, with 19 (59.3%) of these "super users" being Black and exclusively breastfeeding (although only 87 out of the 290 patients in this cohort (30%) were both Black and exclusively breastfeeding; see Figure 2A). Patients with lower parity, that is, patients who had experienced their first birth, asked more questions (*P*<.001) and completed more surveys (*P*<.001) than patients who had already birthed 1 or more children. Each unit increase in parity decreased the total number of questions by 0.36 (Figure 2B).

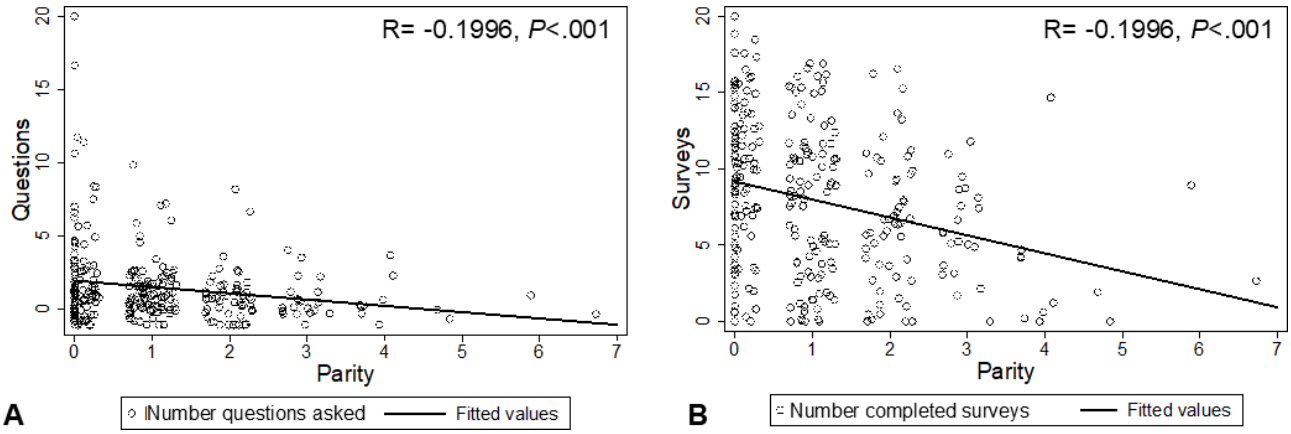

Table . Engagement data by patient demographics.

Demographic	Black race	White race	Other race	*P* value	Private insurance	Medicaid insurance	*P* value	Breast-milk only	Formula only	Both	*P* value

Completed surveys, median (IQR)	6 (3-10)	12 (7-15)	8 (4-12)	<.001	10 (6-14)	6 (3-10)	<.001	10 (5-13)	4 (1-7)	7 (4-9)	<.001

[a]Total number of patients with 0,1,2, and 3+ questions.

[b]Total number of patients with <4 or 4+ questions.

Figure 2. Parity versus number of questions asked (2A) and completed surveys (2B). Dots represent individual patients and were jittered to minimize overplotting.

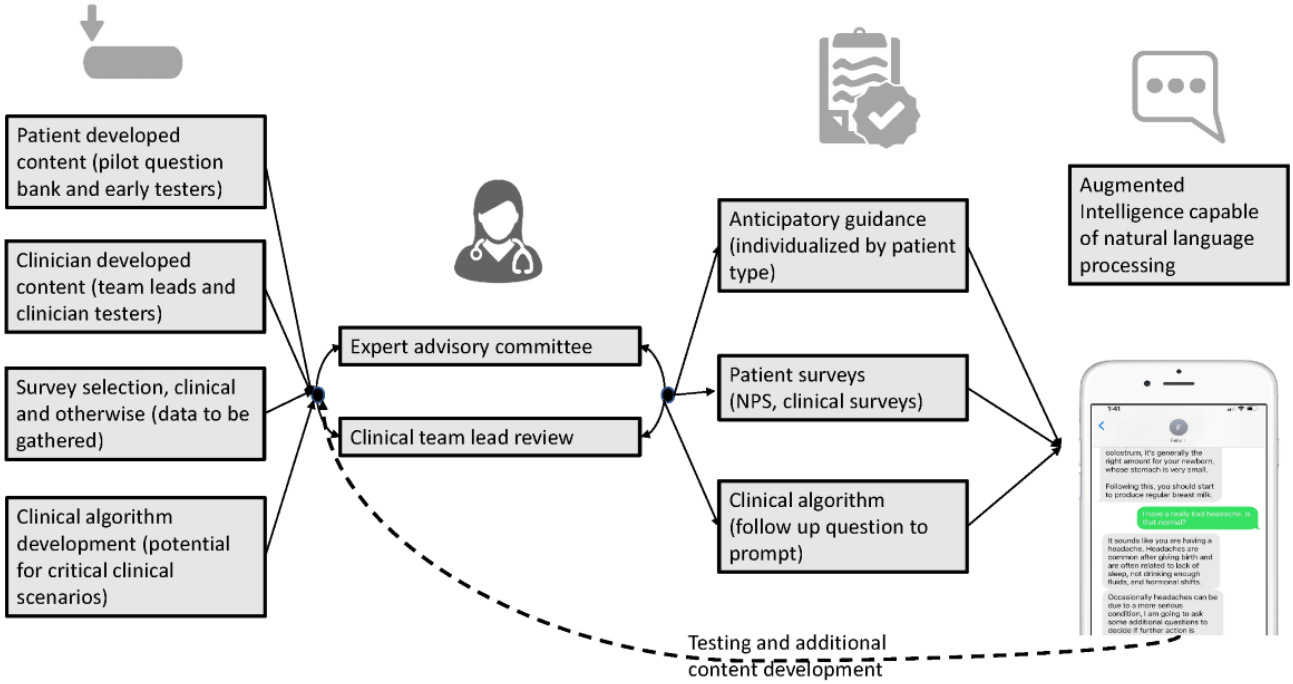
A total of 422 questions were asked by patients, 177 (42%) were prompted and 244 (58%) were unprompted. In addition, 211 (50%) questions of patient questions were related to infant concerns, 135 (32%) to maternal health, 72 (17%) to lactation concerns, and 4 (1%) to social work concerns. Approximately, 325 (73%) of all patient questions could be answered by the conversational agent with an overall chatbot accuracy of 77% (correctly answered questions/correctly answered plus incorrectly answered questions) with no difference in accuracy by parity, race, or insurance status. The additional 97 (27%) questions were not answered as they occurred concurrently with a survey (58/97) or had no developed content (39/97), these are

XSL•FO
RenderX

excluded from the overall accuracy rate reported here. As this was a fluid development process, responses were created to questions that were missing content for future users.

Discussion

Here we report on the development of a comprehensive postpartum conversational agent that leverages NLP to support patients during the "fourth trimester." Satisfaction from patients using this texting program was the highest among Black patients with high rates of engagement by all users regardless of race. The maternal health crisis is real in the United States and impacts Black patients at significantly higher rates [5,20]. Contrary to the current design of prenatal care where emphasis is placed on the pregnant patient and not the postpartum patient, we aimed to design a scalable approach to support patients during the fourth trimester by SMS text messages using augmented intelligence and NLP through a novel postpartum conversational agent. Its holistic rather than problem-based design gives this technology the potential for scalability beyond what previous models or interventions have been able to achieve. We have shown here that patient engagement is high (>98% interaction rate and >93% survey completion rate) and that patient satisfaction in Black patients is high, with Black patients were more likely to promote this program than White patients (P=.047). As we look to solutions for the maternal health crisis, we must keep a critical eye on the impact that racism has on health and find solutions that specifically target these disproportionately impacted populations.



A confounding aspect to the engagement data presented here is the time during which we collected data: March-August 2020. Our go-live date for the program coincided very closely to the start of the shut-down related to the COVID-19 pandemic with local restrictions going into effect in the second week of patient use with this platform. The influence of this may have had a significant impact on patients' experience with this platform and health care in general, especially in this cohort of patients who all completed the program by the end of 2020. Yet, we have continued to use this technology at our institution and will be able to determine whether and how moving out of the global pandemic impacts user engagement and patient satisfaction. Given the iterative nature of development, additional limitations include that significant improvements that were made over time (NLP improvement, mapping improvement) may not be reflected here (such as accuracy). Engagement by feeding method is confounded by race, with Black patients less likely to be exclusively breastfeeding, and NPS results are confounded by low response rates (<30%). An additional limitation of our engagement data presented here is that no qualitative interview of patients was performed. Without qualitative feedback from patients it is hard to draw any conclusions about the reason for NPS score disparity by race.

There are several outstanding questions that we have and plan to address in future work with this technology. First, we plan to report on the clinical outcomes on a larger cohort of patients with a specific focus on health care use and postpartum health goals such as visit attendance rates, ED and readmission rates as well as breastfeeding and contraception acceptance. In terms of health care use, we hope to gather data on number of phone calls to the office as well as amount of time per patient needed to manage concerns. In addition to these clinical and health care use outcomes, a key component to successful and broad implementation of such a program is intentional learning from the patients and providers who use this program. This allows for continued improvements and iterations on the program. We hope that future qualitative work with both providers and patients will help to elucidate barriers and facilitators to such a program. Within the framework of our layered program design, we have purposefully designed for flexibility in who, for instance, is asked to manage alerts or what content to include in the program to fit different hospital systems and teams.

We continue to use and expand upon this program at our own institution with to date over 1800 patients using this postpartum SMS text message–based support. Beyond our own application, we very much hope that the framework for the development of a comprehensive health care conversational agent (Figure 3) can help other clinical teams in their development, regardless of the specific clinical need addressed.

Abstract

Background: Medical image segmentation is crucial for diagnosis and treatment planning in radiology, but it traditionally requires extensive manual effort and specialized training data. With its novel video tracking capabilities, the Segment Anything Model 2 (SAM 2) presents a potential solution for automated 3D medical image segmentation without the need for domain-specific training. However, its effectiveness in medical applications, particularly in abdominal computed tomography (CT) imaging remains unexplored.

Objective: The aim of this study was to evaluate the zero-shot performance of SAM 2 in 3D segmentation of abdominal organs in CT scans and to investigate the effects of prompt settings on segmentation results.

Methods: In this retrospective study, we used a subset of the TotalSegmentator CT dataset from eight institutions to assess SAM 2's ability to segment eight abdominal organs. Segmentation was initiated from three different z-coordinate levels (caudal, mid, and cranial levels) of each organ. Performance was measured using the dice similarity coefficient (DSC). We also analyzed the impact of "negative prompts," which explicitly exclude certain regions from the segmentation process, on accuracy.

Results: A total of 123 patients (mean age 60.7, SD 15.5 years; 63 men, 60 women) were evaluated. As a zero-shot approach, larger organs with clear boundaries demonstrated high segmentation performance, with mean DSCs as follows: liver, 0.821 (SD 0.192); right kidney, 0.862 (SD 0.212); left kidney, 0.870 (SD 0.154); and spleen, 0.891 (SD 0.131). Smaller organs showed lower performance: gallbladder, 0.531 (SD 0.291); pancreas, 0.361 (SD 0.197); and adrenal glands—right, 0.203 (SD 0.222) and left, 0.308 (SD 0.234). The initial slice for segmentation and the use of negative prompts significantly influenced the results. By removing negative prompts from the input, the DSCs significantly decreased for six organs.

Conclusions: SAM 2 demonstrated promising zero-shot performance in segmenting certain abdominal organs in CT scans, particularly larger organs. Performance was significantly influenced by input negative prompts and initial slice selection, highlighting the importance of optimizing these factors.

Introduction

Medical image segmentation is a critical task in radiology, playing a vital role in diagnosis, treatment planning, and clinical research [1,2]. Traditionally, this process has been labor-intensive, requiring manual delineation by skilled radiologists. However, recent advancements in deep learning have revolutionized this field, expanding the scope of automated

XSL•FO
RenderX

analysis and significantly enhancing performance across diverse medical imaging tasks.

The Segment Anything Model (SAM), introduced by Meta AI, represented a significant leap forward in image segmentation technology [3]. Trained on over a billion masks, SAM demonstrated remarkable versatility in segmenting a wide array of objects across various domains. SAM's zero-shot performance—its ability to segment objects it has never seen during training—in medical images has been extensively evaluated [4,5], and specialized models such as MedSAM [6], which underwent additional training for medical imaging applications, have been introduced. These developments have demonstrated SAM's potential in radiological domains, including CT and magnetic resonance imaging (MRI). However, SAM was primarily designed for 2D image segmentation, which imposed inherent limitations on its direct applicability to 3D volumetric data.

SAM 2, released in July 2024, introduced video segmentation capabilities [7], applicable to 3D medical imaging like CT scans. Although not specifically designed for medical use, its zero-shot ability and video tracking features offer a promising approach to 3D medical image segmentation, potentially overcoming limitations of traditional methods that require extensive domain-specific training. Testing SAM 2's zero-shot performance is crucial because it could significantly reduce the need for large, annotated medical datasets and specialized model training, potentially accelerating the deployment of artificial intelligence in various medical imaging applications.

SAM 2's zero-shot performance in radiology and the impact of input factors remain understudied, despite evaluations in surgical video segmentation [8] and specialized versions like Medical SAM2 [9]. We assess SAM 2's zero-shot performance in medical imaging, examining how target organ size, initial slice selection, and negative prompts influence its segmentation accuracy. These factors are crucial for optimizing SAM 2's performance in radiological applications.

We focused our evaluation on abdominal organs due to their significant clinical importance. Morphological and size analysis of these organs is crucial for disease detection [10]; pancreatic atrophy may indicate highly fatal pancreatic cancer [11] and liver morphology changes can signal cirrhosis [12]. Renal atrophy is associated with chronic kidney diseases [13], and a recent study has shown that kidney volume measurements obtained through accurate segmentation models effectively predict kidney function [14]. These volumetric assessments require precise 3D segmentation, making abdominal imaging an ideal test case for evaluating SAM 2's capabilities in clinically relevant scenarios.

This comprehensive evaluation combining zero-shot performance assessment and input factor analysis is one of the earliest investigations for SAM 2 applied to 3D medical imaging. Our exploration is analogous to large language models, where performance varies significantly based on prompt adjustments [15]. By examining prompt engineering in segmentation, we aim to provide deeper insights into adapting general-purpose AI models for specialized medical imaging applications.

Methods

This study was conducted as a retrospective study and adheres to the Checklist for Artificial Intelligence in Medical Imaging (CLAIM): 2024 Update [16,17].

Ethical Considerations

We used the openly available TotalSegmentator dataset [18], a CT image segmentation dataset. The TotalSegmentator dataset is released under the Creative Commons Attribution 4.0 International license, permitting unrestricted reuse for research. The original CT images were collected retrospectively at University Hospital Basel. The Ethics Committee Northwest and Central Switzerland (EKNZ) approved a waiver of ethical approval for that retrospective study (BASEC Req-2022–00495). No additional ethics review was required for this secondary analysis. Patient consent was waived by the EKNZ due to the deidentified, retrospective nature of the original data collection. All CT images in the TotalSegmentator dataset were fully deidentified of any protected health information before public release. The dataset contains anonymized images and no patient identifiers. No financial or other compensation was provided to participants for the original data collection, and none was provided for this secondary analysis.

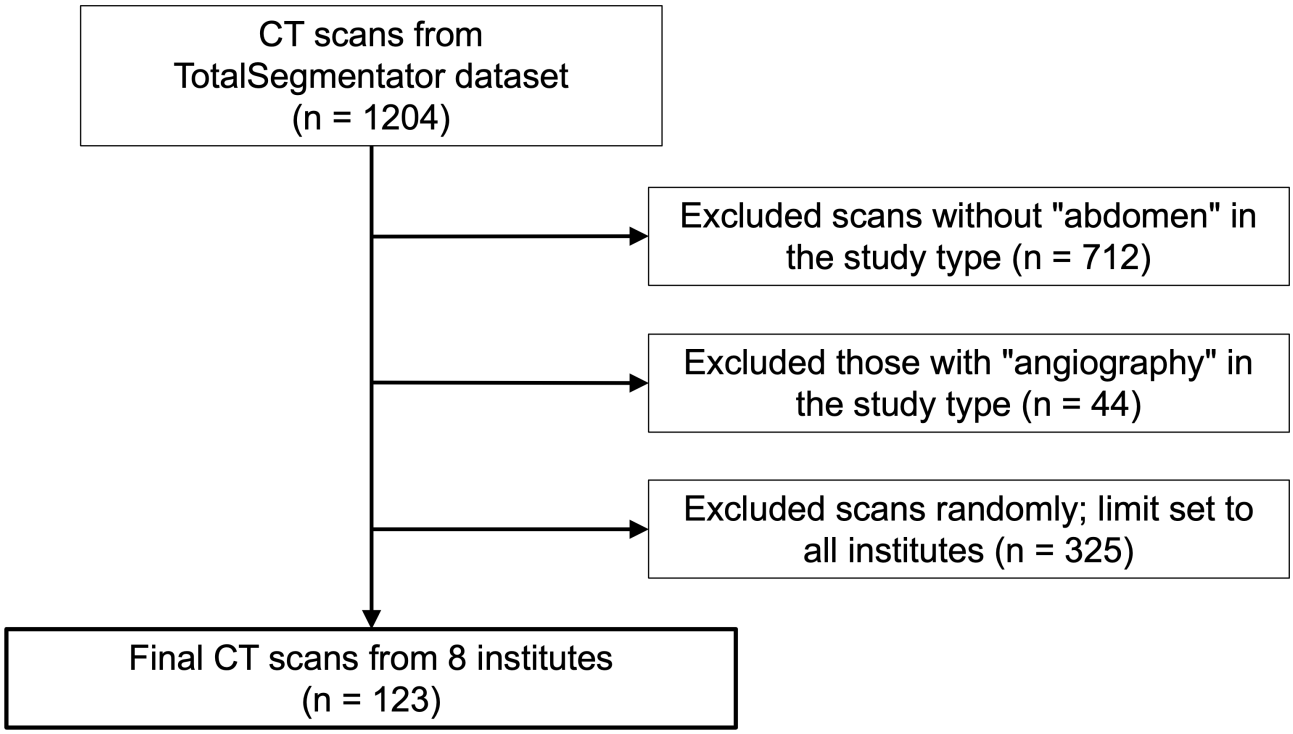
Dataset

We aimed to evaluate the segmentation performance of major organs within the imaging range of abdominal CT, one of the most common medical imaging modalities. To conduct this performance evaluation, we used a subset of the TotalSegmentator CT dataset version 1.0 [18]. The TotalSegmentator dataset is a large-scale, multiorgan segmentation dataset collected from eight institutions. We selected this dataset for its comprehensive organ segmentation masks and available institutional metadata for each case. These segmentation masks underwent expert verification to ensure high quality, making the dataset particularly suitable for our study.

Our study included cases that encompassed the abdominal region, while CT angiography scans were excluded from the analysis.

To ensure representation from all eight institutions while managing the dataset size, we implemented a sampling strategy. We set a maximum of 20 cases per institution and randomly selected cases up to this limit. For institutions with fewer than 20 cases, all available cases were included.

We focused on 8 major abdominal organs for our analysis:



1. Liver
2. Right kidney
3. Left kidney
4. Spleen
5. Gallbladder
6. Pancreas
7. Right adrenal gland
8. Left adrenal gland

These organs were selected based on their clinical significance and visibility in standard abdominal CT scans. To account for

XSL•FO
RenderX

potential annotation deficiencies, we excluded segmentation masks with extremely small volumes by setting a threshold of 100 voxels. Masks below this threshold were omitted from the analysis. The dataset selection flowchart is illustrated in Figure 1.

Figure 1. Flow diagram illustrating the CT scan selection process from the TotalSegmentator dataset for evaluation of SAM 2. CT: computed tomography; SAM 2: Segment Anything Model 2.

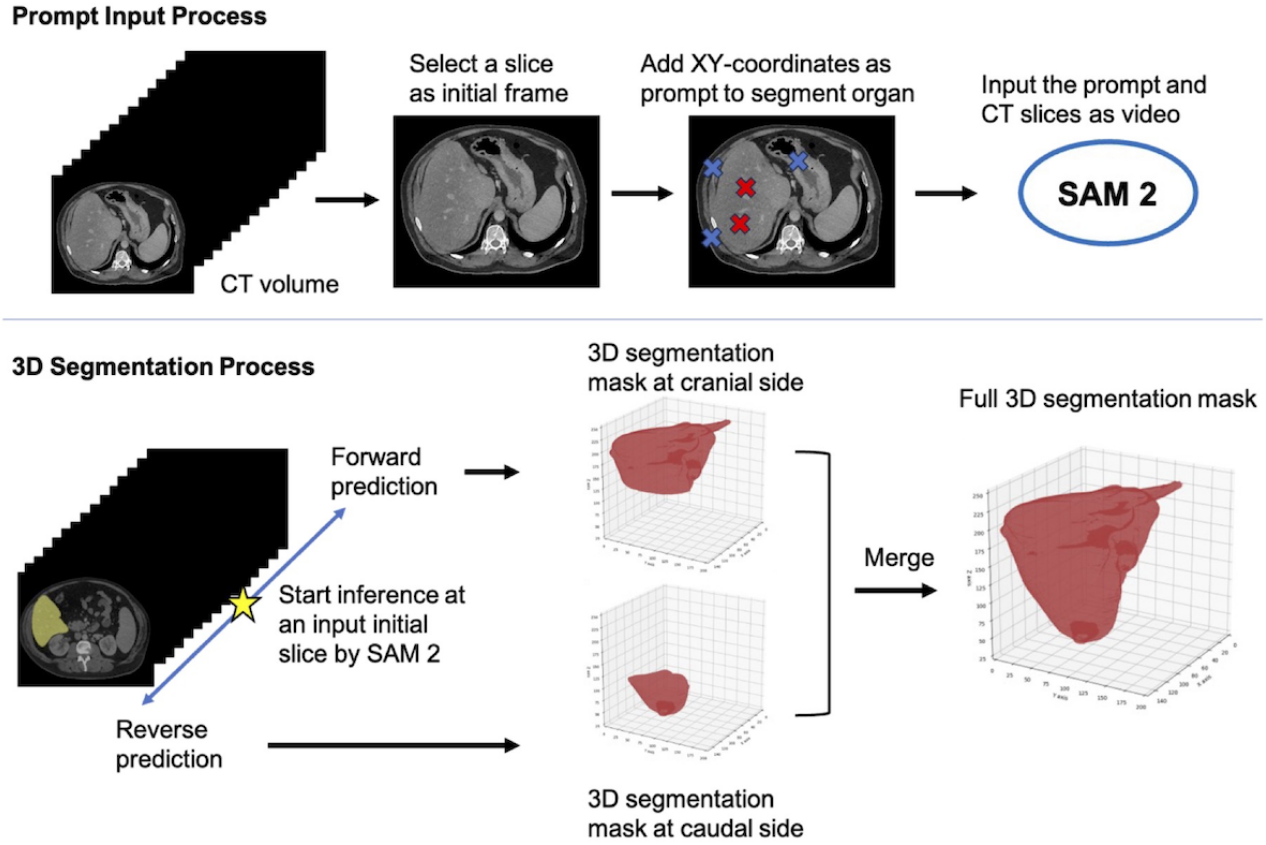
Data Preprocessing

The dataset was available in NIfTI file format. For SAM 2 inference, we extracted each horizontal slice from the 3D volumes to create subsets of 2D images for each scan. We applied windowing to the CT scans, using a window level of 50 and a window width of 400 Hounsfield units. Following windowing, we performed min-max scaling on the data. The scaled values were then converted to 8-bit integers, resulting in a range of 0 - 255. These processed 2D images were saved as sequential JPEG files.

For SAM 2 inference, we selectively processed only the slices containing abdominal organs. This approach focused on optimizing computational efficiency, resulting in faster inference speeds.

Analysis of Organ Mask Volumes

For the volumetric analysis, we used the existing segmentation masks from the TotalSegmentator dataset to calculate the volume of each organ in voxels. We chose to measure in voxels rather than physical units, as our model inputs do not consider voxel scale.



Additionally, we analyzed cross-sectional areas of organ masks along the z-axis. For each organ, we calculated mean mask areas at the 25th, 50th, and 75th percentile z-coordinates, corresponding to the initial prompt locations used in SAM 2 segmentation.

SAM 2 Implementation for 3D Medical Image Segmentation

SAM 2 is a segmentation model not specifically designed for medical images, but for general video content such as sports or animal footage. These models are trained on a large-scale dataset, enabling them to perform segmentation on any object. SAM 2's main feature is its ability to support not only 2D images but also videos. By providing coordinates indicating the target object for segmentation, SAM 2 can track and segment objects appearing within the video. An overview of CT volume segmentation using SAM 2's video predictor is shown in Figure 2.

XSL•FO
RenderX

Figure 2. Workflow of 3D medical image segmentation using SAM 2. This figure illustrates a two-stage process for 3D medical image segmentation. The top row shows the prompt input process, where a slice is selected from a CT volume as an initial frame and XY-coordinates are added as prompts for organ segmentation (red crosses: positive prompts; blue crosses: negative prompts). These are then input into SAM 2. The bottom row depicts the 3D segmentation process, where SAM 2 performs forward and reverse predictions to generate 3D segmentation masks at both cranial and caudal sides. These masks are ultimately merged to create a full 3D segmentation mask of the target organ. CT: computed tomography; SAM 2: Segment Anything Model 2.

Adaptation for 3D Medical Imaging

Although SAM 2 was originally intended for tracking objects in general videos, we recognized that 3D volumes such as CT and MRI scans can be considered as videos composed of numerous 2D images. Using publicly available datasets with segmentation masks, we applied preprocessing compatible with SAM 2's video prediction capabilities. This allowed us to construct a pipeline capable of performing multiorgan segmentation in a zero-shot manner, without additional training of SAM 2.

Bidirectional Prediction Approach

While SAM 2's video prediction is unidirectional, it can process in both directions from the initial frame. To obtain a complete segmentation mask for the entire volume, we implemented a simple bidirectional approach: forward direction from the starting slice to the cranial end reverse direction from the starting slice to the caudal end. The two segmentation masks obtained from these bidirectional inferences were then merged to create a complete 3D segmentation mask.

Model Inference and Prompt Setting

SAM 2's video prediction requires input of both the video (numbered 2D images) and prompt (coordinates for the target object). We used axial slices for prompt input, as these views serve as the foundation of radiological interpretation in clinical practice. This approach aligns with the standard workflow of radiologists when adapting SAM2 for medical image analysis. In practice, the prompt must be manually specified by a user. However, given the need to evaluate a large number of objects, we devised an algorithm to automatically obtain prompts:

1. Z-coordinate focus: Using 25th (caudal-level), 50th (mid-level), and 75th percentiles (cranial-level) for comprehensive organ representation.
2. Random selection within organ boundaries:
   - Five positive prompts from within the segmentation mask
   - Five negative prompts were sampled from regions 2 - 3 voxels outside the mask boundary, excluding the immediate 1-voxel margin

This method maintains reproducibility, reduces bias from the user's prompting skill, and leverages SAM 2's capability to use both positive and negative prompts for improved accuracy.

In this study, we refer to the 3D segmentations initiated at each of these positions as caudal-approach, mid-approach, and cranial-approach, corresponding to segmentations starting from the caudal, mid, and cranial-level slices, respectively.

XSL•FO
RenderX

Model Version

For our study, we selected the "sam2_hiera_large" model due to its superior performance among the available versions. We used version 1.0 of the SAM 2 [19]. Our implementation was carried out using Python (version 3.10.12).

Statistical Analysis

To evaluate the model's performance, we calculated the Dice similarity coefficient (DSC) [20]. This evaluation was performed organ-wise across the dataset to provide a detailed analysis.

We then compared the segmentation performance across the different approaches with or without negative prompts. We performed three pairwise comparisons for the approaches: caudal-approach versus mid-approach, caudal-approach versus cranial-approach, and mid-approach versus cranial-approach. Additionally, we compared performance with and without negative prompts.

When considering organ volumes in detail, we calculated Spearman correlation coefficients to examine the relationship between organ volumes and DSCs [21,22].

To account for multiple comparisons, we applied the Bonferroni correction. After Bonferroni correction, a P value of <.05/3 (approximately 0.0167) was considered statistically significant.

All statistical analyses were conducted using SciPy (version 1.14.0).

Results

Data Characteristics

Our sampling strategy resulted in a total of 123 scans. Twenty scans each were selected from five institutions, while the remaining three institutions contributed 5, 5, and 13 cases respectively. The average age of the patients in our selected sample was 60.7 (SD 15.5) years. The gender distribution was nearly equal: 63 male and 60 female individuals.

903 organ segmentations were obtained from 123 scans. 12 masks with volumes of 100 voxels or smaller were then excluded from the analysis, and the final dataset consisted of 891 organ segmentations.

Analysis of Organ Mask Volumes and Areas

Organ volumes, measured in voxels and are detailed in Table 1. The liver was the largest organ, followed by the spleen; kidneys were next in size, with similar volumes on the left and right side. Compared to the liver's mean volume, the pancreas was approximately 1/25th the size of the liver; the gallbladder was less than 1/70, and both adrenal glands were less than 1/400. These three organs (ie, pancreas, gallbladder, and adrenal glands) can be categorized as small organs.

Table . Descriptive statistics of organ volumes in voxels derived from computed tomography scan mask volumes.

Organ	Organ volumes (voxels), mean (SD)	Min[a]	Max[b]	Samples (n)
Liver	465,008.6 (156,091.00)	19,768	963,401	119
Right kidney	39,381.57 (18,122.20)	216	79,713	108
Left kidney	41,246.74 (21,144.60)	666	129,706	111
Spleen	71,730.34 (45,884.40)	13,818	303,676	115
Gallbladder	6,247.61 (4,902.72)	170	20,763	89
Pancreas	18,526.41 (8,502.56)	707	37,855	116
Right adrenal gland	1,101.86 (465.47)	216	2590	118
Left adrenal gland	1,259.03 (522.81)	135	2977	115

[a]Min: Minimum

[b]Max: Maximum

Organ cross-sectional area analysis showed diverse trends across eight organs. The liver was the largest in size, increasing caudally to cranially. The pancreas steadily increased while adrenal glands, though smallest, peaked at mid-level. The details are provided in Figure S1 in Multimedia Appendix 1.

Multiorgan Segmentation Performance

We evaluated the performance for multiorgan segmentation using different starting slice positions. The DSCs are reported as mean (SD) to reflect performance variability. All results are detailed in Table 2.

XSL•FO
RenderX

Table . DSCs[a] for multiorgan segmentation by different approaches (ie, caudal, mid, and cranial).

Organ and approach	DSC,[a] mean (SD)	*P* value[b]
Liver		caudal versus mid: <.01 caudal versus cranial: <.01mid versus cranial: .07
caudal	0.821 (0.192)	
mid	0.754 (0.223)	
cranial	0.702 (0.259)	
Right kidney		caudal versus mid: .03 caudal versus cranial: .16 mid versus cranial: <.01
caudal	0.862 (0.189)	
mid	0.862 (0.212)	
cranial	0.801 (0.270)	
Left kidney		caudal versus mid: .40 caudal versus cranial: .15 mid versus cranial: .15
caudal	0.870 (0.154)	
mid	0.825 (0.221)	
cranial	0.808 (0.242)	
Spleen		caudal versus mid: <.01 caudal versus cranial: .017 mid versus cranial: .56
caudal	0.891 (0.131)	
mid	0.839 (0.187)	
cranial	0.768 (0.302)	
Gallbladder		caudal versus mid: .95 caudal versus cranial: <.01mid versus cranial: .08
caudal	0.527 (0.288)	
mid	0.531 (0.291)	
cranial	0.461 (0.314)	
Pancreas		caudal versus mid: .92 caudal versus cranial: <.01mid versus cranial: <.01
caudal	0.353 (0.168)	
mid	0.361 (0.197)	
cranial	0.287 (0.209)

caudal	0.203 (0.222)	
mid	0.177 (0.235)	
cranial	0.112 (0.178)	
Left adrenal gland		caudal versus mid: <.01 caudal versus cranial: <.01mid versus cranial: .08
caudal	0.308 (0.234)	
mid	0.252 (0.226)	
cranial	0.226 (0.238)	

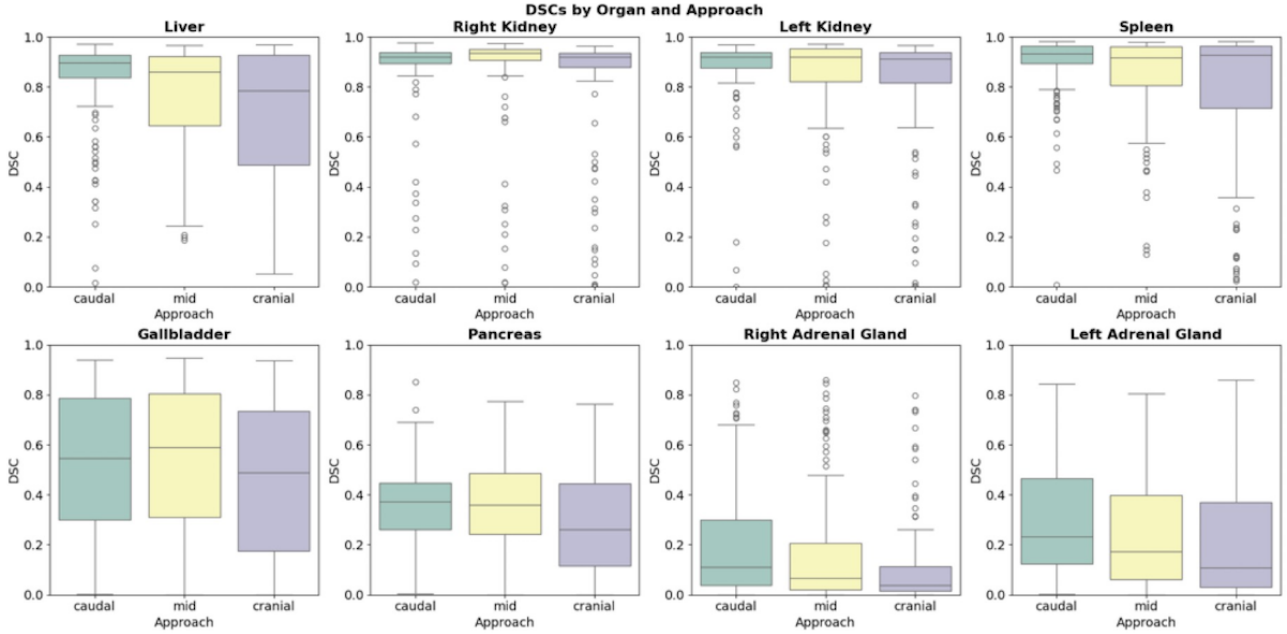
[a]DSC: Dice Similarity Coefficient.

[b]*P* values from Wilcoxon signed-rank tests are provided for comparisons between approaches (caudal vs mid, caudal vs cranial, and mid vs cranial).

The left kidney demonstrated the best overall performance, maintaining high DSCs across all starting positions: mean 0.870 (SD 0.154) , mean 0.825 (0.221), and 0.808 (SD 0.242) for the caudal-approach, mid-approach, and cranial-approach, respectively. Notably, it was the only organ showing no

XSL•FO
RenderX

statistically significant differences between any starting positions (all $P>.0167$).



The box plots (Figure 3) show that most organs reached DSCs above 0.8, with some approaching or nearly reaching 1.0. However, the box plots also reveal instances of very low DSC values approaching 0 across various organs and approaches, indicating significant variability in segmentation performance.

Starting slice level had a significant impact on most organs. Organs demonstrated various patterns in segmentation performance depending on the starting level. The liver showed a significant decrease in performance as the starting position moved superiorly, with DSC dropping from mean 0.821 (SD 0.192) with mean caudal-approach to 0.702 (SD 0.259) with cranial-approach ($P<.01$). Smaller organs such as the pancreas, adrenal glands, and gallbladder showed the most pronounced impact of the starting position. For these organs, performance significantly decreased when changing from a caudal-approach to a cranial-approach (all $Ps<.01$).

Larger organs such as liver, kidneys, and spleen consistently demonstrated higher DSCs compared to smaller organs across all approaches. A moderate correlation was observed across all settings when using caudal-approach ($\rho=0.731$; $P<.01$), mid-approach ($\rho=0.698$; $P<.01$), and cranial-approach ($\rho=0.699$; $P<.01$) (12,13). As shown in Table 3, when correlation coefficients were calculated separately for each organ, fair correlations were demonstrated for almost all items, particularly for smaller organs.

We also investigated the impact of including negative prompts on segmentation performance across different organs, focusing specifically on the caudal-approach (Table 4 and Figure S2 in Multimedia Appendix 1). All organs except the liver ($P=.32$) and spleen ($P=.27$) demonstrated significant increases in DSC ($P<.01$) with the inclusion of negative prompts.

Figure 3. Box plots of DSCs for eight organs (displayed in separate subplots) across three approaches: caudal-approach, mid-approach, and cranial-approach. Each subplot shows the distribution of DSCs (y-axis, range 0 - 1) for a specific organ, with the three approaches compared along the x-axis. DSC: Dice Similarity Coefficient.

Table . Spearman correlation coefficients between ground truth values of organ volumes and dice similarity coefficients in caudal, mid, and cranial levels.

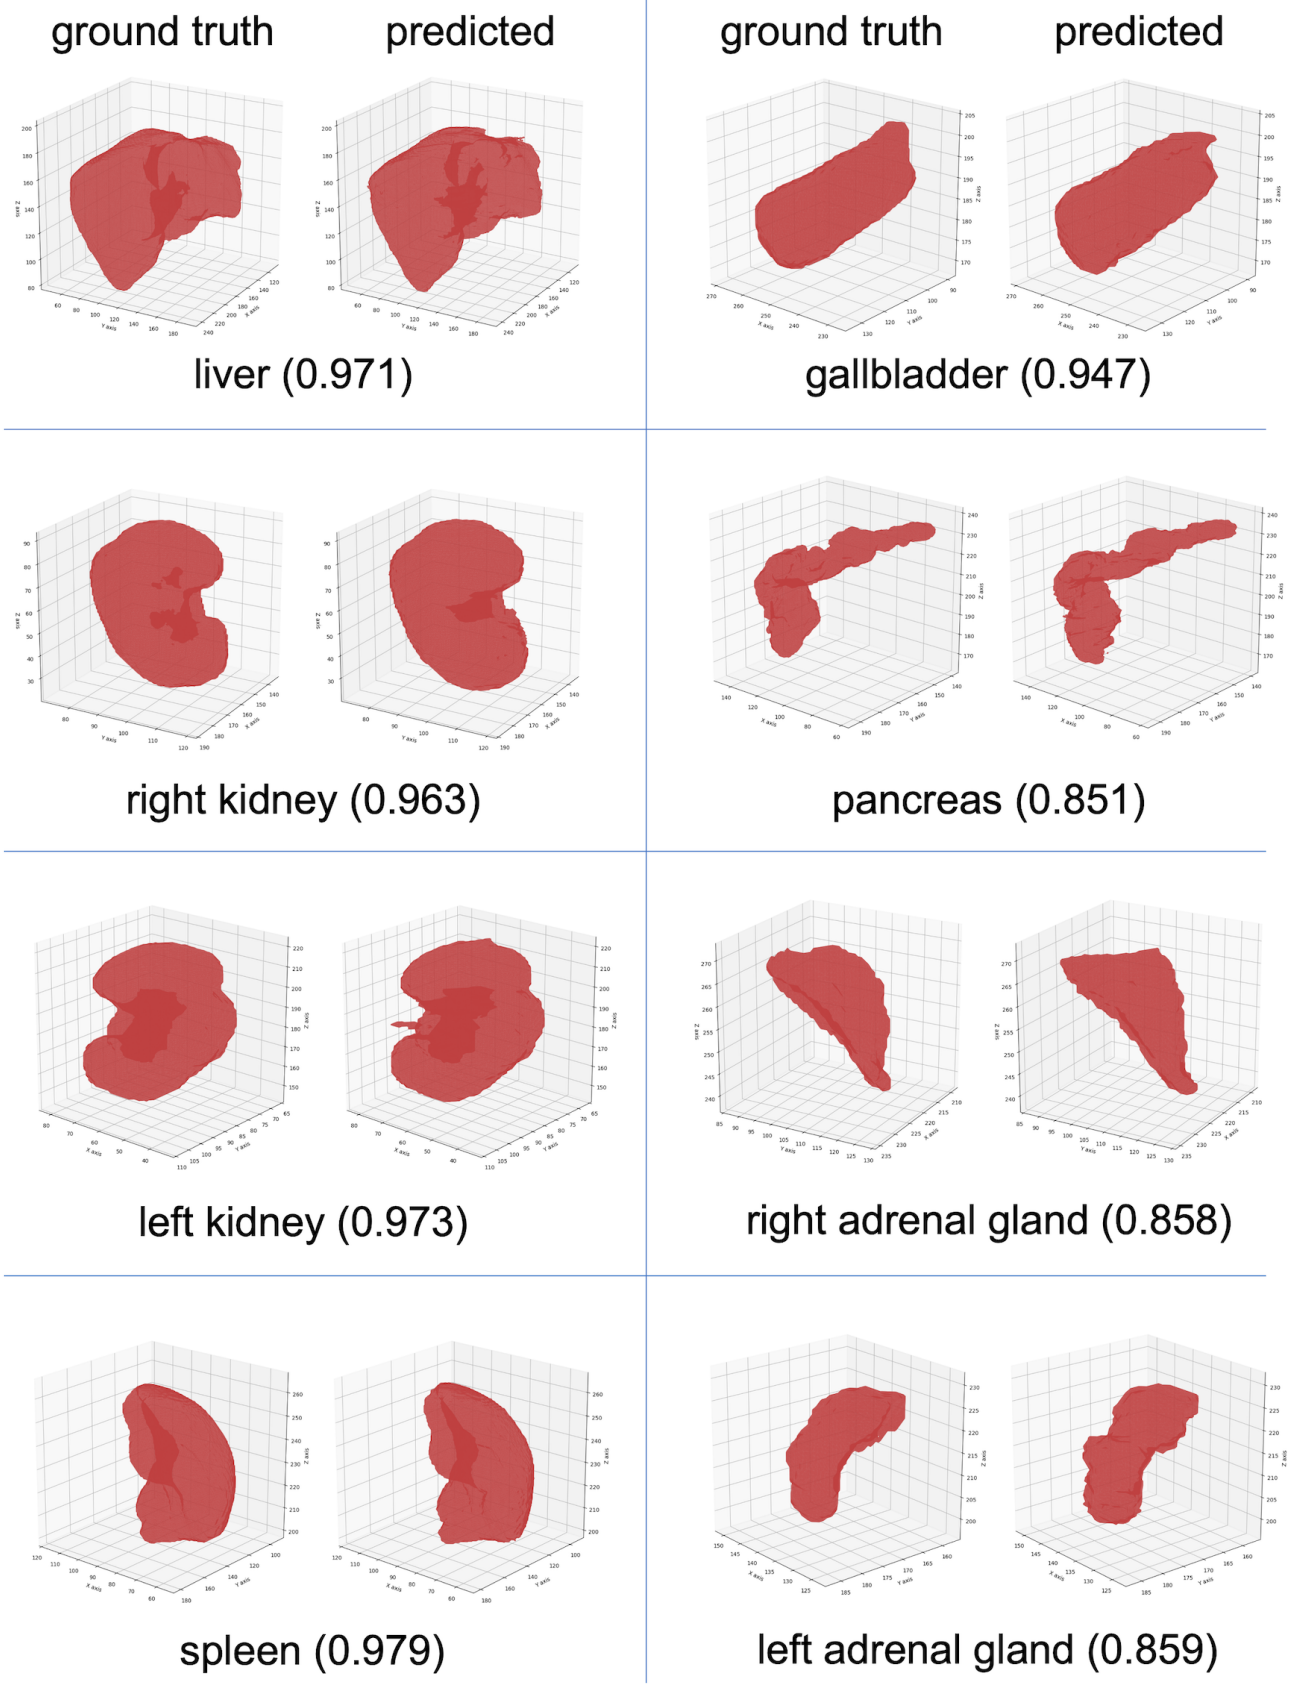
Organ	Spearman correlation coefficient, ρ (caudal) ρ[a]	*P* value	Spearman correlation coefficient, ρ (mid)[a]	*P* value	Spearman correlation coefficient, ρ (cranial)[a]	*P* value
Liver	0.328	<.01	0.0489	.60	0.163	.08
Right kidney	0.231	.02	0.347	<.01	0.509	<.01
Left kidney	−0.0107	.91	0.293	<.01	0.295	<.01
Spleen	0.38	<.01	0.307	<.01	0.355	<.01
Gallbladder	0.499	<.01	0.509	<.01	0.469	<.01
Pancreas	0.475	<.01	0.386	<.01	0.379	<.01
Right adrenal gland	0.371	<.01	0.424	<.01	0.278	<.01
Left adrenal gland	0.452	<.01	0.339	<.01	0.447	<.01

[a]Spearman rank correlation coefficient (ρ) was used to examine the relationship between object volumes and dice similarity coefficients.

Table . Comparison of multiorgan segmentation performance without negative prompts.

Organ	DSC[a] mean (SD)	Difference[b]	*P* value[c]
Liver	0.785 (0.244)	−0.036	.32
Right kidney	0.858 (0.203)	−0.004	<.01
Left kidney	0.847 (0.192)	−0.023	<.01
Spleen	0.867 (0.213)	−0.024	.27
Gallbladder	0.438 (0.338)	−0.089	<.01
Pancreas	0.277 (0.197)	−0.076	<.01
Right adrenal gland	0.084 (0.151)	−0.119	<.01
Left adrenal gland	0.190 (0.230)	−0.118	<.01

[a]DSC: dice similarity coefficient.



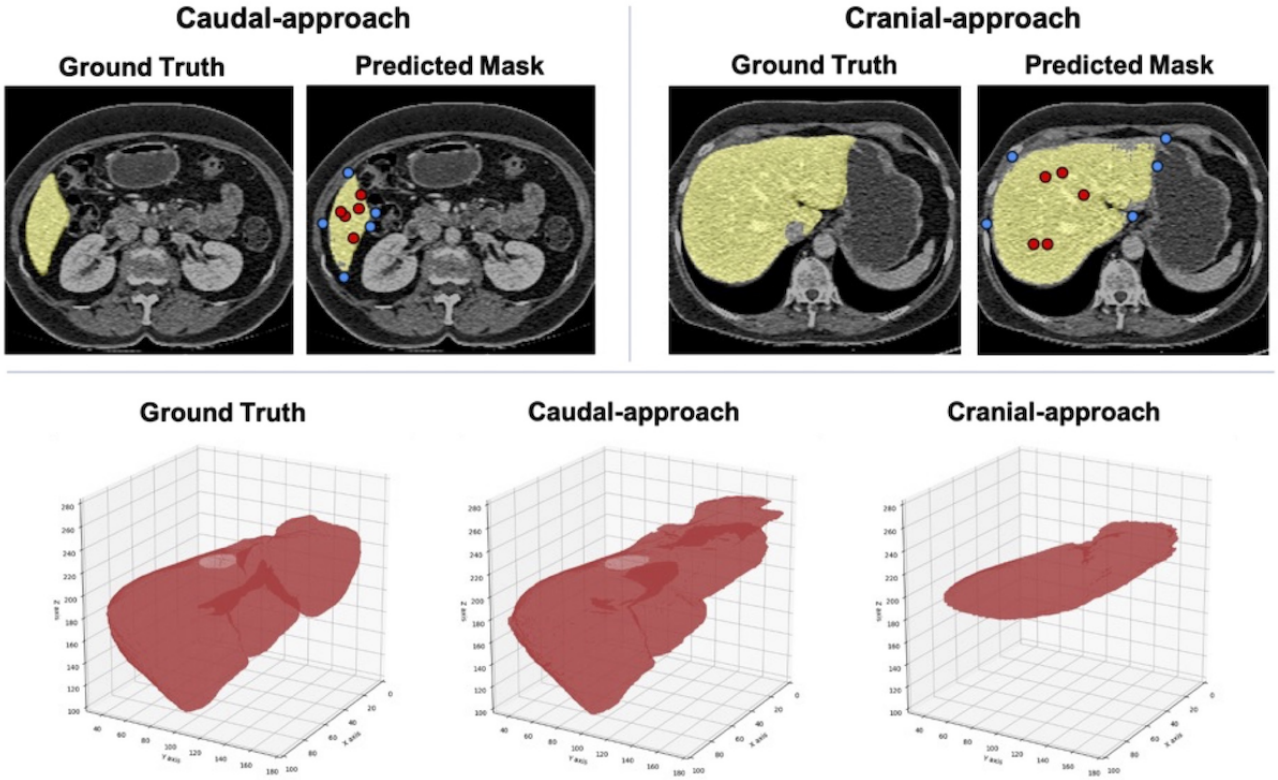
[b]Change when negative prompts are excluded (negative values indicate lower performance without prompts).

[c]*P* value represents the results of Wilcoxon signed-rank tests comparing performance with, and without negative prompts for each organ.

In Figure 4, we present the highest DSC masks, excluding cases where the ground truth segmentations were incomplete. The highest performing masks, as visualized, generated for each organ in 3D were nearly indistinguishable from the ground truth.

XSL•FO
RenderX

Figure 4. Successful segmentation results for eight abdominal organs. Each row shows different organ with ground truth (left) and predicted (right) 3D masks. Values in parentheses indicate the DSC for each segmentation. DSC: dice similarity coefficient.



On the other hand, there were cases where the performance fluctuated significantly due to differences in the approach. We present an example of the liver segmentation results in Figure 5. The DSC decreased by 0.564 (from 0.924 with caudal-approach to 0.360 with cranial-approach). For the caudal-approach, the initial slice segmentation appears to have

XSL•FO
RenderX

been easier due to clear contrast with the surroundings. The cranial-approach resulted in lower DSC values compared to the caudal-approach. Visual inspection of the segmentation results showed incomplete masking and potential inclusion of the inferior vena cava in the liver mask, particularly in areas where boundaries between the liver, inferior vena cava, and abdominal wall were less distinct.

Figure 5. Comparison of segmentation results using caudal-approach and cranial-approach, showing 2D axial slices with ground truth and predicted mask for both initial slices (top row, with yellow representing the ground truth of liver, blue and red points indicating negative and positive prompts, respectively), alongside 3D renderings of liver segmentation for ground truth, caudal-approach, and cranial-approach (bottom row).

Discussion

To our knowledge, this is the first research that not only validates the performance of zero-shot SAM 2 on abdominal organs but also considers the impact of prompt input strategies such as slice positioning and negative prompts. Our findings demonstrate the potential of SAM 2, a general-purpose segmentation model in segmenting abdominal organs from CT scans. SAM2 showed promising performance for larger organs with clear boundaries, such as the liver, kidneys, and spleen, achieving a mean DSC of 0.821 - 0.891. Although SAM 2 was not specifically designed for medical image analysis, its notable performance suggests potential applicability to a wide range of organs and lesions. The choice of initial prompt position had a significant impact on segmentation accuracy, and the optimal position depended on the organ. Excluding negative prompts led to a significant decrease in DSC for all organs except the spleen and liver, highlighting their importance in segmentation accuracy. SAM 2 struggled with smaller and less defined structures such as the adrenal glands, pancreas, and gallbladder, resulting in lower DSCs. Interestingly, we observed a moderate positive correlation between organ volume and DSCs (ρ=0.731, P<.01), suggesting that volume size is one of several key factors influencing segmentation accuracy.

While prior studies have explored zero-shot segmentation performance in CT and MRI [23,24], our research makes several unique contributions to this emerging field. Ma et al [23] conducted a comprehensive benchmarking of SAM 2 across multiple medical image modalities and demonstrated its potential for transfer learning in the medical domain. Similarly, Dong et al [24] explored various prompt strategies and propagation directions for 3D segmentation. In contrast, our work specifically examines abdominal CT imaging, analyzing how prompt positioning and negative prompts significantly influence segmentation outcomes. Unlike previous studies, we investigated segmentation from clinically relevant positions (ie, caudal, mid, and cranial) and found that optimal starting positions vary by organ, with negative prompts being crucial for smaller organ segmentation.

A key advantage of SAM 2 is its ability to generate segmentation masks with just a few clicks on a single slice, drastically reducing the workload for radiologists who previously relied on labor-intensive manual annotations. Furthermore, optimizing prompt input strategies is essential for achieving even greater model performance, as evidenced by SAM's history of various prompt optimization techniques, including automatic prompt generation and learnable prompts [25]. Although the scores are lower compared to previous supervised methods, which can achieve mean DSCs in the upper 0.9 range for some organs, they are still notably high for a zero-shot prediction. Moreover, the ability to segment an entire 3D volume by simply selecting and clicking on a target structure in a single slice is particularly

XSL•FO
RenderX

significant. This aligns with challenges typically observed in abdominal organ segmentation, even with supervised 3D models. Notably, supervised approaches like TotalSegmentator (based on nnUNet [26]), UNet [27], SegUNet [28], and SwinUNETR [29] also tend to show lower DSC for bilateral adrenal glands and gallbladder compared to other organs [30], a trend mirrored in SAM 2's performance. Segmentation performance can be inferred to depend on multiple factors related to the 3D morphology, volume size, and contrast with surrounding tissues of target structure. These findings suggest the importance of optimizing prompts taking into account the characteristics of the targeted structure.

Our study had several limitations. First, our validation relied on a single dataset of abdominal CT scans, despite being a multi-institutional study. For studies focused on abdominal organs, there are publicly available datasets such as AbdomenCT-1K [31], which is included in AbdomenAtlas [32,33]. To expand the validation to other anatomical structures and imaging modalities, datasets such as Vertebral Segmentation [34], TotalSegmentator's MRI [35] and Duke Liver datasets [36] could also be considered, all of which include segmentation masks for their respective targets. Expanding our validation using these resources would allow for a more robust evaluation. Additionally, as our approach was designed to address zero-shot performance validation, we did not perform any additional training such as fine-tuning. Performance improvements can be expected by using task-specific supervised methods instead of zero-shot. Furthermore, while we used an automated approach to evaluate a large number of organs, there is potential for improved accuracy through manual prompts inputting.

In conclusion, SAM 2 has demonstrated promising zero-shot performance in segmenting certain abdominal organs in CT scans, particularly larger organs with clear boundaries, highlighting its potential for cross-domain generalization in medical imaging. However, further improvements are needed for smaller and less distinct structures. Our study underscores the importance of applying general models to unseen medical images and optimizing input prompts, which together could significantly enhance the accuracy of medical image segmentation.

Data Availability

The datasets generated or analyzed during this study are available in the Zenodo repository [37].

Abstract

Background: Pressure ulcers (PUs) and incontinence-associated dermatitis (IAD) are prevalent conditions in clinical settings, posing significant challenges due to their similar presentations but differing treatment needs. Accurate differentiation between PUs and IAD is essential for appropriate patient care, yet it remains a burden for nursing staff and wound care experts.

Objective: This study aims to develop and introduce a robust multimodal deep learning framework for the classification of PUs and IAD, along with the fine-grained categorization of their respective wound severities, to enhance diagnostic accuracy and support clinical decision-making.

Methods: We collected and annotated a dataset of 1555 wound images, achieving consensus among 4 wound experts. Our framework integrates wound images with categorical patient data to improve classification performance. We evaluated 4 models—2 convolutional neural networks and 2 transformer-based architectures—each with approximately 25 million parameters. Various data preprocessing strategies, augmentation techniques, training methods (including multimodal data integration, synthetic data generation, and sampling), and postprocessing approaches (including ensembling and test-time augmentation) were systematically tested to optimize model performance.

Results: The transformer-based TinyViT model achieved the highest performance in binary classification of PU and IAD, with an F1-score (harmonic mean of precision and recall) of 93.23%, outperforming wound care experts and nursing staff on the test dataset. In fine-grained classification of wound categories, the TinyViT model also performed best for PU categories with an F1-score of 75.43%, while ConvNeXtV2 showed superior performance in IAD category classification with an F1-score of 53.20%. Incorporating multimodal data improved performance in binary classification but had less impact on fine-grained categorization. Augmentation strategies and training techniques significantly influenced model performance, with ensembling enhancing accuracy across all tasks.

Conclusions: Our multimodal deep learning framework effectively differentiates between PUs and IAD, achieving high accuracy and outperforming human wound care experts. By integrating wound images with categorical patient data, the model enhances diagnostic precision, offering a valuable decision-support tool for health care professionals. This advancement has the potential to reduce diagnostic uncertainty, optimize treatment pathways, and alleviate the burden on medical staff, leading to faster interventions and improved patient outcomes. The framework's strong performance suggests practical applications in clinical settings, such as integration into hospital electronic health record systems or mobile applications for bedside diagnostics. Future work should focus on validating real-world implementation, expanding dataset diversity, and refining fine-grained classification capabilities to further enhance clinical utility.

Introduction

Background

Pressure ulcers (PUs) and incontinence-associated dermatitis (IAD) are significant challenges in clinical settings due to their prevalence and impact on patient health and well-being. The global prevalence of PUs is estimated to be 12.8% [1], while studies have estimated the IAD prevalence to be between 5.6% and 50% [2]. These wounds not only cause physical discomfort but also pose risks of infection and prolonged hospital stays, increasing health care costs and diminishing the quality of life for affected individuals.

Accurately distinguishing between PUs and IAD poses a considerable challenge for health care providers and wound care experts. Both conditions share similar presentations, yet their underlying causes and optimal treatment approaches differ vastly. This ambiguity not only complicates diagnosis but also delays appropriate interventions, potentially exacerbating patient discomfort and prolonging healing times [3].

To address this challenge, the KIADEKU project [4] was initiated to develop an innovative artificial intelligence (AI) system capable of distinguishing between PUs and IAD using wound image data and key patient information.

Goal of This Study

The goal of this study is to advance wound care by developing a robust multimodal deep learning framework for the fine-grained classification of PUs and IAD. By integrating wound images with categorical patient data, we aim to enhance diagnostic accuracy in distinguishing between these conditions and in categorizing their respective wound severities. We conduct extensive benchmarking of state-of-the-art convolutional and transformer-based models, emphasizing optimal performance while ensuring computational efficiency for practical deployment in clinical settings. The optimized model addresses the challenging task of accurately classifying PU and IAD wounds, providing valuable insights and tools to support clinical decision-making and guide future research in wound classification.

Related Work

Deep learning has significantly advanced wound classification, including PUs and other wound types. Various studies have explored different deep learning architectures and techniques to improve diagnostic accuracy and efficiency. Table 1 summarizes key contributions in this domain.

While previous studies have demonstrated the effectiveness of deep learning for wound classification, they predominantly rely on image data alone. However, accurate wound diagnosis often depends on both visual appearance and key clinical factors, such as wound location, patient mobility, and incontinence severity. To our knowledge, no existing study rigorously integrates multimodal data fusion, combining wound images with categorical patient information. Our approach leverages this additional patient context, allowing the model to capture clinically relevant patterns that purely image-based models may overlook, thereby significantly improving diagnostic precision and decision support. Furthermore, our approach involves extensive benchmarking of state-of-the-art convolutional and transformer-based models, as well as various training techniques, augmentations, and postprocessing methods to enhance performance. This comprehensive evaluation sets our method apart in both scope and effectiveness, contributing to a novel multimodal framework for fine-grained wound classification that can support clinical decision-making and guide future research in this domain.

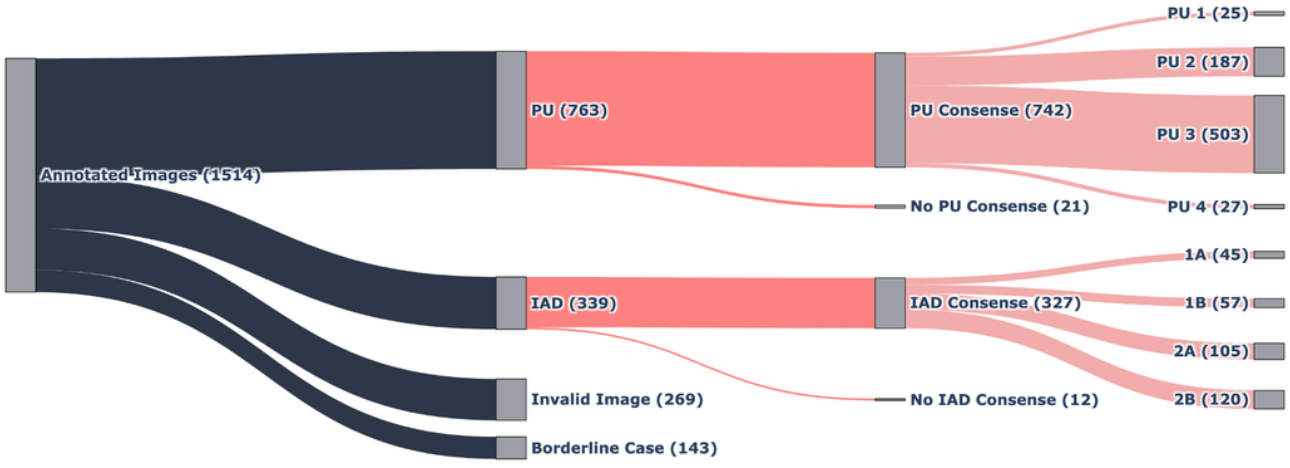
Methods

Dataset

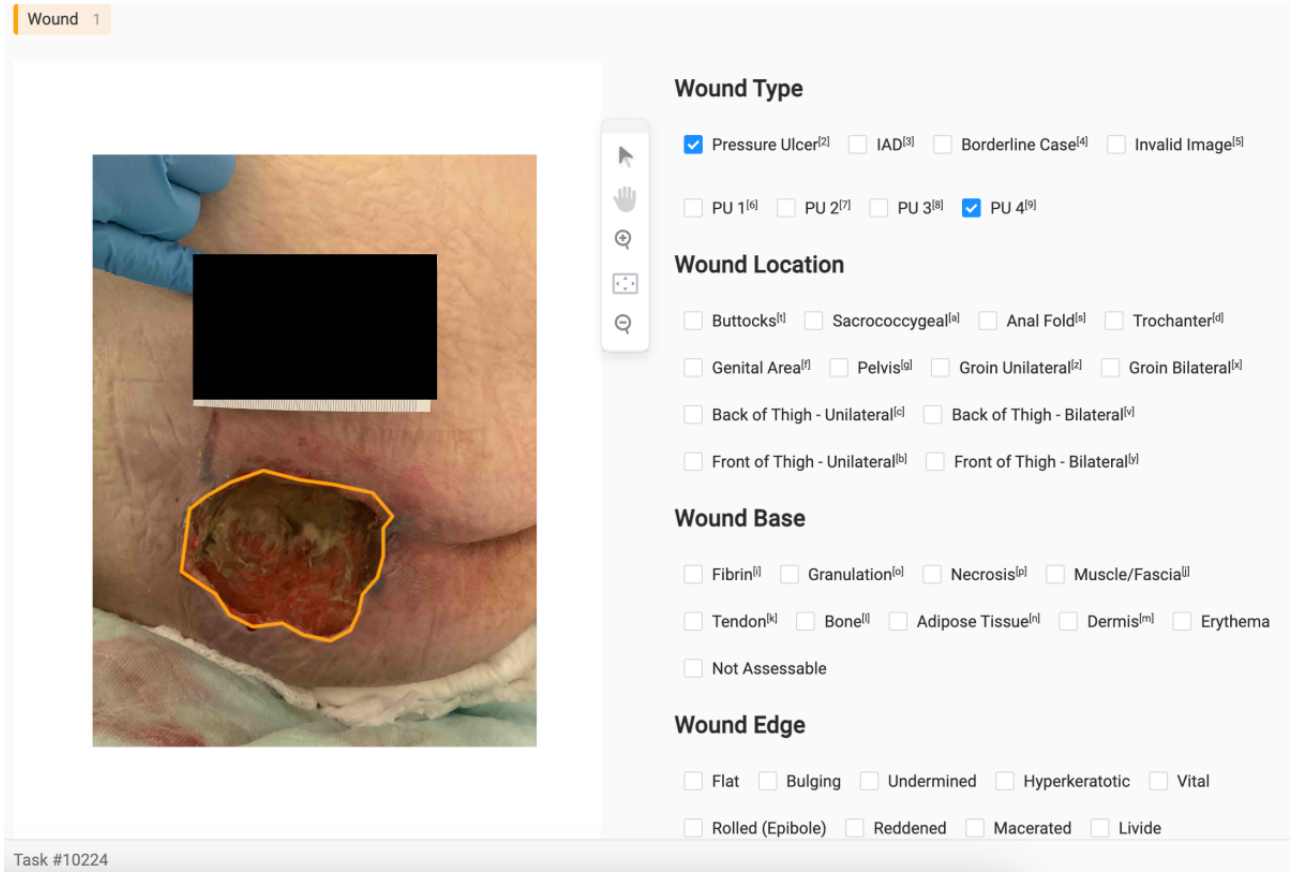
In this study, we use a new wound dataset collected and annotated over a 2-year period as part of the KIADEKU project. The data originate from the project partners Ludwig Maximilian University University Hospital and Essen University Hospital and were annotated by 4 wound experts with extensive clinical experience in wound management using the Label Studio Software [24]. Considering the difficulty of the task, we enforced a strong ground truth by having all images annotated by 3 wound experts and only used images where 2 wound experts reached consensus in their annotations.



The annotators categorized each image as either IAD, PU, invalid, or borderline case (both wounds present) and assessed the categorization of each wound type. For PU classification, we followed the *International Classification of Diseases*-10 standard [25], which defines 4 degrees (1-4) of PU wounds. Similarly, for IAD classification, we used the Ghent Global IAD Categorization Tool (GLOBIAD) [26], which categorizes IAD wounds into 4 distinct categories: 1A, 1B, 2A, and 2B. Figure 1 shows an exemplary annotation interface.

Employing the described annotation protocol, a dataset of 1555 images was annotated, from which 1514 images received consensus validation among the annotators. Analysis of the data revealed a generally balanced distribution between the 2 principal wound types under study, PUs and IAD, as depicted in Figure 2. The dataset comprised 763 images of PU and 339 images of IAD.

Of the 763 images categorized as PUs, consensus was achieved for 742 images regarding their specific PU category. The distribution of these categories, as illustrated in Figure 2, reveals a significant class imbalance. Notably, categories 1 and 4 are markedly underrepresented, containing only 25 and 27 images, respectively, compared to 187 images in category 2 and 503 in category 3. This pronounced disparity in class sizes is a critical factor that must be considered when interpreting the training results.



Of the 339 images initially classified as IAD, a consensus on the specific IAD category was reached for 327 images. The class distribution within these categories, as depicted in Figure 2, is relatively balanced compared to the distribution observed in PU categories. Category 2B is the most represented, with 120 images, followed by category 2A with 105 images, 1B with 57 images, and 1A with 45 images. Although this distribution is less skewed than that observed in the PU categories, the smaller sample size overall remains a significant consideration for model training and validation.

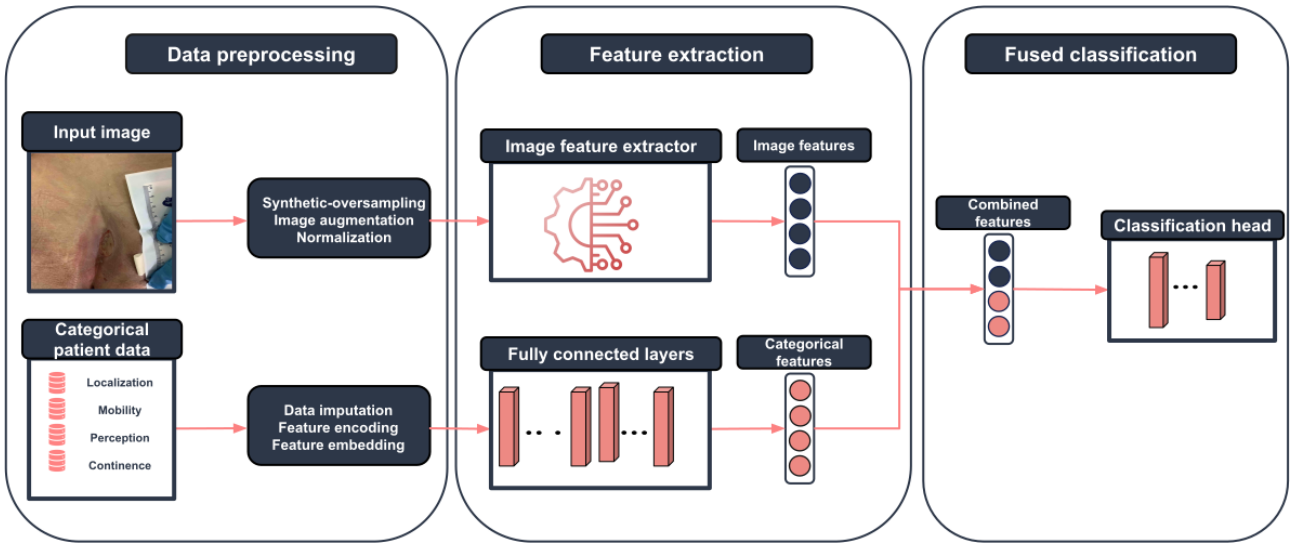
Methodology

Our proposed classification framework is specifically designed to handle and classify both images and categorical data effectively, as shown in Figure 3.



Initially, the original images undergo several preprocessing steps. These steps include image augmentations and normalization to standardize the input data, alongside the generation of synthetic data points by fine-tuning a stable diffusion model and using these synthetic samples to oversample the minority classes across tasks. We then compare the performance of this approach with traditional oversampling techniques that rely on original data points. For categorical patient data (eg, wound location, mobility, perception ability, and continence status), missing values were addressed using mode imputation, where the most frequent value for each feature was assigned. In cases where missing values exceeded 20% of the dataset for a particular feature, the affected samples were excluded to prevent bias. Additionally, images with conflicting expert annotations (ie, cases where consensus was not reached) were removed to maintain ground truth integrity. After data preprocessing, we extract features from each modality. Image features are extracted using various feature extractors from the Timm [27] library, renowned for their robustness and efficiency; in parallel, categorical features are derived using a simple feed-forward neural network designed to capture the essential characteristics of the embedded categorical data.

In the final stage of our framework, we employ 3 distinct modality fusion techniques to integrate image and categorical features before classification. In the concatenation-based fusion, features from both modalities are directly concatenated to form a comprehensive feature set, which is then passed to a classification head. In the cross-attention-based fusion, categorical features are projected into the image feature space, and a multihead attention mechanism is applied to capture their interactions. In the gated fusion, a gating mechanism adaptively balances the contributions of both modalities, allowing the model to learn the optimal weighting before classification. Each approach ensures effective multimodal integration while leveraging different fusion strategies. The combined feature set is then fed into a final classification head, which is tasked with making the final prediction based on the integrated data.

This setup facilitates a systematic examination and evaluation of various data preprocessing strategies, training techniques, and postprocessing approaches, both independently and in combination. This rigorous methodology allows for a comprehensive comparison and assessment of their efficacy in various combinations across our designated tasks.

XSL•FO
RenderX

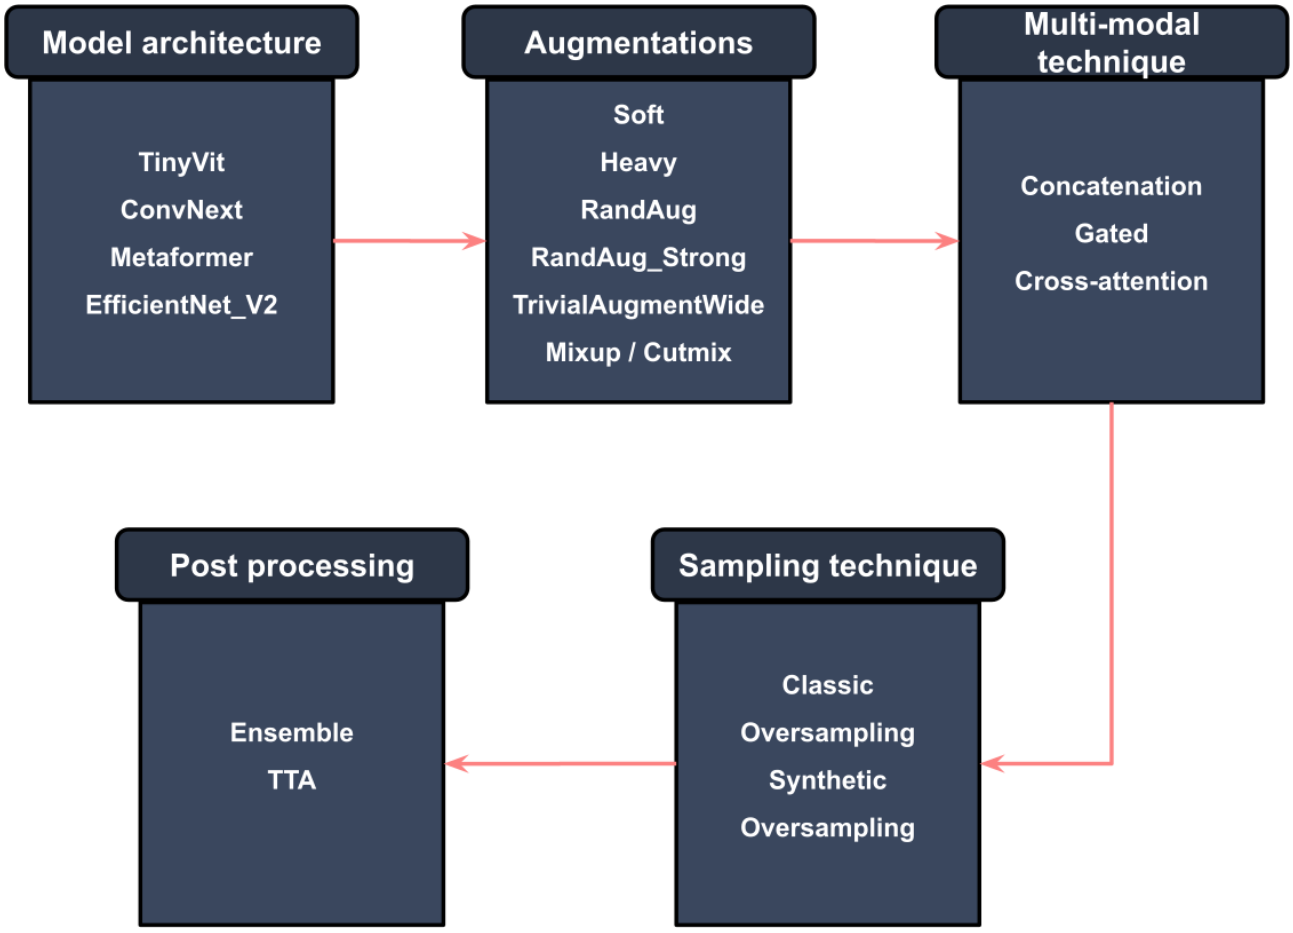


Figure 3. Multimodal architecture visualization illustrating the use of data preprocessing and feature extraction, before fusing the features for the final classification.

Experimental Setup

To maintain a manageable number of experiments, we did not evaluate every possible combination. Instead, we benchmarked various components individually and sequentially integrated the optimal variations for subsequent tests. Specifically, we first identify the model architecture that achieves the highest average rank across our metrics and use this model as the basis for testing different augmentation techniques. The best performing augmentation variation, as determined by the average metric rank, is then used to assess different training techniques. Finally, the best combination of model, augmentation, and training technique is used to benchmark the most effective postprocessing strategy. For a visual representation of this benchmarking flow, refer to Figure 4.

Figure 4. Visualization of experiment setup and benchmark flow. TTA: test-time augmentation.

XSL•FO
RenderX

Training

The general training procedure involves setting the learning rate to 0.0001 and resizing the input images to 384x384 pixels. We use a batch size of 64, with the AdamW optimizer to manage weight decay, and the CrossEntropyLoss loss function for training. The learning rate is adjusted using a CosineAnnealingWarmRestarts scheduler, starting with a cycle length of 10 epochs and a minimum learning rate of 1e-6. Training is performed on an NVIDIA A100 graphics processing unit, with early stopping enabled and a patience of 15 epochs to prevent overfitting. The dataset is initially split into an 80:20 ratio for training and testing. The training set is further divided into 5 equal parts (folds) for cross-validation to enable robust model evaluation.

Models

To evaluate and identify the best possible model for the binary classification task of IAD and PU, as well as the fine-grained wound category classification within these wound types, we selected 4 models with approximately 25 million parameters to ensure a fair comparison and fast inference speed. Using transfer learning, we employed pretrained models from the Timm library, which were originally trained on ImageNet [27]. Our selection includes 2 convolution-based models and 2 transformer-based models, chosen for their exceptional performance relative to their parameter count, as evidenced by Timm's test results on the ImageNet benchmark. For the convolution-based models, we selected a pretrained ConvNeXtV2 model [28,29] and a pretrained EfficientNetV2 model [30,31]. These models are chosen for their state-of-the-art performance and efficiency, making them highly suitable for a wide range of computer vision tasks. The ConvNeXtV2 incorporates advanced architectural enhancements, while EfficientNetV2 uses a novel scaling approach for optimal accuracy and computational efficiency. For the transformer models, we included the MetaFormer [32] and TinyViT [33,34]. The MetaFormer is selected for its innovative design that enhances transformer capabilities, while TinyViT, a distilled vision transformer, is designed to retain high accuracy with fewer parameters and computational resources, making it suitable for resource-constrained environments.

Augmentations

We evaluate 6 distinct augmentation techniques comprising 3 randomized methods and 2 custom-designed variants and the use of CutMix/MixUp [35]. Initially, we test the RandAugment [36] method using its PyTorch implementation with default settings. To explore more robust options, we employ an intensified version of RandAugment, increasing the augmentation count to 4 and the magnitude to 12. Additionally, we assess the PyTorch implementation of TrivialAugmentWide [37] with default parameters, a straightforward approach that applies a single, random augmentation to each image. Moreover, we introduce 2 proprietary augmentations developed for exploratory purposes. The first, a mild augmentation set, incorporates random affine transformations, perspective adjustments, and rotations. The second, a more intensive augmentation suite, applies random flips, rotations, color jittering, affine transformations, perspective adjustments, and Gaussian blurring, all implemented using the torchvision transformation library. Finally, we evaluate CutMix and MixUp augmentation using the PyTorch v2 implementation, where images are randomly augmented with either CutMix or MixUp using a random selection strategy, ensuring diverse augmentation during training.

Training Techniques and Postprocessing

Next, we explore various training variations and postprocessing techniques used in this study. Initially, we incorporate multimodal data in our training, which includes both patient images and tabular data detailing wound location, mobility, perception ability, and urinary plus fecal continence. Each factor of mobility, perception, and continence is quantified on a scale from 0 to 4. A joint fusion approach is adopted for multimodal classification, where image embeddings are combined with tabular data embeddings, followed by a final classification head.

Concerning sampling strategies, we address the low sample size in certain classes by employing oversampling techniques to balance class distributions. In addition to classic oversampling, we introduce a synthetic data generation approach by fine-tuning a stable diffusion model to generate artificial images for the minority classes. This allows us to augment underrepresented categories with high-quality synthetic samples. We compare the performance of this approach against traditional oversampling methods to assess its effectiveness in mitigating class imbalance. In terms of postprocessing, we implement ensembling to enhance model performance and robustness by averaging predictions from all 5 folds. Furthermore, test time augmentation is employed by averaging predictions of the original image with 4 additional variants that have undergone mild augmentations such as random flips, rotations, and slight color jitter.

Evaluation Metrics

To assess the performance of the various models and training strategies, we employ several key metrics. The evaluation metrics used in this study include F1 score, area under the receiver operating characteristic curve (AUROC), and average precision (AP). All metrics were implemented using the torchmetrics library [38]. These metrics were chosen based on informed estimations and insights from Maier-Hein et al [39] recommendations.

Ethical Considerations

Ethical approval for this study was granted by the Ethics Committee of the Medical Faculty of the University of Duisburg-Essen on October 4, 2022 (ref number: 22 - 10905-BO). The study involved retrospective analysis of de-identified image data, and no direct contact with participants occurred. As such, informed consent was not required. All data were processed in compliance with applicable privacy and data protection regulations. In addition, the overall KIADEKU project is registered with the German Clinical Trials Register (Deutsches Register Klinischer Studien (DRKS)) under the registration number DRKS00029961.

Results

Overview

Table 2 presents the performance metrics of our best models across the 3 classification tasks. For the binary classification between PU and IAD, the model achieved an F1-score of 93.23%, an AUROC of 0.9852, and an AP of 0.9813. In the PU category classification, the model obtained an F1-score of 75.43%, an AUROC of 0.9384, and an AP of 0.8616. For the IAD category classification, the F1-score was 53.20%, with an AUROC of 0.8391 and an AP of 0.5927.

When examining the optimal combinations per task (refer to Table 3), it is observed that, from an architectural standpoint, transformer models exhibit a superior performance compared to convolution-based models. An exception to this trend is noted in the IAD Category Classification task, where the ConvNeXtV2 model achieves the highest overall performance.

Table . Performance of the best models.

Technique	F_1-score	AUROC[a]	AP[b]
Binary	0.9323	0.9852	0.9813
PU[c] category	0.7543	0.9384	0.8616
IAD[d] category	0.5320	0.8391	0.5927

[a]AUROC: area under the receiver operating characteristic curve.

[b]AP: average precision.

[c]PU: pressure ulcer.

[d]IAD: incontinence-associated dermatitis.

Table . Best benchmark result overview.

Task	Model	Augmentation	Multimodal technique	Sampling technique	Post processing
Binary	TinyViT	TrivialAugmentWide	Cross-attention	None	Ensemble
PU[a] category	TinyViT	RandAug Strong	None	Synthetic oversampling	Ensemble
IAD[b] category	ConvNeXtV2	Heavy	None	Synthetic oversampling	Ensemble

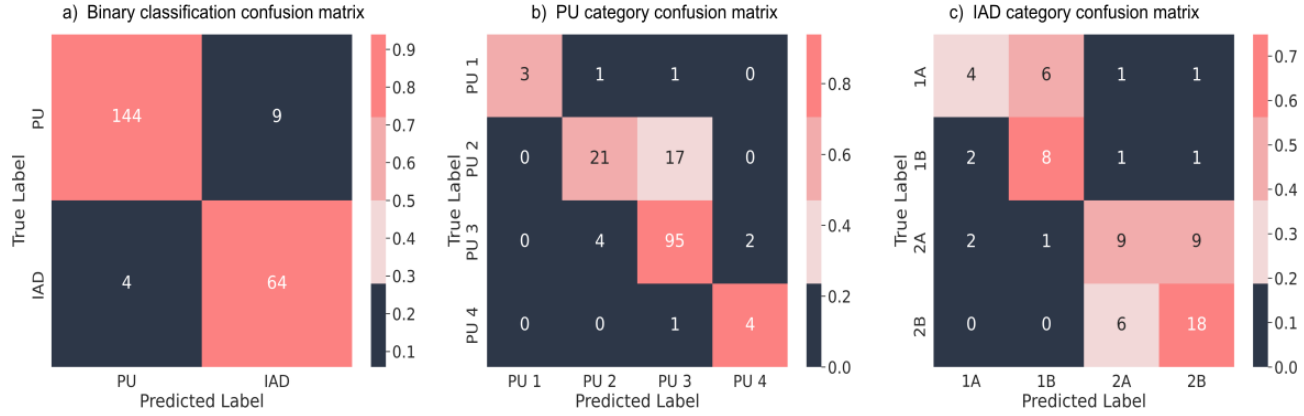
[a]PU: pressure ulcer.

[b]IAD: incontinence-associated dermatitis.

Regarding augmentations, lighter augmentations enhance performance in the binary classification task. Conversely, the finer category classification tasks benefit from more intensive augmentations, including a heavy augmentation set and significant variations of RandAugment .

Training techniques also show variability across tasks. Multimodality training proves advantageous for the binary classification, whereas it detracts from performance in fine-grained category classification. The cross-attention-based modality fusion approach shows the best performance for the binary classification task. Tailored sampling strategies yield the most substantial performance enhancements, particularly for the PU and IAD category classification tasks, where significant class imbalances are present. Both classic and synthetic oversampling improve performance in these tasks, with the synthetic approach achieving superior results. However, for the binary classification task, neither method provides a noticeable performance increase compared to the standard training regimen.

In the realm of postprocessing techniques, there is a discernible preference for ensembling, which enhances performance across all evaluated tasks. While test-time augmentation also positively impacts performance most of the time, its effectiveness is not as pronounced as that achieved through ensembling.



Detailed performance metrics for the tasks are provided in the multimedia appendices (Multimedia Appendices 1-3).

In examining the outcomes of the confusion matrices for the optimal combinations per task, as depicted in Figure 5, a more nuanced understanding of the results and the inherent complexities of the tasks is achieved. The binary classification task demonstrates a high degree of accuracy, achieving low rates of false positives and false negatives, despite the presence of slight class imbalance between the 2 categories. The classification of PU categories presents notable challenges, particularly for categories 1 and 2, which are characterized by their low frequency within the dataset. A mixup between PU-2 and PU-3 is observed to be the most common misclassification, indicating a degree of ambiguity in their differentiation.

A similar pattern is observed in the classification of IAD categories. Categories 1 and 2 prove challenging to classify accurately due to their limited sample sizes. Conversely, categories 3 and 4, while yielding better classification results, also exhibit tendencies for mutual misclassification.

XSL•FO
RenderX

Figure 5. Confusion matrices showing the best benchmarks for different classification tasks: (a) binary classification, (b) pressure ulcer (PU) category, and (c) incontinence-associated dermatitis (IAD) category.

Performance Comparison

To evaluate our model's performance, we conducted a comparative analysis against the initial hospital inputs recorded in the primary hospital systems, as well as the annotation performance of 2 wound experts and a health care provider without extensive wound expertise on the test dataset. Since the primary hospital system does not include detailed wound degree information, we limited this comparison to binary classification. Specifically, because the electronic health records in the hospitals only document the presence of PU, we assumed that all other labels correspond to IAD for the purposes of this comparison. Furthermore, we assessed model performance solely on the subset of data labeled as PUs.

As shown in Table 4, our AI model demonstrates a significant improvement in both accuracy and F1 score compared to the initial hospital inputs and health care provider annotations. Notably, the model also slightly outperforms the wound care experts on the test dataset, indicating its potential to assist in clinical decision-making.

In addition to this binary classification analysis, we evaluated the model's performance on the test datasets with respect to individual wound degree classification, as shown in Table 5. Also, in this more complex classification task, the AI model outperforms the individual wound experts and health care providers.

Table . Model performance comparison binary.

Method	All images		PU[a] only
	Accuracy	F_1-score	Accuracy
AI[b] model	0.9412	0.9323	0.9532
Primary system	0.8190	0.7260	0.8366
Wound expert 1	0.8959	0.8774	0.9281
Wound expert 2	0.8914	0.8773	0.8889
Health care provider	0.8190	0.7736	0.9150

Discussion

Principal Findings

In this study, we developed a multimodal deep learning framework for the fine-grained classification of PUs and IAD, along with their respective wound severities. By integrating wound images with categorical patient data, we aimed to enhance diagnostic accuracy and support clinical decision-making in wound care management.

Our extensive evaluations demonstrated that transformer-based architectures, particularly TinyViT, achieved superior performance across the classification tasks. The TinyViT model attained an F_1-score of 93.23% in the binary classification of PU and IAD, outperforming both wound care experts and nursing staff on the test dataset. This highlights the model's effectiveness in handling complex visual data and its potential to assist clinicians in accurately distinguishing between these 2 conditions. In the fine-grained classification of PU categories, the TinyViT model again showed the best performance with an F_1-score of 75.43%. However, the performance was notably lower than in the binary classification task, indicating the increased difficulty in distinguishing between the stages of PU due to subtle visual differences and class imbalances—particularly in differentiating the PU categories stages 1 and 2. Similarly, for IAD category classification, the ConvNeXtV2 model performed best with an F_1-score of 53.20%, but the overall performance was modest, reflecting challenges in differentiating between IAD severity levels.

These findings indicate that while our models effectively distinguish between PU and IAD, their performance in classifying the specific categories within each condition can be enhanced, particularly due to challenges posed by subtle visual differences and class imbalances. Misclassifications often occurred between adjacent categories, which may be due to overlapping visual features and insufficient samples in certain classes. This underscores the need for larger and more balanced datasets to enhance model training and improve classification accuracy in fine-grained tasks. To address this, future research could focus on targeted data collection to increase underrepresented classes. Additionally, exploring advanced synthetic data generation techniques could provide valuable insights, as our study demonstrated the effectiveness of stable diffusion–based synthetic oversampling.

The integration of multimodal data, which combines images with patient information, was beneficial in the binary classification task, enhancing the model's ability to differentiate between PU and IAD. This highlights the importance of contextual clinical information in supporting image-based diagnoses. However, the inclusion of multimodal data had less impact on the fine-grained classification tasks. This may be because the categorical patient data do not provide sufficient granularity to assist in distinguishing between wound severities within PU or IAD. Augmentation strategies played a significant role in model performance. Lighter augmentations were more effective for the binary classification task, possibly because they preserved essential image features while providing variability. In contrast, more intensive augmentations benefited the fine-grained classification tasks by helping the models generalize better to subtle variations in wound appearances. This indicates that augmentation techniques should be tailored to the specific requirements of each classification task.

Synthetic data generation and oversampling proved particularly effective in mitigating class imbalances in the PU and IAD category classification tasks, enhancing the model's ability to learn from underrepresented classes. Notably, the synthetic oversampling approach demonstrated superior performance compared to traditional oversampling, highlighting its potential for improving classification in highly imbalanced settings. In terms of postprocessing, ensembling predictions from multiple folds consistently improved model performance across all tasks, providing more robust and reliable results. While test-time augmentation also contributed to performance gains, its impact was less pronounced compared to ensembling.

These findings contribute valuable insights into the development of more effective diagnostic tools and algorithms for wound classification. By addressing the challenges identified, future work can focus on enhancing the precision and utility of clinical assessments, ultimately improving patient care outcomes.

Limitations

This study, while providing significant insights into the classification of PU and IAD using advanced AI techniques, has certain limitations that warrant consideration. The dataset used, although comprehensive, may not adequately represent the vast diversity of clinical environments and patient demographics. This could limit the generalizability of the findings to other settings or populations. Additionally, inherent class imbalances within the dataset, despite efforts to mitigate their effects through techniques like oversampling and synthetic data generation, might have influenced the model's learning, potentially skewing the accuracy toward more frequently represented classes.

Moreover, the integration of multimodal data did not uniformly improve performance, indicating that its effectiveness varies depending on the data's context and characteristics. This suggests a need for further investigation into which data types are most useful and how they should be integrated.

Furthermore, the study did not exhaustively evaluate every conceivable combination of models, augmentations, training techniques, and postprocessing methods. Instead, selections were based on educated predictions, leveraging the highest-performing techniques from prior phases of the research. This approach, while efficient, may have overlooked potentially effective combinations that could offer further insights or enhanced performance. Additionally, fine-grained classification remains a challenging task due to subtle visual differences between wound categories. Future work should explore attention mechanisms to highlight key image regions and improve model focus, as well as few-shot learning techniques to enhance performance on underrepresented classes. Lastly, the comparison of the model's performance with wound care experts and primary systems is constrained by the specific test dataset used in this study, and as such, the findings may not be fully

XSL•FO
RenderX

generalizable to broader and more diverse datasets or clinical scenarios.

Conclusions

This study has successfully implemented a framework for classifying PUs and IAD using advanced artificial intelligence methodologies. By systematically evaluating various computational strategies, including different model architectures, augmentation techniques, training methods, and postprocessing approaches, this research provides valuable insights into optimizing AI-driven wound classification models and their potential for real-world clinical application.

The exploration revealed that transformer-based models, notably the TinyViT, generally outperform other architectures, highlighting their suitability for complex visual data processing in fine-grained applications. The effectiveness of different augmentation strategies varied with the complexity of the classification task, emphasizing the need for tailored approaches depending on the specific requirements of the data and the classification objectives.

Furthermore, the study highlights the value of multimodal data integration in enhancing classification accuracy in specific contexts, though its effectiveness varies across tasks. In addition, our findings emphasize the importance of addressing class imbalances, where both classic and synthetic oversampling significantly improved performance, particularly in tasks with severe class disparities. Notably, synthetic oversampling demonstrated superior effectiveness, suggesting that generative models can serve as a powerful tool for augmenting underrepresented classes. Finally, the superior performance of ensembling in postprocessing underscores its potential as a robust strategy for improving prediction reliability, particularly in clinical applications.

In conclusion, our work presents a highly effective classification model capable of accurately distinguishing between PU and IAD images. This model can serve as a valuable tool to assist health care providers in making correct diagnoses, thereby enhancing clinical decision-making and improving patient outcomes in wound care management. The application of our model has the potential to streamline the diagnostic process, reduce the burden on medical staff, and ensure that patients receive appropriate and timely treatment. Furthermore, our extensive benchmarking provides a valuable reference and guidance for future research and development in wound image classification, contributing to the advancement of practical applications within the domain.

Acknowledgments

We would like to express our sincere gratitude to the wound care experts and nursing staff at University Hospital Essen and Ludwig Maximilian University Hospital Munich for their invaluable assistance in data collection and annotation. We also thank the KIADEKU project team for their collaboration and support throughout this study. This work was supported by the German Federal Ministry of Education and Research (V6KIP039)

Data Availability

The code used in this study will be made publicly available on GitHub [40]. Model weights can be shared upon request. Due to the sensitive nature of the medical image data obtained from a private hospital, the datasets used in this study are not publicly available and cannot be shared to protect patient privacy and confidentiality.

Abstract

Background: Insufficient participant enrollment is a major factor responsible for clinical trial failure.

Objective: We formulated a machine learning (ML)–based framework using clinical laboratory parameters to identify participants eligible for enrollment in a bioequivalence study.

Methods: We acquired records of 11,592 patients with gastric cancer from the electronic medical records of Kyungpook National University Hospital in Korea. The ML model was developed using 8 clinical laboratory parameters, including complete blood count and liver and kidney function tests, along with the dates of acquisition. Two datasets were collected: (1) a training dataset to design an ML-based candidate selection method and (2) a test dataset to evaluate the performance of the proposed method. The generalization performance of the ML-based method was confirmed using the F_1-score and the area under the curve (AUC). The proposed model was compared with a random selection method to evaluate its efficacy in recruiting participants.

Results: The weighted ensemble model achieved strong performance with an F_1-score above 0.8 and an AUC value exceeding 0.8, demonstrating its ability to accurately identify valid clinical trial candidates while minimizing misclassification. Its high sensitivity further enhanced the model's efficiency in prioritizing patients for screening. In a case study, the proposed ML model reduced the workload by 57%, efficiently identifying 150 valid patients from a pool of 209, compared to the 485 patients required by random selection.

Conclusions: The proposed ML-based framework using clinical laboratory parameters can be used to identify patients eligible for a clinical trial, enabling faster participant enrollment.

Introduction

Inadequate participant recruitment may lead to failure in a clinical trial, ultimately delaying new drug development and increasing costs [1-7]. Tasks comprising the recruitment process, such as prescreening, consent, screening, and communication between the participant and the study staff for the clinical trial, are inevitably labor intensive [2,3,8-10]. For instance, researchers manually review large volumes of electronic medical records (EMRs) during the prescreening process to identify potential candidates. Despite advances in the methodologies for each process in clinical trials, a systematic approach for enhancing the efficacy of participant enrollment is lacking.

Artificial intelligence (AI) has various applications in every section of the industry, and a machine learning (ML)–based optimal design of clinical trials has entered the sphere of pharmaceuticals [11]. Several AI techniques for identifying, screening, and enrolling appropriate participants for clinical

XSL•FO
RenderX

trials have been introduced, and some have been employed commercially [1,4,8].

Corporates such as Mendel, Deep 6 AI, and Antidote have developed and provided AI solutions for clinical trial recruitment [12-16]. These commercial services use massive data such as demographics, laboratory, imaging, and multiomics data to facilitate faster recruitment and provide full-service recruitment [14,15]. Jin et al [17] reported that a result from a user study using large language model framework, TrialGPT, to support patient matching resulted in a 42.6% decrease in the screening time [18]. Another AI approach is clinical trial digital twin technology [18-21]. Digital twin technology creates virtual patients that replicate individual characteristics, enabling the prediction of clinical responses [18,19,21]. By utilizing digital twins, the required sample sizes for clinical trials can be reduced [18,19,21]. These informatics-based tools are expected to improve recruitment efficiency, directly influencing the success rate of clinical trials [1,4,5].

Eligibility criteria specify the qualification of participants in clinical trials, and this component comprises structured information, including diagnoses and laboratory results, and unstructured information, such as clinical free text. Previous AI studies have primarily focused on developing advanced natural language processing and optical character recognition techniques for extracting unstructured data [2,3,6,8-10]. As AI technology is rapidly changing, most research and services have developed AI tools using both structured and unstructured data [12,14-16,22]. However, complicated preprocesses (eg, annotation), discrepancies between EMR systems and databases of institutions (eg, noninteroperable algorithms), and high costs limit their application. Moreover, highly sophisticated eligibility criteria can render the generalization of algorithms challenging.

In contrast, clinical laboratory test data and typical structured data can be readily incorporated into an EMR-utilizing algorithm, given that these data are comparatively more objective than other unstructured data [23,24]. Mohammad et al [11] have suggested that disclosing the pretest probability of a specific test result can be clinically meaningful for some laboratory tests.

In bioequivalence studies of drugs, clinical laboratory tests such as hematology and blood chemistry tests are included as eligibility criteria. Participants considered suitable by the investigator based on laboratory results are allowed to take part in the bioequivalence study. Therefore, prescreening through clinical laboratory tests is considered to be effective in quickly selecting potential candidates.

Accordingly, we formulated an ML-based framework to identify participants using the clinical laboratory test values of candidates. In this study, we chose to compare the ML-based method with a random selection method, which we considered representative of the common practice in clinical settings where patient lists are screened sequentially. Collectively, the objective of this study was to develop a simple and rapidly applicable ML algorithm that could assist in participant identification for bioequivalence study enrollment.

Methods

Study Design

In total, records of 11,592 patients with gastric cancer were acquired from the EMRs of Kyungpook National University Hospital in Korea from 2011 to 2019. Clinical laboratory parameters (including complete blood count and liver and kidney function tests) and acquisition dates were acquired to develop the ML-based model to predict relevant laboratory data of patients on a future date. The laboratory parameters selected were those used in the eligibility criteria for bioequivalence testing of anticancer drugs in patients with gastric cancer. We developed the model using 8 basic and straightforward parameters such as complete blood count (hemoglobin, neutrophil count, platelet count), liver function tests (total bilirubin, aspartate aminotransferase, alanine aminotransferase, alkaline phosphatase), and kidney function tests (creatinine), which are minimal tests capable of assessing health status. These parameters enable a simple and efficient preliminary assessment of potential screening candidates.

“Label 1” was assigned when the candidate’s clinical laboratory data fell within the valid range, while “label 0” indicated data outside the valid range (Table 1). A patient was considered a valid candidate for a clinical trial only if all predicted laboratory data met the eligibility criteria. To design an ML-based candidate selection method, the dataset was divided into training and test sets; data collected from 2011 to 2018 were used for training, while data from 2019 were reserved for testing (Table 1). This time-based split ensured a fair evaluation of the model’s performance by avoiding any temporal overlap, thereby reflecting real-world scenarios where future data (test data) would not be available during model training. Additionally, this approach allowed us to assess the model’s ability to generalize unseen data while accounting for potential temporal effects, such as advances in medical technology or shifts in population health trends. By adopting this methodology, we aimed to provide a realistic evaluation of the model’s performance in clinical settings.

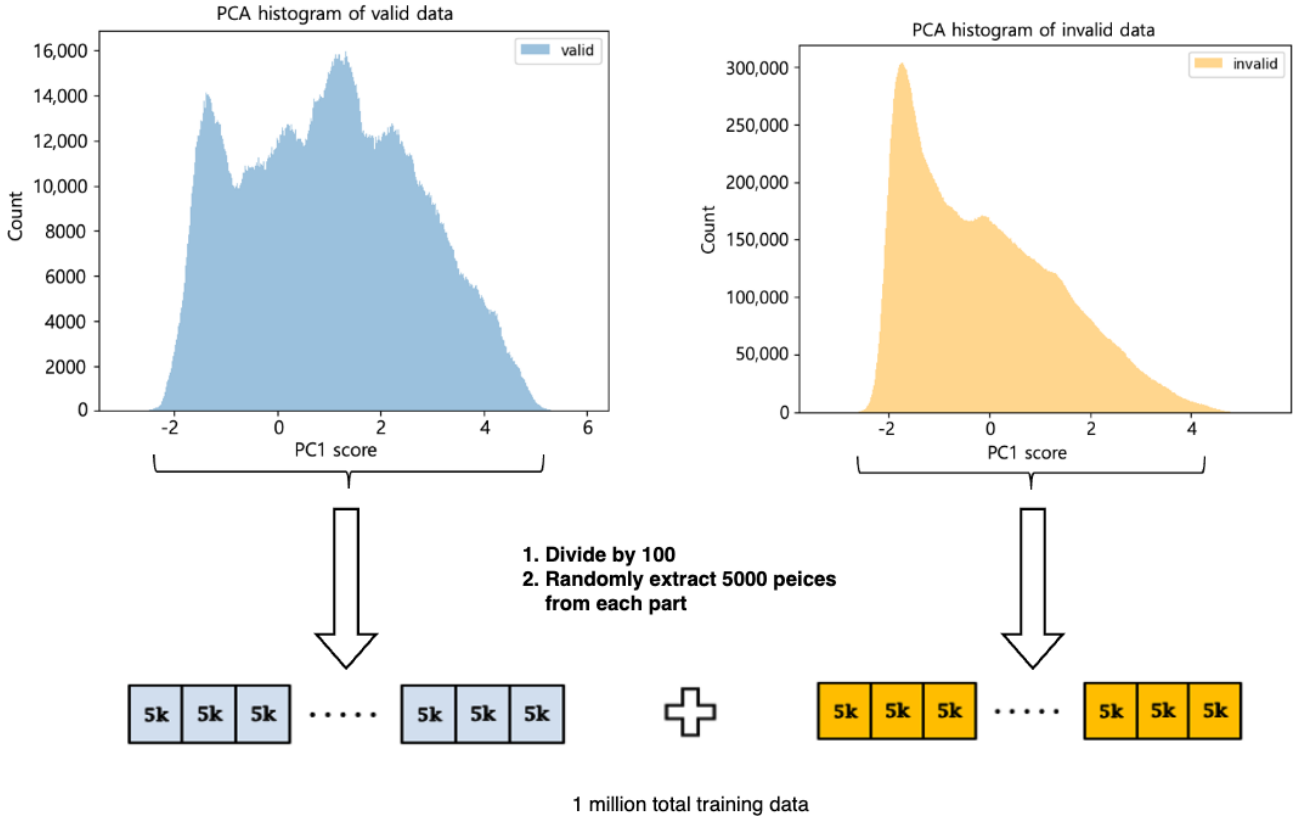
[c]ALP: alkaline phosphatase.

Ethical Considerations

This study was approved by the Kyungpook National University Hospital Institutional Review Board (KNUH 2020-04-023), and a waiver of consent was authorized. All research was performed in accordance with the guidelines of the Declaration of Helsinki, and only deidentified data were used and analyzed in our retrospective study.

Data Preprocessing

We attempted to resolve the issues of aperiodicity and imbalance in the training dataset by applying the combination method and principal component analysis (PCA). First, to analyze the trend of laboratory data changes, at least 3 sequential data points of laboratory data and acquisition dates were required. However, given the nonperiodical patient visits to the hospital, the intervals between each data point were inconsistent. To compensate for the aperiodicity of the data, the distribution of data points was increased by computing a simple combination method as follows:



$$C(n,k)=P(n, k)k!=n!(n-k)!k! \quad (1)$$

where P indicates the permutation function, n is the number of data points, and k is the number of selected sequential data points (4 in this study). Therefore, 4 sequential data points with 8 values, comprising 6 initial values to analyze the trend of data changes and 2 values as target data to verify the analysis model, were generated as one data group. For example, if a patient had 10 laboratory data points, 210 data groups, including 8 values, were augmented. Each laboratory data value was normalized by the minimum and maximum values of data distribution, and the acquisition date values are represented by |acquisition date − a screening date| / N, where N is a normalization factor. Finally, each data group was encoded by considering whether the last 2 values were within the valid range. Table S1 in Multimedia Appendix 1 presents the number of training data points obtained using the combination method.

The augmented training dataset was intuitively visualized by applying the first principal component, as shown in Figure 1. Although Equation 1 helps resolve aperiodicity, the problem of nonuniform distribution in the dataset persisted in both valid and invalid classes. Thus, to compensate for the nonuniform distribution of training data groups, we normalized the imbalanced data into 100,000 even training data points of each laboratory parameter by dividing the data distribution into 100 regions and randomly extracting 5000 data points from each region (Figure 1). Moreover, we attempted to correct the data imbalance by selecting the same number of data points for each label class. Table S2 in Multimedia Appendix 1 lists the numbers of training and test datasets.

ML-Based Selection Method

There are various models in ML, and the performance of each model can vary greatly depending on how the elements of the process, such as data preprocessing, feature engineering, model selection, hyperparameter tuning, and ensembling, are configured. Therefore, specialized knowledge and experience are required, making it difficult for nonexperts to use the same skills as experts. To solve this problem, automated ML (AutoML) simplifies and automates the mentioned complex processes, so that nonexperts can easily use ML and expect the same performance as experts.

AutoGluon-Tabular is an AutoML and an open-source library developed by Amazon Web Services [25]. Figure 2 shows the architecture in this study that utilizes it. The input data is applied with various ML models (KNeighbors, random forest, Extra Trees, Light Gradient-Boosting Machine [LightGBM], Extreme Gradient Boosting [XGBoost], CatBoost, and NeuralNet) and a stacked ensemble technology that combines them, and the output is the probability value that predicts whether the patient is valid.

XSL•FO
RenderX

Results

The present study consisted of two parts: (1) the generalization performance of the ML-based model was confirmed with various evaluation metrics, including accuracy, sensitivity, specificity, precision, F_1-score, and area under the curve (AUC); and (2) the proposed model was compared using a random selection method to evaluate its efficacy in participant recruitment.

The training results for each model were evaluated as F_1-scores (Table 2). The weighted ensemble model resulted in the highest average F_1-score of 0.91 (SD 0.076). The weighted ensemble model exhibited the best performance in terms of precision and recall. Among the same ML models, detailed models were classified according to parameters such as the size and calculation method. As shown in Table 2, we observed that the F_1-score for the weighted ensemble model was over 0.8 during the training process, indicating strong performance. An F_1-score above 0.8 is generally considered strong, as it reflects a good balance between precision and recall, which is crucial in clinical applications where both false positives and false negatives can have significant consequences. Precision measures how many of the predicted valid candidates are truly valid, while recall reflects how many of the actual valid candidates were correctly identified by the model. A high F_1-score ensures that the model is not only accurate in predicting valid candidates but also minimizes the risk of misclassifying candidates who could otherwise be eligible for clinical trials.

We evaluated the performance of the classification task of the ML algorithm (Table 3). The receiver operating characteristic curves for each clinical parameter are shown in Figure S1 in Multimedia Appendix 1. In Table 3, the overall AUC value exceeded 0.8, demonstrating high performance. An AUC value exceeding 0.8 is considered high, indicating that the model has a strong ability to discriminate between valid and invalid candidates. The AUC measures the model's ability to distinguish between eligible and noneligible patients, and an AUC value closer to 1 signifies excellent performance. This is particularly important in clinical settings, where the model's ability to prioritize the right candidates can improve the efficiency and accuracy of the screening process. What we found particularly noteworthy in the results shown in Table 3 was the high sensitivity. A higher sensitivity means that the probability of correctly identifying patients who fall within the valid range is increased. We can prioritize patients with a higher probability of being in the valid range based on model predictions, and by sequentially conducting additional tests, quickly screen for an appropriate and statistically significant sample size for clinical trials, ultimately contributing to a more efficient and successful trial.

For the application test, we evaluated the effectiveness of the proposed model for identifying eligible patients from the test dataset. First, assuming prescreening dates from December 1, 2019, to December 31, 2019, laboratory data were collected from 2019. One test dataset was constructed by retrieving the last 3 laboratory data points per patient during the period. Table 4 presents the number of clinical trial participants used for the application test. In the actual hospital EMR, no alkaline phosphatase test data were available for patients with gastric cancer during this period. Cases were classified according to their valid ratio to the total. We designated the parameters as case 1 when the number of valid data was <50%, case 2 when it ranged between 50% and 60%, and case 3 when it was >60%.

Figure 3 shows the number of valid and invalid patients by probability from 0 to 1. The number of invalid patients by probability was first drawn as a histogram, and then the valid patients were drawn on top of it by accumulating them. As can be seen in the results, there were fewer valid patients and more invalid patients on the side where the predicted probability was close to 0, while there were more valid patients and fewer invalid patients on the side where the probability was close to 1. Through this, we can see that the results predicted by ML are

XSL•FO
RenderX

reliable, and it is advantageous to select patients with high probability values for patient screening.

Finally, valid candidates were identified by extracting patients in the order of highest predicted probability from the proposed model, and the results were compared with random findings. Figure 4 shows the results concerning the identification of valid patients for clinical trials. For example, in the case of hemoglobin, we aimed to identify 150 clinically suitable patients out of 673 total patients, where 203 patients met the eligibility criteria. As shown in Figure 4, our proposed model identified 150 valid patients by screening only 209 high-probability candidates. In contrast, a random selection process required screening 485 patients to find 150 valid patients. This demonstrates an approximate 57% reduction in workload.

Figure 5 shows a comparison of clinical trial participants in the order of probability of the proposed model and random method. Compared with the random selection method, more valid patients were distributed at the top of the proposed result, and more invalid patients were distributed at the bottom. When selecting patients for clinical trials, if the patients sorted by the proposed method are assigned from the top, it is possible to determine suitable target patients faster than with the random method.

Overall, the proposed ML model identified valid participants for clinical trials faster than the random selection method. In particular, as seen in the case of hemoglobin and creatinine, in case 1 and case 2, that is, when the valid rate was <60%, the proposed model identified valid participants considerably faster.

Table . The training results of the classification task evaluated by the F_1-score.

Discussion

Principal Findings

We developed an ML-based framework to support the prescreening of clinical research using clinical laboratory tests to reduce the workload of reviewing structured data of eligibility criteria. We developed a protypical but practical framework using clinical laboratory data and achieved high accuracy and a 57% workload reduction compared to random selection when identifying 150 valid patients. Based on our results, we expect that the framework will potentially reduce investigators' burden and shorten the recruitment period by assisting with conventional manual prescreening.

Prescreening involves the process of selecting candidates for screening, a cumbersome manual task that requires a heavy burden of research personnel at this stage [2,3,8-10]. The most efficient known method for determining eligibility criteria–matching candidates is as follows: candidates are randomly prioritized by research staff, and one staff member is selected to review and narrow the potential list for screening. Although several AI-based tools for assisting the recruitment of participants have been introduced, there are a few tools to support prescreening [1], and relevant studies using only structured information, such as laboratory results, are limited. Recently developed AI-based recruitment services offer a significant advantage in performing precise and rapid clinical trial participant matching by incorporating both structured and unstructured data. However, these services can be costly to implement. In contrast, our study suggests a practical alternative to more comprehensive but potentially cost-prohibitive AI-based recruitment services by showing that efficient prescreening can be conducted using laboratory data alone. This approach provides a more accessible and cost-effective method for individual researchers to apply in their bioequivalence studies.

Considering the framework of this study, the primary contribution is the establishment of a ranked list of potential participants for trial enrollment in an intuitive manner. A simple list of potential candidates can be valuable in informing the decision to review additional eligibility criteria, thereby alleviating the burden of manual prescreening and preventing underestimation due to manual review. Advantages of the framework include simple and time-saving characteristics, the requirement for only a few laboratory data among numerous EMR data, and effortless implementation through AutoGluon-Tabular. The utilization of programs such as AutoGluon-Tabular makes it easy for beginners to employ ML. In addition, ML with techniques tuned for performance improvement can be utilized by experts with minimal time and effort, making our approach more accessible.

We speculate that the irregularity of patient visiting schedules and the imbalance of the clinical laboratory parameters remain major driving limitations in the present ML-based framework. To overcome these defects, we carefully designed the algorithm using the PCA method (Table S2 in Multimedia Appendix 1 and Figure 1). However, further research is required to refine the solutions to combat aperiodicity and imbalanced data.

The proposed system can be integrated into clinical trial recruitment workflows as a decision-support tool for the

XSL•FO
RenderX

prescreening process. Currently, prescreening candidates for clinical trials often involves manually reviewing large volumes of patient data to determine eligibility. By automating the selection process, our system can generate a ranked list of potential participants based on clinical laboratory parameters, allowing research staff to focus their manual review efforts on high-priority candidates. This integration could be achieved by embedding the system into existing EMR systems. The framework can process patient data directly from the EMR, analyze the eligibility criteria, and provide a prioritized candidate list in real time. Additionally, the ranked list can be updated dynamically as new patient data becomes available, ensuring that the recruitment process is both efficient and adaptive to changing conditions.

The clinical data used in this study were collected from a specific institution (Kyungpook National University Hospital) and from patients with a specific condition, which may limit the generalizability of the findings. Therefore, further diversification of the data and additional validation are necessary. Moreover, in terms of ethics, AI models should not replace human judgment in the clinical trial participant selection process, but rather serve as an assistive tool for initial screening. In addition to the limitations of generalizability due to the data source, integrating this system into clinical workflows may encounter challenges such as compatibility with diverse EMR platforms, requiring standardized data formats and robust interoperability. Training research staff to effectively use the system and ensuring transparency in AI decision-making processes will be critical for fostering trust and adoption. Moreover, ethical and regulatory compliance regarding patient data usage must be carefully managed to address privacy concerns and uphold clinical trial standards

Our future work will focus on improving the generalization of the framework. First, we plan to apply this method to screen patients for bioequivalence studies involving cancers other than gastric cancer. Bioequivalence studies of anticancer drugs are mostly conducted on patients under follow-up after curative treatment and are performed to demonstrate the equivalence of bioavailability. Therefore, compared to clinical trials aimed at evaluating efficacy, the eligibility criteria are not quite complicated. Additionally, the presence of similar criteria makes the framework developed in this study likely to be easily generalizable.

Second, while researchers typically utilize both structured and unstructured data in the screening process, this study is limited to the use of structured data. However, we expect that screening with an ML-based framework, followed by incorporating unstructured data, could help reduce the overall workload. We aim to enhance the framework to integrate unstructured data for a more comprehensive screening process. Third, we recognize the importance of comparing our approach to existing methods, and plan to include such comparisons in future research. In this study, we targeted structured information from patients; considering unstructured and structured information may therefore enhance the generalization of the framework, covering comprehensive eligibility criteria. In addition, we plan to conduct a prospective study to compare the proposed framework with conventional methods. Collectively, we anticipate that the framework will cover a wide disease spectrum and expand its applicability to clinical trials from other institutions.

Conclusion

We proposed an AI support framework utilizing structured information on eligibility criteria to select appropriate candidates for clinical trial enrollment. This method could accelerate the efficiency of prescreening processes and can be applied to various clinical trials.

Abstract

Background: The early detection of clinical deterioration and timely intervention for hospitalized patients can improve patient outcomes. The currently existing early warning systems rely on variables from structured data, such as vital signs and laboratory values, and do not incorporate other potentially predictive data modalities. Because respiratory failure is a common cause of deterioration, chest radiographs are often acquired in patients with clinical deterioration, which may be informative for predicting their risk of intensive care unit (ICU) transfer.

Objective: This study aimed to compare and validate different computer vision models and data augmentation approaches with chest radiographs for predicting clinical deterioration.

Methods: This retrospective observational study included adult patients hospitalized at the University of Wisconsin Health System between 2009 and 2020 with an elevated electronic cardiac arrest risk triage (eCART) score, a validated clinical deterioration early warning score, on the medical-surgical wards. Patients with a chest radiograph obtained within 48 hours prior to the elevated score were included in this study. Five computer vision model architectures (VGG16, DenseNet121, Vision Transformer, ResNet50, and Inception V3) and four data augmentation methods (histogram normalization, random flip, random Gaussian noise, and random rotate) were compared using the area under the receiver operating characteristic curve (AUROC) and the area under the precision-recall curve (AUPRC) for predicting clinical deterioration (ie, ICU transfer or ward death in the following 24 hours).

Results: The study included 21,817 patient admissions, of which 1655 (7.6%) experienced clinical deterioration. The DenseNet121 model pretrained on chest radiograph datasets with histogram normalization and random Gaussian noise augmentation had the highest discrimination (AUROC 0.734 and AUPRC 0.414), while the vision transformer having 24 transformer blocks with random rotate augmentation had the lowest discrimination (AUROC 0.598).

Conclusions: The study shows the potential of chest radiographs in deep learning models for predicting clinical deterioration. The DenseNet121 architecture pretrained with chest radiographs performed better than other architectures in most experiments, and the addition of histogram normalization with random Gaussian noise data augmentation may enhance the performance of DenseNet121 and pretrained VGG16 architectures.

Introduction

Clinical deterioration is common in hospitalized patients and can lead to adverse outcomes, including increased morbidity and mortality if not identified and managed properly [1]. The early detection of patient deterioration and timely intervention can improve patient outcomes [2]. Various early warning scores (EWS) have been developed to identify the deterioration risk by monitoring different clinical variables, and the implementation of machine-learning EWS, such as the electronic cardiac arrest risk triage (eCART) score, has been associated with improved mortality [3-6]. Current EWS rely on structured

XSL•FO
RenderX

data, such as vital signs and laboratory values, to predict clinical deterioration and ignore other data modalities that could potentially enhance prediction accuracy [7]. This results in lower detection and higher false-positive rates for these scores that could be mitigated by incorporating additional modalities [8].

Because respiratory failure is a common cause of clinical deterioration, the use of computer vision models with chest radiographs is a promising direction for improving EWS performance [9]. Although traditional computer vision models have historically been used to analyze chest radiographs, prior work on chest radiographs is limited to identifying specific diagnoses [10-12]. In some recent studies, chest radiographs are used to detect lung disease [[13,14]], acute respiratory distress syndrome [15], pneumonia [16,17], tuberculosis [18,19], and COVID-19 [20]. However, to facilitate other tasks with comprehensive machine understanding, chest X-ray interpretation models are being more commonly used with the help of computer vision and transformer-based natural language processing models [21,22]. The advancements in predictive analytics with deep learning methods have led to increased capabilities to extract meaningful information from medical images, including chest radiographs [23]. However, deep learning models have never been trained with chest radiographs to predict clinical deterioration outside the intensive care unit (ICU). There are numerous deep learning architectures for chest radiograph prediction models, such as VGG16, ResNet50, DenseNet121, and Vision Transformer, and the performance of these models is unknown for this specific task. Additionally, there are different data augmentation techniques available to further enhance the performance of a vision model by improving model generalization, but it is unknown whether these data augmentation techniques would improve the performance of the prediction model for this task.

To address these knowledge gaps, the objective of this study was to compare different computer vision architectures and augmentation methods with chest radiographs for predicting clinical deterioration. Our training pipeline incorporates extensive hyperparameter tuning through Bayesian optimization and validates the generalizability of models in a separate hold-out test set. The findings of our experiments have important implications for researchers developing computer vision deep learning models for clinical applications with chest radiographs.

Methods

Ethical Considerations

The study protocol was reviewed and approved by the University of Wisconsin Institutional Review Board (approval #2019 - 1258). This study was a secondary analysis of limited HIPAA data from hospital electronic health records. The study was approved with a waiver of informed consent.

All direct identifiers of patients whose data were used in this study were de-identified prior to analysis to ensure participants privacy and confidentiality. Minimal necessary identifiable information was accessed or stored during the study beyond possible HIPAA data in clinical notes, radiological images, and real dates.

Participants did not receive any compensation for this data analysis, as no new data were collected and no direct contact with participants occurred.

Study Population and Data Collection

All adult patients (age ≥18 years) hospitalized at the University of Wisconsin Health System (UW Health) between 2009 and 2020 with an elevated eCART score ≥93 (which is the threshold used in clinical practice at UW Health) on the medical-surgical wards were eligible for inclusion in this retrospective cohort study. The eCART score [3] is a validated EWS currently in clinical practice and cleared by the Food and Drug Administration that combines demographics, vital signs, and laboratory results in a gradient-boosted machine model to predict future clinical deterioration. The rationale for only including patients with an elevated score is based on creating an enriched cohort where chest radiograph models can enhance the prediction and mitigate the false-positive alerts from these scores. Furthermore, this simplifies the prediction task to a single time point, making it more feasible to compare multiple models and augmentation strategies. Patients with a chest radiograph within 48 hours before the first elevated eCART score were included in the study. Available anterior-posterior or posterior-anterior views were included in the study cohort. In addition to chest radiographs, additional study variables that were collected included patient demographics, admission time, vital signs, laboratory values, patient location, and discharge disposition, which were all collected via the clinical research data warehouse. Figure 1 shows the patient encounter flow chart for inclusion into the analytic cohort.

XSL•FO
RenderX

Figure 1. Study inclusion criteria flow diagram.

Outcome

The study outcome of clinical deterioration was defined as a direct ward-to-ICU transfer or ward death within 24 hours of the time of the patient's first elevated eCART score.

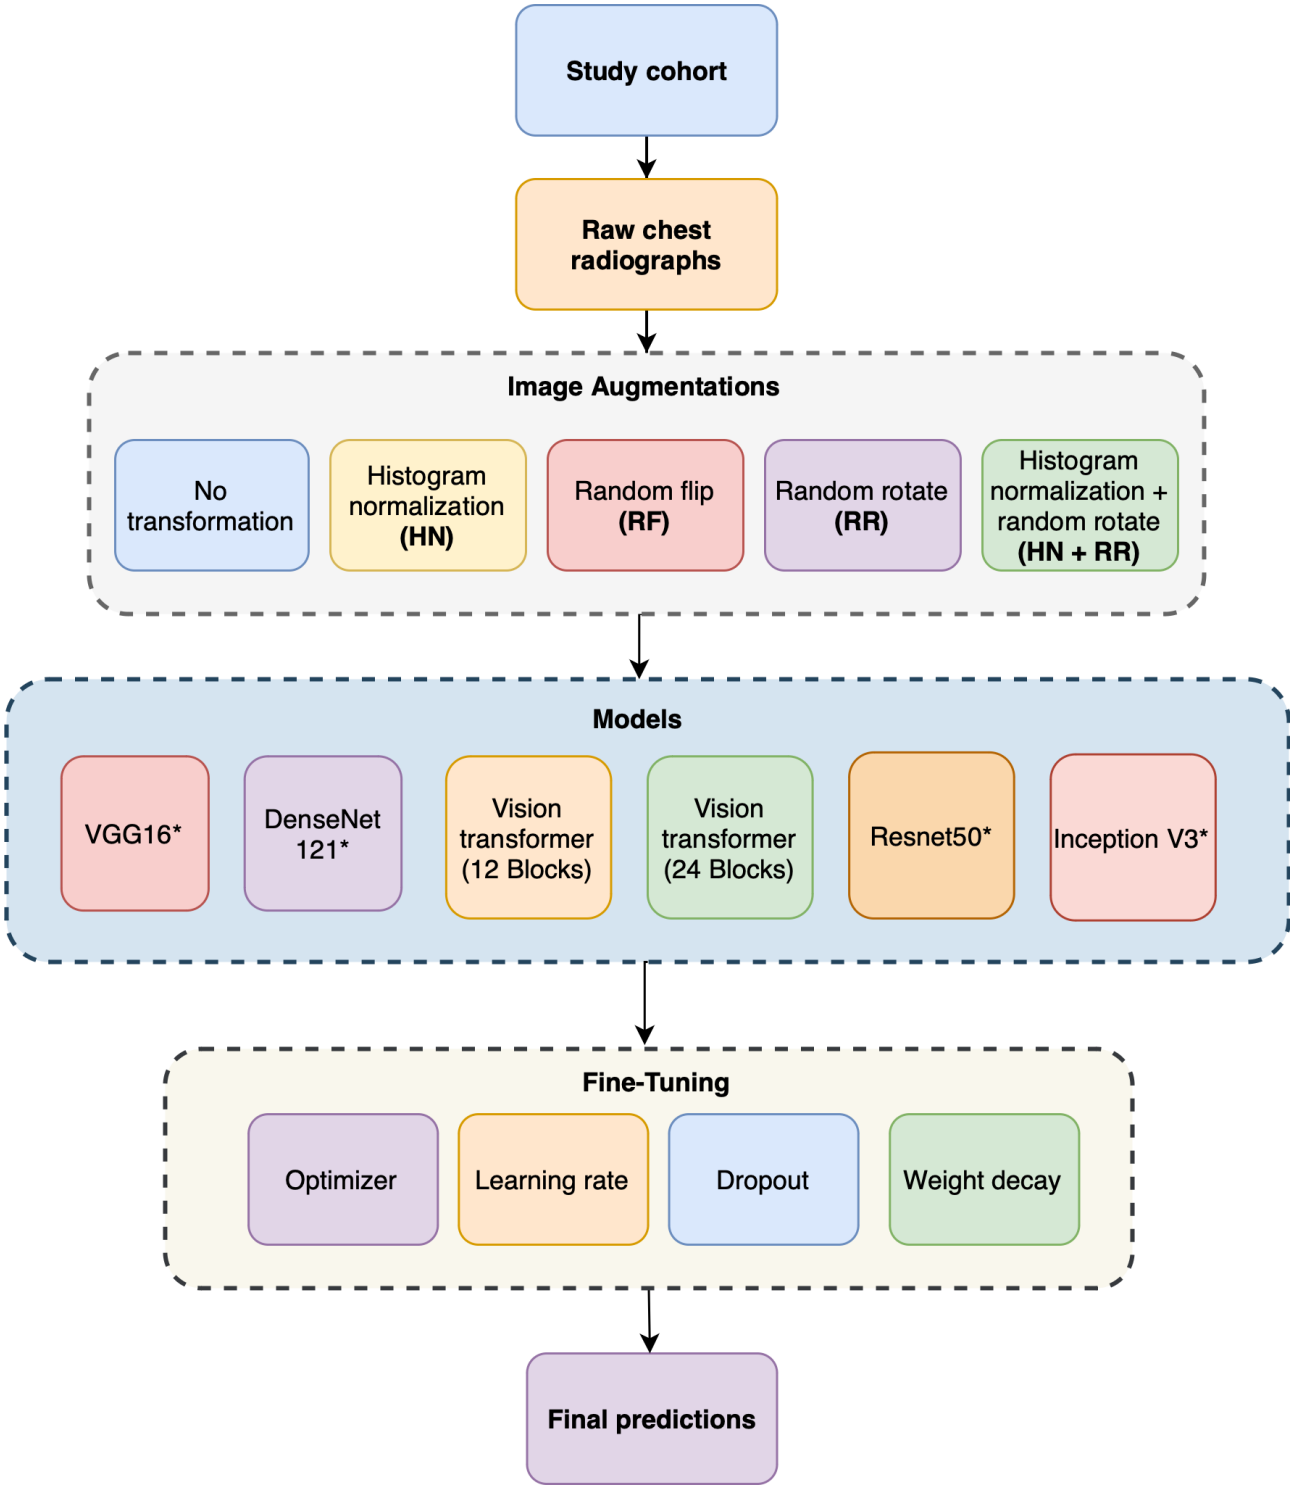
Data Preprocessing

The chest radiograph closest to (but before) the time of the elevated eCART score was used to predict the corresponding deterioration outcome. To address variations in image acquisition and processing protocols, all radiographs were rescaled to a uniform size of 224×224 pixels using nearest neighbor interpolation. Additionally, to address the variabilities in imaging exposure levels, pixel intensity values were normalized to a range of [0, 1] by applying min-max scaling. The clinical deterioration outcome (ie, ICU transfer or mortality within 24 hours from the prediction time point) was encoded as binary labels, with one-hot encoding used for the binary prediction task. These preprocessing steps ensured the creation of a high-quality robust dataset for training deep learning models to predict clinical deterioration from chest radiographs.

Model Development

For the prediction task, computer vision deep learning models were trained and optimized with the dataset created from the cohort. Five publicly available computer vision models were compared for our task: (1) VGG16 [24], (2) DenseNet121 [25], (3) Vision Transformer [26], (4) ResNet50 [27], and (5) Inception V3 [28]. DenseNet121 is a convolutional neural network notable for its dense connections between layers, improving efficiency and reducing risk of overfitting, and VGG16 is known for its simplicity using a series of convolutional layers with small filters followed by max pooling layers. The Vision Transformer model is based on the transformer architecture and uses the self-attention mechanism to process the images. The main rationale of adopting these computer vision models for clinical deterioration tasks is that they are widely used in other chest radiograph detection tasks in clinical setups [29-31]. In addition, these models are easy to implement, and various pretrained weights are readily available. As clinical tasks require fine-grained image understanding for different tasks, these models provide that performance with a

XSL•FO
RenderX



manageable model size. However, the main shortcoming of using these models is they do not provide any generalized image understanding for explainability.

We used two different versions of the VGG16 architecture, one using randomly initialized weights (without pretraining) and the other using model weights pretrained on ImageNet [32]. Two different versions of the DenseNet121 architecture were also used: one with model weights pretrained on Imagenet [32] and one pretrained on publicly available radiograph datasets [33]. Specifically, the radiograph datasets used for pretraining consisted of the following datasets: NIH aka Chest X-ray14 [34], PC aka PadChest [35], CheX aka CheXpert [36], MIMIC-CXR [37], OpenI [38], Google [39], and RSNA Pneumonia Detection Challenge [40]. For the Vision Transformer model, we trained two models without any pretrained weights of two different sizes, one with 12 transformer blocks and another with 24 transformer blocks. We employed batch normalization layers after every block to ensure the stability of the optimization process during the model training. Figure 2 presents the overall structure of this study.

For each of the above architectures, we compared them with and without different preprocessing and data augmentation approaches. These included histogram normalization, random rotation (±15 degrees), horizontal flipping, and the addition of random Gaussian noise. Briefly, histogram normalization addresses the regional discrepancy of exposure levels in the case of some images. Additionally, given the presence of noise and artifacts during the acquisition of the radiographs, random Gaussian noise, which was implemented as 0.1 probability with 0 mean and 0.1 standard deviation, may make the models more robust to noise in the input image samples. Figure 3 shows the examples of all the augmentation methods we have used in this work.

We used the Bayesian optimization algorithm to find the optimal hyperparameters that maximize the area under the receiver operating characteristic curve (AUROC). Details of the hyperparameters are presented in Multimedia Appendix 1. To make the training procedure faster, we used Ray Tune [41] to parallelize the hyperparameter search process in a multi-GPU environment. We trained the model with a randomly selected 60% of the encounters in the dataset and validated it with the development set consisting of 20% of the encounters to optimize hyperparameters and determine the final settings. The remaining 20% of the encounters were completely separated for independent final model evaluation of the optimized models as a test set. We trained the models for 20 epochs and decreased the learning rate by a factor of 0.5 in every epoch. During the training, early stopping was used if the validation AUROC failed to improve in three consecutive epochs. We used Adam mini-batch gradient descent optimization with a batch size from the search space of 32, 64, and 128.

Model Evaluation

All combinations of image augmentations and deep learning computer vision architectures for the clinical deterioration task were evaluated using the test dataset. Predicted probabilities for the deterioration outcome were calculated for every encounter during the evaluation. Model discrimination was assessed using the AUROC and its 95% CI, calculated via the DeLong method [42] as the primary metric and the area under the precision-recall curve (AUPRC) as the secondary metric. The p-values of the AUROC scores are presented in Multimedia Appendix 1. As $P<.001$ in all cases, our AUROC scores are statistically significant.

Data cleaning and cohort selection with descriptive analysis were conducted using Stata version 16.1 (StataCorp). We used Python version 3.8.10, along with the Monai framework version 1.2.0 (NVIDIA) and Pytorch version 2.0.0 (Facebook) to develop the deep learning models. Additionally, the AUROC score and its 95% CI were calculated using FastDeLong implementation from VMAF (Video Multimethod Assessment Fusion; Netflix) [43].

Results

Cohort Characteristics

A total of 258,621 admissions occurred during the study period, and 92,845 had an elevated eCART score. Of these, for 21,817 admissions, a chest radiograph was obtained within 48 hours of the time of the elevated score and was included in the analysis (Figure 1). The characteristics of the final cohort are presented in Table 1. The patients in the final cohort had a median age of 63 (IQR 52-74) years, with a higher likelihood of being male (56.1%, 12,249/21,817); 5.7% were black (1252/21,187). The median time to eCART score elevation from admission was 21.8 (7.1-47.6) hours and the median time to eCART score elevation from the last radiograph was 9 (7.1-47.6) hours. About 7.5% (1655/21,817) of the encounters had an outcome event, including 4.1% (893/21,817) cases of in-hospital death.

Table . Population characteristics of the study cohort (N=21,817).

Variable	Value
Age, years, median (IQR)	63 (52-74)
Female, n (%)	9568 (43.9)
Black race, n (%)	1252 (5.7)
Elevated eCART[a] score, n (%)	1655 (7.59)
Time to the elevated eCART score from admission, hours, median (IQR)	21.8 (7.1-47.6)
Time to the elevated eCART score from the last radiograph, hours, median (IQR)	9.0 (7.1-47.6)
In-hospital mortality, n (%)	893 (4.1)

Across all architectures and augmentation combinations, the DenseNet121 model pretrained with chest radiographs and augmented with histogram normalization and Gaussian noise had the highest AUROC (0.734) across all the models. Similarly, when averaged across all augmentation methods, the DenseNet121 models pretrained with chest radiographs had a higher average discrimination than any other architecture in terms of the AUROC (0.714). The vision transformer architectures (12 and 24 transformer blocks) performed similarly to each other on average and had worse average AUROC than other models (0.642 and 0.640 for 12 and 24 transformer blocks, respectively). In terms of the AUPRC, DenseNet121 pretrained with chest radiographs and augmented with histogram normalization and Gaussian noise also had the highest performance (0.414). Accordingly, compared with other models, Inception V3 pretrained with ImageNet had the highest AUPRC (0.388) on average.

In terms of the image augmentation methods, the histogram normalization with random Gaussian noise image augmentations had the best mean AUROC (0.696) when averaged across all architectures, followed by histogram normalization augmentation alone (0.694). The random rotate augmentation had the worst average performance in terms of the AUROC (0.666). In terms of the AUPRC, histogram normalization with random Gaussian noise image augmentations also had the highest average AUPRC (0.319) across the models, and the models with no transformation alone had the next highest average AUPRC of 0.310. Unlike the AUROC results, the random flip augmentation had the worst AUPRC among all the four other augmentation methods.

Discussion

Principal Findings and Comparison With Previous Works

In this retrospective study with over 20,000 hospital admissions, we compared three deep learning computer vision architectures and four image augmentation methods for the early detection of clinical deterioration. We found that the DenseNet121 model pretrained on different publicly available chest radiographs had better discrimination than the VGG16 and Vision Transformer models based on the average AUROC metric. Among different image augmentation methods, a combination of histogram normalization and random Gaussian noise augmentations achieved higher AUROCs and AUPRCs on average than random flip and random rotate transformation. In all of the cases, we found that random flip and random rotate transformation lowered the discrimination compared to the baseline model in terms of both AUROC and AUPRC metrics. To the best of our knowledge, this is the first study to compare different computer vision models and image augmentation methods for predicting clinical deterioration outside the ICU. These findings have important implications in the field of using deep learning models to correctly identify patients showing clinical deterioration and to improve existing EWS applications in health systems.

Although DenseNet121 pretrained on chest radiographs achieved the maximum discrimination with histogram normalization and random Gaussian noise data augmentation, our investigation found multiple models exhibiting competitive performance across different data augmentation methods considering the AUROC. This may be due to our extensive hyperparameter search with Bayesian optimization that enables all models to achieve similar performances. Overall, the pretrained models performed better with respect to the models trained from scratch. This is consistent with the existing literature, as pretrained models already learned the fundamental building blocks of features (eg, lines and shades) from large number of images of the pretrained dataset [44,45]. However, as the VGG16 model was pretrained on the ImageNet [32] dataset, which is a collection of thousands of general-purpose images, and our dataset only contains chest radiographs, there may be a domain gap present in this scenario that prohibits the maximum benefits of the pretraining network. To analyze and mitigate that domain gap, we compared the performance of the DenseNet121 network pretrained on ImageNet and on a collection of the radiograph dataset. In almost all of the cases, DenseNet121 pretrained on radiographs outperformed the DenseNet121 model pretrained on ImageNet in terms of both the AUROC and AUPRC metrics. These experimental results proved our hypothesis and provided important insights into the use of pretrained networks with chest radiograph datasets. A prior study involving the classification of chest radiographs also found DenseNet networks achieving superior performance [10], which aligns with our findings. For example, Alhudhaif et al found that DenseNet201 achieved the highest discrimination in determining COVID-19 pneumonia with chest radiographs [10]. However, another work by Sitaula et al found that the VGG-16 model performed better than the DenseNet121 model for the classification of COVID-19 chest radiographs [11]. This discrepancy may be explained by differences in hyperparameter settings and the use of pretrained weight initialization. They tuned the hyperparameters manually, whereas we tuned the hyperparameters automatically with Bayesian optimization. As the DenseNet121 network is deeper than VGG-16 in terms of the number of layers, better hyperparameter tuning may enable DenseNet121 to learn more complex relationships without overfitting, hence achieving better performance than the VGG-16 network. Although DenseNet121 has more layers than VGG-16, DenseNet121 has fewer parameters than VGG-16 (7.98M vs 138.36M parameters). This parameter efficiency may reduce the risk of overfitting, which is important in medical imaging applications where datasets are often small. We also found that the Vision Transformer model underperformed in almost all the cases compared to other CNN-based models in the clinical deterioration prediction task. This finding contrasts with the recent success of Vision Transformer in general computer vision tasks [46]. However, in the case of classification tasks with radiographs, the lack of pretraining may harm the performance of the Vision Transformer models [47]. For the networks where we compared performance with random initialization and a pretrained model, in most of the cases, the pretrained model performed better than the randomly initialized one. This could be the main cause for the underperformance of the Vision Transformer models in our work, as we trained it from scratch.

In this study, we found that the models trained with histogram normalization combined with random Gaussian noise among different image augmentation methods achieved better

XSL•FO
RenderX

performance, exhibiting the highest AUROC four times and the highest AUPRC three times for different architectures with different combinations of pretraining methods. However, the other two augmentation methods, random flip and random rotate, actually worsened the performance. Our findings align with the existing literature presenting performance improvements with histogram normalization and Gaussian random noise. Gielczyk et al showed that the combination of histogram normalization and Gaussian random noise achieved higher performances than the baseline method in detecting COVID-19 and pneumonia with chest radiographs [48]. However, this can be task dependent involving the useful features of that particular task. Lakhani et al presented a deep convolutional neural network for determining the presence and position of endotracheal tubes where random rotation and random flip augmentation achieved higher performances over the baseline values [12]. As that task was geometry-dependent, regularization introduced by random rotate and random flip augmentation might improve the performance. In contrast, our task of predicting clinical deterioration is not geometry dependent and hence did not benefit from geometric transformations like random rotate and random flips. These insights might be helpful in selecting appropriate image augmentation techniques in models involving chest radiographs.

Strengths

Our study has several important strengths. First, our study cohort consisted of elevated-risk patients with an eCART score ≥93. Predicting deterioration in these patients is more challenging due to their rapid and unpredictable progressions compared to lower-risk patients. Second, we compared multiple deep learning architectures to evaluate their efficacy in predicting clinical deterioration. This comparative approach allows for a more robust understanding of a model's performance in this context. Furthermore, by testing different data augmentation methods, the study explores ways to improve model performance. This aspect is crucial for enhancing the generalizability and robustness of the models. Incorporating Bayesian optimization with a large search space provides the models to achieve the most optimal performance.

Limitations

Our study also has some limitations. First, we only considered the latest radiograph for our models to avoid bias and complexity. Although we reasoned that the latest radiograph conveys the most updated features of patients, prior radiographs and trends over time might carry important features for the model to predict clinical deterioration. Second, we focused on a few popular deep learning architectures with four different augmentation methods. Although recent studies have introduced numerous computer vision architectures, a more comprehensive study would be difficult considering our study's dataset size. Third, in the deterioration prediction model, we only considered the features on chest radiographs. Incorporating other modalities, such as structured data and clinical notes, could improve the accuracy and robustness of our models and will be an interesting future work. Finally, even though our study is the largest of its kind, this was a single-center study, and future studies in other centers are needed to evaluate the external validity of our models.

Conclusion

Our study demonstrates that the DenseNet121 model pretrained on chest radiographs often outperforms VGG16 and the Vision Transformer model with chest radiographs for the prediction of clinical deterioration. Furthermore, we found that model performance improves with histogram normalization along with random Gaussian noise augmentation in most models in terms of both the AUROC and AUPRC metrics. These results show that accurate prediction of patient clinical deterioration is feasible by utilizing chest radiographs while offering valuable insights into the use of computer vision-aided risk prediction.

Acknowledgments

Abstract

Background: The application of large language models (LLMs) in analyzing expert textual online data is a topic of growing importance in computational linguistics and qualitative research within health care settings.

Objective: The objective of this study was to understand how LLMs can help analyze expert textual data. Topic modeling enables scaling the thematic analysis of content of a large corpus of data, but it still requires interpretation. We investigate the use of LLMs to help researchers scale this interpretation.

Methods: The primary methodological phases of this project were (1) collecting data representing posts to an online nurse forum, as well as cleaning and preprocessing the data; (2) using latent Dirichlet allocation (LDA) to derive topics; (3) using human categorization for topic modeling; and (4) using LLMs to complement and scale the interpretation of thematic analysis. The purpose is to compare the outcomes of human interpretation with those derived from LLMs.

Results: There is substantial agreement (247/310, 80%) between LLM and human interpretation. For two-thirds of the topics, human evaluation and LLMs agree on alignment and convergence of themes. Furthermore, LLM subthemes offer depth of analysis within LDA topics, providing detailed explanations that align with and build upon established human themes. Nonetheless, LLMs identify coherence and complementarity where human evaluation does not.

Conclusions: LLMs enable the automation of the interpretation task in qualitative research. There are challenges in the use of LLMs for evaluation of the resulting themes.

artificial intelligence; generative AI; large language models; ChatGPT; machine learning; health care

Introduction

Background

Qualitative studies in health care shed light on the perceptions, narratives, and discourses that underlie human behavior. This approach enhances understanding of both clinicians and patients' experiences and expectations, thereby informing decision-making for health policy [1]. Traditionally, these studies involved data collection through face-to-face interviews, observation or artifact analysis, transcription, and manual human coding for sense-making. Recent online advances, such as social media interactions, online reviews, news articles, and in-depth forum discussions, allow researchers and policy makers to collect larger data samples at lower time costs compared with direct interviews [2]. The advent of text mining tools, which allow researchers to cluster text samples into groups based on statistical similarity, has enabled partial automation of the sense-making step. For instance, the use of natural language processing (NLP) to identify risk factors from unstructured free-text clinical notes [3]. Yet, these tools provide only the groupings, leaving the human to apply thematic interpretation [4,5].

Recent advances in generative artificial intelligence (AI) provide valuable tools for researchers conducting qualitative studies,

XSL•FO
RenderX

offering support in both data analysis and interpretation. In particular, large language models (LLMs), which are statistical models built using internet-scale datasets, can generate human-style writing in response to natural-language prompts, and assist in analyzing textual data to identify patterns, themes, and underlying meanings [6]. LLMs can aid researchers in conducting thematic analysis by identifying recurrent themes, concepts, or ideas across a dataset supporting the automation of thematic interpretation.

Previous Work

Topic modeling is a popular approach to uncovering insights in text mining. It identifies patterns in word usage and clusters words into topics, making it a popular method for exploring large, unstructured text datasets. Latent Dirichlet allocation (LDA) is a widely applied method for topic modeling. Previous work has used LDA modeling to analyze social media data and derive insights on key topics [4,7,8]. Despite the new perspectives LDA approaches offer for scientific research [9], using LDA for topic modeling presents challenges [10], notably the significant role of human interpretative contribution in the process [11], which limits scalability. In addition, there is a noted lack of user-friendly tools that support the entire workflow, necessitating a human-in-the-loop to interpret the derived topics. In this paper, we argue that LLMs can help resolve some of the challenges of LDA analysis, specifically in interpreting and labeling topics.

LLMs are emerging as an increasingly reliable and effective tool for interpretative qualitative research, combining the scale that computational techniques allow for with the human's qualitative logic [12,13]. Previous studies show that ChatGPT (OpenAI) yields comparable results to manual coding with substantial time savings [14]. These studies compare emergent themes in human and AI-generated qualitative analyses, revealing similarities and differences. For instance, some themes are recognized by human coders but missed by ChatGPT, and vice versa [15]. LLMs can highlight novel connections within the data that are not apparent to human coders. In both deductive and inductive thematic analysis, ChatGPT extended the researchers' views of the themes present in the data [12].

There are challenges associated with the use of LLMs. In the previously cited study [14], ChatGPT was able to recreate the themes originally identified through more traditional methods. However, it was less successful at identifying subtle, interpretive themes, and more successful with concrete, descriptive themes. LLMs may miss themes that require a deep understanding of context or specific domain knowledge. For example, themes related to niche cultural practices or specific professional areas may not be accurately identified by AI without targeted training.

LLMs can also reflect biases present in its training data, potentially overlooking or misinterpreting themes that deviate from its learned patterns. On the other hand, LLM analyses can identify patterns and themes that might be overlooked by human coders due to their preconceived notions or cognitive biases. Further challenges associated with the use of LLMs are shown in Table 1.

Table . Challenges of large language models.

Challenge	Description	Citations
Ambiguity resolution	LLMs[a] might struggle to disambiguate certain terms or topics, leading to unclear topic categorization.	[16,17]
Overfitting	LLMs can sometimes focus too much on common or popular topics, missing out on niche or less frequently discussed topics.	[18,19]
Lack of context	Without external knowledge or the ability to track long-term context, LLMs might misinterpret or miss certain topic nuances.	[20]
Bias	LLMs are trained on vast amounts of data, which may contain biases. This can affect topic analysis results.	[21,22]
Overgeneralization	LLMs might overly generalize topics, missing out on specific subtopics or nuances.	[23]
Sensitivity to input	Small changes in input phrasing can sometimes lead to different topic interpretations by the LLM.	[24]
Memory limitations	Due to token limits, LLMs might not capture very long or detailed discussions effectively for topic analysis.	[25]
Interactivity limitations	While LLMs can process static text effectively, they might struggle with dynamic topic analysis, where user feedback or real-time adjustments are required.	[26]

[a]LLM: large language model.

XSL•FO
RenderX

Given these challenges, some studies suggest that the most effective qualitative analyses may involve a combination of human and AI insights, as human coders often recognize nuanced themes related to context, emotions, and cultural subtleties that AI may miss. For example, a study demonstrates the feasibility of AI as a research assistant, presenting a successful case-study of human-AI collaboration in research by merging the efficiency and accuracy of ChatGPT with human flexibility and context awareness [27]. In addition, the usefulness of ChatGPT in qualitative analysis may depend on the researcher's ability to ask appropriate questions (prompts), with the output evaluated and supplemented by a human researcher before the final report and publication [28].

There is little guidance in the literature about how LLMs can be integrated into thematic analysis. Challenges associated with the use of LLMs, including overgeneralization and overfitting, need to be investigated in the context of using LLMs for interpreting the relevance of identified topics. Our focus in this work considers inductive thematic analysis, where themes are derived from data without preconceived frameworks, and semantic analysis, in which themes are identified within the explicit content of the data [29]. We plan to consider a hybrid inductive and deductive approach in future work [30].

Study Objectives

This study considers the possibility of enhancing human productivity by applying LLMs in the interpretation and labeling stage of topic modeling. We present a case study in which data were gathered from an online forum and grouped using text mining tools, and then interpreted for themes in parallel: (1) by human coders and (2) by providing text samples from each classification group to an LLM and prompting the LLM for thematic summarization.

We compared the human- and LLM-generated themes along 4 qualitative dimensions: alignment, convergence, coherence, and complementarity. Based on this analysis, we demonstrate the feasibility of using an LLM to support human thematic interpretation for qualitative research and offer insights into where researchers may find benefit in using LLMs to support thematic interpretation, and where they should exercise caution.

Methods

Overview

The proposed methodology is based on three phases: (1) construction of a dataset and topic modeling using LDA, (2) labeling identified groups into topics through human interpretation and through use of LLM, and (3) comparison of identified topics.

Data Collection and Preprocessing

The data comprises discussions from a publicly accessible Nurse Forum [4]. Data come from posts aggregated over 28 2-week periods from March 2020 to April 2021. Our preprocessing approach ensures that the data is clean, standardized, and focused on the most relevant linguistic features, allowing for a clearer identification of the key aspects discussed in the nurse forum over time. Texts were tokenized using the Python library Gensim [31]. Preprocessing included lowercasing and removing punctuation to ensure uniformity and reduce noise in the text. Stop words, including domain-specific terms like "covid" and "covid 19," were removed, in addition to those in the Natural Language Toolkit (NLTK) library, to focus on meaningful content. Bigram and trigrams were added to the corpora to identify common multiword expressions, which enhances the detection of contextually significant phrases. Finally, texts were lemmatized using SpaCy (Explosion) [32], retaining only nouns, adjectives, verbs, and adverbs, to normalize words to their base forms and reduce dimensionality.

Topic Modeling

Topic modeling was conducted using LDA to identify underlying themes in the text data. The LDA algorithm began with random assignments of topics to documents and words to topics. Through iterative optimization, it adjusts these assignments based on the likelihood of word-topic and topic-document distributions. We experimented with different numbers of topics and adjusted hyperparameters, to find the optimal model configuration. Coherence scores, which measure the semantic similarity of words within a topic, were computed for each run. Higher coherence scores indicate more meaningful and interpretable topics. The model with the highest coherence score was selected [33].

This optimal model is then used to extract the top keywords for each topic, summarizing the themes present in the data. The distribution of topics across the corpus was visualized to interpret their prevalence in individual documents and the entire dataset, providing insights into the prominent themes discussed in the nurse forum during the specified period.

Identification of Topics Through Human Interpretation

Thematic analysis was conducted by 2 coders working independently to familiarize themselves with the data by exhaustively reading the top 10 posts within each topic (ranked based on coherence scores) generated by the topic models [34]. The selected theme names for the labeled topics were compared, which achieved an initial interannotator agreement of 68% (210/310), and 94% (292/310) after a subsequent round. For the remaining 6% (18/310), the underlying posts were examined together to resolve the disagreements, which left no unresolved annotations. The interpretation analysis resulted in 16.5% (15/310) of the identified themes being categorized as having low coherence.

Theme Derivation Using Large Language Models

Following topic modeling, an LLM was used to derive themes from the identified topics. We created a custom function that takes a system message and a list of user-assistant message pairs, ensuring proper formatting and role assignment. We use the GPT-3.5 based model, specifying the structured messages, temperature, and seed for reproducibility [35]. The system prompt is embedded ensuring consistency in use of the associated set of instructions. The model was chosen for its advanced NLP capabilities, including context-awareness and adaptability to specific thematic contexts, and accessibility to the research team. The prompt instructs ChatGPT to generate

XSL•FO
RenderX

themes and subthemes for more nuanced theme identification, addressing the issue of overly broad categorizations observed in initial experiments. An overview of the modeling steps is provided in Multimedia Appendix 1.

Comparison of Identified Topics

The reliability of coding textual data can be challenging as the goal in content analysis is to attain a "scientific" analysis characterized by reliability, which implies stability in the phenomenon being studied and explicit analytic procedures to ensure that any reasonably qualified person would yield identical results [36]. Intercoder agreement emerges as a key tool in achieving a reliable coding scheme, assessing the extent to which coders assign identical codes to the same set of data [34]. A 5-item ordinal scale typically measures this agreement, with the anchors of "Perfect Agreement," representing where coders completely agree on codes or categories assigned to data, and "Slight Agreement," representing very little consensus, or significant disagreement, among the coders in how they code the data. This agreement scale is provided in Multimedia Appendix 1.

A novel 7-point scale was developed following a pilot test conducted by two of the authors to address the complexities of comparing codes generated by humans and ChatGPT. This scale, presented in the first column of Table 2, focuses on exploring the complementary and divergent insights between human-generated and ChatGPT-generated codes. It emphasizes the value of examining differences, especially in cases of low coherence among human-coded data, which allows researchers to uncover nuanced perspectives and understandings contained in ChatGPT-generated themes and within subthemes variability, with the possibility of revealing new and meaningful insights. It serves as a dynamic tool that stresses the importance of learning from intercoding differences rather than seeking strict agreement and validation, as is valued among qualitative researchers [37].

Table . Agreement between large language model (LLM) and human coding.

Agreement scale	Number of topics, n	Rate of agreement, %
ChatGPT and human coding themes are aligned, coders largely interpret and code the data in a consistent manner.	95	30.6
Substantial agreement: ChatGPT's subthemes are aligned with human coding, some subthemes provide complementary perspectives or unique insights.	101	32.6
Substantial agreement: ChatGPT's themes are divergent, human coding classified as low coherence.	51	16.5
Moderate agreement: there is a reasonable level of consensus between ChatGPT and human coding, but there are significant differences in interpretation or coding for some subthemes.	15	0
Fair agreement: ChatGPT's themes are considered too broad, there are substantial discrepancies between ChatGPT's subthemes compared with human coding.	30	0
Poor agreement: ChatGPT's theme specific, yet divergent from human coding.	4	0
Poor agreement: ChatGPT's theme specific, yet low coherence in human coding.	14	0
Grand total	310	79.7

We then use GPT-4 for topic comparison, accessing the ChatGPT engine through an application programming interface (API) for programmatic purpose. Each prompt included the human-coded themes and the LLM-generated themes, requesting the LLM to assess the agreement based on 4 criteria: alignment, convergence, coherence, and complementarity between the themes. A detailed overview of the prompts is provided in Multimedia Appendix 1.

Alignment assesses the correspondence between ChatGPT and human themes in terms of contextual agreement between the themes [38], rather than lexical agreement. Convergence provides a similar comparison at the level of specific "ChatGPT Subthemes" with reference to the "Human Theme." Coherence evaluates the logical consistency within the "ChatGPT Theme" and its subthemes, emphasizing the cohesion in both logic and meaning [39]. Complementarity looks at whether the ChatGPT subthemes offer valuable additional insights or perspectives that enhance the human theme by providing detailed mechanistic explanations that align with and build upon the established human theme without contradicting it [40,41],

LLM outputs were parsed to extract values for alignment, coherence, convergence, and complementarity. Human coders then compared the remaining results of reliability analysis with the LLM-generated comparison.

RenderX

Ethical Considerations

This study does not involve human subjects, identifiable private information, or direct interactions with individuals. Instead, it relies exclusively on publicly available, anonymized social media posts. Consequently, institutional review board approval was deemed unnecessary.

Results

Analysis of Reliability

The LDA analysis identified 310 topics. In thematic analysis, the team considered the topics identified, groups of words, and representative blog post samples in each topic and categorized the 310 topics into 58 subthemes.

A total of 2 authors independently classified the level of agreement on each topic against the themes and subthemes generated by ChatGPT, using the 7-point agreement scale in Table 2. The authors then met to compare assessments and resolve disagreements. The overall reliability is estimated at 79.7% (247/310), which represents substantial agreement according to the intercoder reliability benchmark [36].

Table 2 provides a breakdown of agreement along the comparison scale, with 30.6% (95/310) reflecting taxonomic agreement in themes identified by the human coder and ChatGPT. For example, in one case the human-coder's theme is "PPE resource availability and control" and the ChatGPT theme is "Mask Availability and Usage in Healthcare Settings."

In 32.6% (101/310) of the themes the agreement is at the subtheme level. For example, in one instance the human-coded theme is "Testing policies in different settings," while the ChatGPT theme is "Challenges and Controversies Surrounding COVID-19 Testing," which was not considered at the same level of specificity of the human coder's theme. The ChatGPT subthemes are "Allocation of Testing Resources," "Flaws in Testing Systems," and "Impact on Public Health and Society." In the first subtheme the discussion revolves around whether COVID-19 tests should be prioritized for hospitalized patients or health care workers, matching the theme identified by humans. Adding to the reliability of the method, we have the agreement on the lack of coherence of the posts included in the LLM topic, representing 16.5% (51/310) of the topics.

Alignment and Convergence

LLM provided results on alignment and convergence that we compare with the human evaluation of agreement. The results are displayed in Table 3.

XSL•FO
RenderX

Table . Analysis of alignment (theme level) and convergence (subtheme level).

		Alignment: Compare the "human theme" and the "ChatGPT theme"			Convergence: Compare the specifics in "ChatGPT Subtheme" with the "human theme."		
Agreement scale	Total, n	Aligned, n	Misaligned, n	Meets expectation, %	Convergent, n	Divergent, n	Meets expectation, %
ChatGPT and human coding themes are aligned, coders largely interpret and code the data in a consistent manner.	95	86[a]	9	91	86[b]	9	91
Substantial agreement: ChatGPT's subthemes are aligned with human coding, some subthemes provide complementary perspectives or unique insights.	101	90[a]	11	89	91[b]	10	90
Substantial agreement: ChatGPT's themes are divergent, human coding classified as low coherence.	51	6	45[c]	88	5	36[d]	71
Moderate agreement: there is a reasonable level of consensus between ChatGPT and human coding, but there are significant differences in interpretation or coding for some subthemes.	15	10[a]	5	67	11[b]	4	73
Fair agreement: ChatGPT's themes are considered too broad, there are substantial discrepancies between ChatGPT subthemes compared with human coding.	30	18	12	0	17	13[d]	43
Poor agreement: ChatGPT's theme specific, yet divergent from human coding.	4	1	3[c]	75	1	2	0

XSL•FO
RenderX

		Alignment: Compare the "human theme" and the "ChatGPT theme"			Convergence: Compare the specifics in "ChatGPT Subtheme" with the "human theme."		
Agreement scale	Total, n	Aligned, n	Misaligned, n	Meets expectation, %	Convergent, n	Divergent, n	Meets expectation, %
Poor agreement: ChatGPT's theme specific, yet low coherence in human coding.	14	2	12[c]	86	1	8[d]	57

[a]Expectation is "aligned" for items in the agreement scale.

[b]Expectation is "convergent" in the agreement scale.

[c]Expectation is "misaligned" in the agreement scale.

[d]Expectation is "divergent" in the agreement scale.

We found high level of alignment and convergence for themes classified as high on agreement by human coder. For scale item 1 there was 91% (86/95) alignment and 91% (86/95) convergence, and for scale item 2, there was 89% (90/101) alignment and 90% (91/101) convergence. As expected, we find misalignment for scale items 3 and 7.

The results for scale item 5 (ChatGPT's themes are considered too broad, there are substantial discrepancies between ChatGPT subthemes compared with human coding) reveal specific nuances of the LLM comparison. Although we expect subthemes to be divergent based on human classification, only 43% (13/30) were classified as divergent by the LLM. For example, a topic labeled by human-coders as "Knowledge about virus," due to posts in general discuss the nature of COVID-19, was labeled by LLM as "COVID-19 and its implications for healthcare workers," which is considered much broader although aligned. However, the first subtheme, "Understanding the nature of coronaviruses and COVID-19" is both aligned and convergent with human-generated theme while the other two subthemes, "Importance of proper PPE and testing for healthcare workers" and "Concerns and challenges in healthcare settings and home care," are clearly divergent from the narrow scope defined by human-theme. Although some subthemes may be tangential, the LLM still classifies them as convergent within a broader framework of idea similarity.

Coherence

Coherence evaluates the logical consistency within the "ChatGPT Theme" and its subthemes. The results are displayed in Table 4. Coherence was high for items 1,2, and 4 in the agreement scale, meeting expectations. We expected coherence to be low for scale item 5. However, contrary to our expectations, ChatGPT identified 97% (29/30) of cases as coherent. Although human interpretation viewed the LLM theme as broad and the subthemes as tangential, the LLM found logical consistency among these items within the broader scope of the theme.

XSL•FO
RenderX

Table . Analysis of coherence and complementarity.

	Analysis of coherence			Analysis of complementarity	
	Coherent, n	Low coherence, n	Meets expectation, %	Complementary, n	Meets expectation, %
ChatGPT and human coding themes are aligned, coders largely interpret and code the data in a consistent manner.	94[a]	1	99	93[b]	98
Substantial agreement: ChatGPT's subthemes are aligned with human coding, some subthemes provide complementary perspectives or unique insights.	101[a]	0	100	97[b]	96
Substantial agreement: ChatGPT's themes are divergent, human coding classified as low coherence.	49	2[c]	4	8	0
Moderate agreement: there is a reasonable level of consensus between ChatGPT and human coding, but there are significant differences in interpretation or coding for some subthemes.	15[a]	0	100	15[b]	100
Fair agreement: ChatGPT's themes are considered too broad, there are substantial discrepancies between ChatGPT subthemes compared with human coding.	29	1[c]	3	26	87
Poor agreement: ChatGPT's theme specific, yet divergent from human coding	3	1	0	1	0
Poor agreement: ChatGPT's theme specific, yet low coherence in human coding	14	0	0	4	0

[a]Expectation is "coherent" in the agreement scale.

[b]Expectation is "complementary" in the agreement scale.

[c]Expectation is "low coherence" in the agreement scale.

Another unexpected result concerns scale item 3, where 96% (49/51) of the topics were marked as coherent despite being rated as "low coherence" by human coders. Contrary to expectations, 49 out of 51 cases were classified as coherent. LLM relies on single posts to generate subthemes with logical consistency. We illustrate this finding with 2 examples.

One topic that ChatGPT themed as "Nurses' Safety and Well-being" with the subthemes of "Personal sacrifices and concerns for personal safety," and "Need for better protection and compensation." However, the second subtheme was generated based on a single post that mentions hazard pay: "It would be nice if hospitals offered hazard pay, but I'm sure they're also hurting financially given all of the new measures they're having to put into place. […]; many are losing a lot of anticipated revenue because they've canceled their non-emergency surgeries." There is insufficient evidence to support the inclusion of this theme.

Another topic ChatGPT themed as "Challenges and Considerations in Nursing and Healthcare" with the subthemes of "Trust and Distrust in Healthcare" and "Disparities in

XSL•FO
RenderX

Healthcare." Although these are considered consistent with theme, the first subtheme is based on a post highlighting the impact of past negative experiences on trust, and the second subtheme is described by ChatGPT as emphasizing the importance of recognizing and addressing disparities that affect various groups, such as gender, age, ethnicity, and socioeconomic status; however, it is based on the following post: "There are disparities... People we love and care about. Yes, I think it's important to identify areas that are of particular concern and groups that are especially vulnerable. We need to learn and use that knowledge to try to improve our collective future."

A total of 2 topics were classified as low coherence, which agreed with the corresponding "low coherence" human theme designation. ChatGPT themed 1 topic as "Medications and Health Concerns" with the subthemes of "Medication Switch and COVID-19," "Casual Conversations and Expressions," and "Concern and Well-Wishes for Health," yet recognized as low coherence. The second topic, ChatGPT themed as "Controversial Issues in Healthcare" and has subthemes of "Use of Hydroxychloroquine for COVID-19 Treatment," "Systemic Racism and Police Brutality," and "Challenges in Ensuring Compliance with Infection Control Measures."

Complementarity

The analysis of complementarity is also provided in Table 4. For scale items 1, 2, and 4 the expectation was that the subthemes provide complementarity to the human-generated theme and the results meet expectations (98% (93/94), 96% (97/101), and 100% (15/15), respectively). For example, one topic with the human-generated theme of "Testing policies in different settings" was associated with the ChatGPT subthemes of "Allocation of Testing Resources," "Flaws in Testing Systems," and "Impact on Public Health and Society." The first subtheme is about whether testing availability should be prioritized for hospitalized patients or health care workers, but the second subtheme highlights significant complementary issues with regards to flaws in the CDC's COVID-19 testing protocols, delays in fixing the tests, and the impact on the ability to detect and track the spread of the virus. The third theme expanded further into the social implications of the impact of inadequate testing resources, limited testing on the perception of the virus's severity, and the potential spread of the virus due to lack of testing and preventive measures.

Conversely, the expectation for the agreement scale item 5 was that complementarity would be low, yet ChatGPT found 87% complementarity. For instance, in the example mentioned above, the topic labeled by human-coders as "Knowledge about virus," the subthemes are considered divergent ("Importance of proper PPE and testing for healthcare workers") and too broad ("Concerns and challenges in healthcare settings and home care") when compared with the scope defined by "knowledge about the virus." The posts on these themes cover diverse topics such as the importance of proper personal protective equipment (PPE), concerns about testing and returning to work, the potential risks involved in home care, questions about Health Insurance Portability and Accountability Act (HIPAA) regulations, and the need for research on treatment options. The complementarity of themes only exists in a very broad sense and can be considered as "out of context."

Discussion

Principal Findings

Our study offers several significant insights into the use of ChatGPT for the augmentation of topic models. A key finding is the importance of considering different levels of abstraction in theme analysis. The division into themes and subthemes is crucial for uncovering specific nuances, addressing the risk of overgeneralization inherent in LLMs.

Furthermore, our exploration of subthemes reveals that LLMs, in general, can resolve ambiguity, aiding in the clear categorization of topics, even from a limited dataset. The effective handling of "low-coherence" topics such as "health disparities" and the complementary insights provided on subthemes of "Testing policies in different settings" demonstrate the LLM's proficiency in navigating and categorizing complex subject matter at the subtheme level.

In terms of overall reliability, our study estimates a 79.7% (247/310) agreement level, positioning it at the high end of substantial agreement (60%-80%) and the low end of almost perfect agreement (80%-100%) on the intercoder reliability benchmark scale. This suggests a robust level of agreement between human coders and the LLM, indicating a reliable consistency in the classification of topics.

However, the examination of alignment and convergence reveals a nuanced aspect of LLM performance. While LLMs exhibit high accuracy in identifying alignment and convergence for topics classified by human analysis as aligned, a notable challenge arises when classifying divergent subthemes. The LLM tends to classify divergent subthemes as convergent, particularly when one of the subthemes converges in similar ideas, leading to a potential misrepresentation of thematic divergence.

The evaluation of coherence, yields an unexpected result, highlighting the issue of "overfitting." Specifically, topics classified as coherent by the LLM contradict human coders' assessments of low coherence. This suggests a potential challenge where ChatGPT may force-fit solutions that match specific data points (posts) but are "too good to be true" from a pattern standpoint, lacking the broader pattern consistency expected in thematic coherence. ChatGPT may be construing the theme based on the wealth of data at its disposal.

The analysis of complementarity confirms that LLMs identify subthemes that provide additional insights to themes in human researchers' findings. LLMs can successfully identify niche topics, showcasing their potential to uncover unique thematic elements.

Our study emphasizes the critical importance of providing adequate contextual framing to ChatGPT-based classification. The challenge of lack of context becomes apparent, as LLMs may misinterpret or overlook certain topic nuances without external knowledge or the ability to track long-term context.

XSL•FO
RenderX

Limitations

The study is limited by (1) our focus on a single social media source and (2) the LLM used. First, we focus on data from a single nurse forum, but future inclusion of additional social media sites, including those used in other countries and by users who speak other languages, may enhance the results reported here. Furthermore, while we used the OpenAI chat completion API (GPT-3.5 and GPT-4) for thematic analysis due to its accessibility to the research team, other language models have since emerged. These newer models should be tested to determine if they perform better in different contexts. Furthermore, we kept the LLM prompts as simple as possible to demonstrate that even using a simple approach the generative AI could produce solid results. Further work can apply fine tuning to prompting and design approaches to enhance the thematic analysis capabilities of LLMs, such as retrieval-augmented generation (RAG). Finally, we focus on inductive thematic analysis and short form content data. We recognize that long-form text data may pose distinct challenges in applying LLMs.

Implications

For the LLM challenges found in this study, such as overgeneralization and overfitting, future study may apply different guardrails, such as implement algorithms that detect and mitigate biases during both training and generation phases. These guardrails monitor and filter the outputs of LLMs addressing different requirements such as hallucinations in LLM outputs [42].

Future research could investigate the potential of feeding raw transcripts into ChatGPT and incorporating AI-generated themes into triangulation discussions. By contributing to triangulation, this approach promises to unveil potential oversights, present alternative perspectives, and highlight inherent researchers' personal biases. By seamlessly incorporating AI into the discourse analysis process, researchers may uncover a richer understanding of the subject matter, fostering a more comprehensive and nuanced exploration of diverse perspectives. This integration not only enhances the depth of analysis but also provides a valuable tool for refining methodologies and mitigating potential biases, ultimately contributing to the advancement of research methodologies in the burgeoning field of AI-driven discourse analysis.

Conclusions

Overall, this study underscores the multifaceted nature of using ChatGPT for thematic analysis, acknowledging both its strengths and challenges. The insights gained contribute to a more nuanced understanding of the capabilities and limitations of LLMs in handling complex topical data in the healthcare field, offering valuable considerations for future research in the intersection of artificial intelligence and discourse analysis.

Abstract

Background: The ever-evolving field of medicine has highlighted the potential for ChatGPT as an assistive platform. However, its use in medical board examination preparation and completion remains unclear.

Objective: This study aimed to evaluate the performance of a custom-modified version of ChatGPT-4, tailored with emergency medicine board examination preparatory materials (Anki flashcard deck), compared to its default version and previous iteration (3.5). The goal was to assess the accuracy of ChatGPT-4 answering board-style questions and its suitability as a tool to aid students and trainees in standardized examination preparation.

Methods: A comparative analysis was conducted using a random selection of 598 questions from the Rosh In-Training Examination Question Bank. The subjects of the study included three versions of ChatGPT: the Default, a Custom, and ChatGPT-3.5. The accuracy, response length, medical discipline subgroups, and underlying causes of error were analyzed.

Results: The Custom version did not demonstrate a significant improvement in accuracy over the Default version (P=.61), although both significantly outperformed ChatGPT-3.5 (P<.001). The Default version produced significantly longer responses than the Custom version, with the mean (SD) values being 1371 (444) and 929 (408), respectively (P<.001). Subgroup analysis revealed no significant difference in the performance across different medical subdisciplines between the versions (P>.05 in all cases). Both the versions of ChatGPT-4 had similar underlying error types (P>.05 in all cases) and had a 99% predicted probability of passing while ChatGPT-3.5 had an 85% probability.

Conclusions: The findings suggest that while newer versions of ChatGPT exhibit improved performance in emergency medicine board examination preparation, specific enhancement with a comprehensive Anki flashcard deck on the topic does not significantly impact accuracy. The study highlights the potential of ChatGPT-4 as a tool for medical education, capable of providing accurate support across a wide range of topics in emergency medicine in its default form.

KEYWORDS

artificial intelligence; ChatGPT-4; medical education; emergency medicine; examination; examination preparation

Introduction

Background

The integration of artificial intelligence (AI) into medical education represents a frontier with the potential to significantly enhance learning outcomes and examination preparation strategies [1-5]. This advancement comes at a crucial time when the medical field faces the dual challenges of rapidly evolving knowledge bases and the increasing complexity of patient care. Among the AI tools making strides in educational contexts, ChatGPT has emerged as a notable platform [6]. Its ability to generate human-like text based on a vast database of information has sparked interest in its application for medical board examination preparation.

Previous studies have shown mixed results regarding the effectiveness of AI in medical education, with certain limitations identified in AI's ability to replicate the depth of understanding needed to answer questions correctly in high-stakes examinations [7-12]. Building upon this background, our study

XSL•FO
RenderX

seeks to determine whether a targeted enhancement of ChatGPT-4 can increase the accuracy of the model in answering board examination questions, particularly for the American Board of Emergency Medicine (ABEM) Examinations.

ChatGPT provides relatively accurate responses to questions in examinations such as the USMLE (United States Medical Licensing Examination) [13,14] and the ABFM (American Board of Family Medicine) examination [5]. This may instill the confidence in takers of these examinations to use ChatGPT as an additional tool to aid in preparation. For instance, when reviewing a question set, the trainee may use ChatGPT to provide the rationale for a correct answer or help them understand the questions that they responded incorrectly to. This provides the potential to streamline the preparation process by reducing the need to consult textbooks or internet-based resources, as retaining interaction with multiple sources, such as a validated question bank, flashcards, and ChatGPT, is likely to bolster confidence in the overall educational outcome [15]. Additionally, the functionality of ChatGPT enables the user to ask follow-up questions or for further clarification if the initial response is insufficient.

In the pursuit of enhancing the capabilities of ChatGPT-4 for emergency medicine board examination preparation, a comprehensive Anki deck was utilized as a resource for custom modification [16,17]. The specific Anki deck chosen, "The Emergency Medicine Residents' Deck," also called "Rob's Emergency Medicine Deck" [18], is a collection of emergency medicine knowledge, aggregating content from various premade decks and covering a wide array of topics pertinent to the field.

The information within this deck is sourced from a variety of educational resources and study aids [18]. The deck's development and maintenance are overseen by medical professionals, with a commitment to regular updates and improvements based on the latest research, peer-reviewed consensus, and user feedback.

Rationale

Medical learners seem to generally have a positive view on generative AI [19-21]. Incorporating its potential with another popular and effective resource [22,23], Anki, could be useful to this population. The hypothesis driving this study posits that a ChatGPT-4 model, when enhanced with the comprehensive knowledge contained in this Anki deck, would outperform its standard counterpart in emergency medicine board examination preparation. This assumption is grounded in the belief that the deck's content could significantly bolster the AI's understanding and response accuracy to examination-relevant questions. Moreover, a positive outcome from this hypothesis could suggest that medical students who use this Anki deck for preparation could potentially be equipped with all the knowledge to excel in the board examination.

The Anki deck was chosen as it is designed to be a comprehensive resource. Additionally, Anki has become one of the most popular study methods among trainees and medical students. The approach of spaced repetition is particularly useful in helping people recall information. While an AI model would not engage in spaced repetition, the content of the decks can be used to train the AI. By using this method, it can allow us to evaluate the performance of ChatGPT when provided with a widely used, evidence-based resource. Relative to other resources such as textbooks, an Anki user endeavors to recall every piece of information in the deck, while a textbook is generally not used in the same way.

Aims and Objectives

This study aimed to explore the efficacy of ChatGPT-4, specifically a custom-modified version tailored with specialized preparatory materials, in the context of emergency medicine board examination preparation. The objectives of this work were to: (1) evaluate the accuracy of ChatGPT-3.5 (released in 2022) in answering board examination style questions, (2) assess the baseline capabilities of the standard ChatGPT-4 model (released in 2023) in answering board examination questions accurately and consistently, and (3) evaluate whether a version custom-trained with a comprehensive flashcard resource exhibits superior performance. This comparison aimed to shed light on the potential of AI as a tool for medical education and identify pathways for its optimization in this domain.

Methods

Resources and Procedure

We used the Rosh In-Training Examination Question Bank, comprising 2000 questions, as the primary resource for questions. In order to customize ChatGPT-4 and transform it into a more specialized emergency medicine language model, "Rob's Emergency Medicine Deck," a comprehensive Anki deck for the ABEM Examinations, was converted to a TXT file and used to train the modified ChatGPT-4 model named "Emergency Medicine Residency Board Examination Expert."

Questions were selected from the question bank by selecting the "unused questions" option during the creation of individual practice examination question sets to ensure random selection and no overlapping questions.

Statistical Analysis

Sample Size

To examine if the sample size of 598 questions that were evaluated out of 2000 questions from the Rosh Review database is sufficient to make a conclusion about the performance of the two language models being equal, the following statistical assessment of the proportion of correct answers in each database was performed: the two-proportion z test was implemented to determine if there is a significant difference in error rates between the two language models; the alpha level of 0.05 was set to test the null hypothesis. The power was set at 0.80. The CIs for the difference between the two proportions were calculated; for the 5% significance level, a CI of 95% that included 0 would imply no significant difference between the error rates of the two language models.

The analysis showed that the two-proportion z score of approximately –0.073 corresponded to a P value of 0.942. Therefore, no statistically significant difference between the error rates indicates equal performance of the two language models. The z score close to 0 is also within the range of typical

XSL•FO
RenderX

sampling variation. In addition, the CIs for the proportions of correct answers using the Wilson Score Interval were approximately 77.3% to 83.6% for Custom ChatGPT-4 versus 77.1% to 83.5% for Default ChatGPT-4. The CI for the differences between the two proportions ranged between –4.7% and 4.3%. This narrow difference between the two proportions included 0, further showing no significant difference in the performance of the two language models.

Hence, a sample size of 598 questions that represent 29.9% of the Rosh Review database is sufficient to reliably assess the performance of the two language models.

Comparative Analysis

The performance of both the default and enhanced ChatGPT-4 models was compared based on the number of correct and incorrect answers. The incorrect responses were categorized according to the reason for error (logical error, informational error, or other), an approach used in previous studies [5,24], and analyzed for patterns.

A logical error is when the response successfully identified the relevant information but failed to effectively transform it into an answer. For example, the model identifies that a patient is struggling with the consistent use of topical acne medications due to a busy schedule and yet selects the answer that is a daily treatment over a less frequent regimen.

An informational error is when ChatGPT missed a crucial detail, either contained within the question or from external sources that should be part of its expected knowledge base. For example, a young woman is seeking birth control with a history of deep vein thrombosis, yet it recommends the oral contraceptive pill when deep vein thrombosis is a contraindication.

All remaining errors that are not related to the nonadequate connection to information, had insufficient consideration of all elements of the information, or had an arithmetic mistake were classified as "other". For example, the model identifies that a patient has cardiac failure yet inaccurately classifies the patient per the New York Heart Association Classification.

Incorrect Response Analysis and Question Type Assessment

For each incorrect response, the explanation provided by ChatGPT-4 was quantified (as response length in characters without spaces). Incorrect questions were classified by type (cardiac emergencies, neurological emergencies, respiratory emergencies, etc) to identify specific areas of weakness.

Statistical Analysis and Data Manipulation

A combination of statistical tests and data manipulation techniques were employed, facilitated by Python. The data were managed and manipulated using Pandas [25], a Python library offering data structures and tools designed for efficient data manipulation and analysis. Tasks such as filtering data, computing descriptive statistics, and organizing data into contingency tables for further statistical testing were conducted.

For statistical analyses, several methods were employed to assess differences in performance between versions of ChatGPT. The McNemar test was carried out using the SciPy library [26] to compare paired nominal data across different subgroups. Additionally, for comparisons involving proportions, the proportions_*z* test function from the Statsmodels library [27], which provides comprehensive classes and functions for estimating different statistical models and performing statistical tests, was used.

Furthermore, the Wilcoxon signed-rank test, through the SciPy library, was applied for the analysis of paired proportions with nonparametric methods to assess the statistical significance of differences between the versions without assuming the normal distribution of the data. CIs for proportions were estimated using a normal approximation method, underlining the assumptions made regarding the distribution of the sample proportions.

Ethical Considerations

As an observational study involving an AI system, there were no human or animal subjects, thus minimizing ethical concerns. Ethical approval was not required for this study in accordance with the criteria of the Clinical Research Ethics Committee of the Cork Teaching Hospitals, University College Cork.

Results

Data Collection

All results were collected from February 24, 2024 to March 13, 2024. The default ChatGPT-4 model was tested by manually entering a randomized selection of 598 questions from the Rosh In-Training Examination Question Bank. The ChatGPT-3.5 model was tested using a randomized selection of 269 questions from the same set of questions presented to the default ChatGPT-4 model.

Comparison of Models

Percent of Questions Correct

Table 1 shows the performance of Custom ChatGPT-4, Default ChatGPT-4, and Default ChatGPT-3.5 on the randomized 598 question Rosh Review bank. Custom ChatGPT-4 and Default ChatGPT-4 answered 481 questions (80.4%, 95% CI 77.3% to 83.6%) and 480 questions (80.3%, 95% CI 77.1% to 83.5%) correct, respectively, with P=.61. These results indicate that the overall performance for correctly answering is similar between the two versions, with overlapping CIs, suggesting no significant difference in their ability. However, Custom ChatGPT-4 significantly outperformed ChatGPT-3.5 by 17.6% while Default ChatGPT-4 significantly outperformed Default ChatGPT-3.5 by 17.5% (P<.001 and P<.001, respectively).

Table . The performance of three language models on the American Board of Emergency Medicine examination using the Rosh Review question bank.

	Custom ChatGPT-4 (n=598)	Default ChatGPT-4 (n=598)	Default ChatGPT-3.5 (n=269)
Number of Correct Questions	481	480	169
Correct (%)	80.4	80.3	62.8

XSL•FO
RenderX

Length of Responses

The Custom ChatGPT-4 had significantly shorter response lengths, 929 (SD=408) characters without spaces versus 1371 (SD=444) characters without spaces for the Default ChatGPT-4 (P<.001). This suggests that Default ChatGPT-4 provided either more comprehensive or verbose responses.

Responses by Discipline

In Table 2, we conducted a subgroup analysis to explore the performance of the Custom ChatGPT-4 and Default ChatGPT-4 versions across 15 different disciplines within emergency medicine. There were no statistically significant differences in the number of correct questions per discipline between Custom ChatGPT-4 and Default ChatGPT-4 in the 15 groups: 12/15 of the subgroups had P=1.0, except ear, nose, and throat (P=.23); obstetrics and gynecology (P=.50); and other (P=.77).

Table . Comparison of custom ChatGPT-4 and default ChatGPT-4 correct performance in Rosh Review subgroup analysis.

Subgroup	Custom ChatGPT-4 (n, %)	Default ChatGPT-4 (n, %)
Cardiology	81 (72.8)	81 (71.6)
Respirology	48 (70.8)	48 (73.5)
Neurology	33 (87.9)	33 (84.9)
Infectious Diseases	72 (84.7)	72 (83.1)
Gastrointestinal	51 (80.4)	51 (82.4)
Renal	15 (80.0)	15 (86.7)
Reproductive	9 (88.9)	9 (88.9)
Endocrine	23 (78.3)	23 (78.3)
Musculoskeletal	37 (73.0)	37 (73.0)
Ear, Nose, and Throat	26 (80.8)	26 (92.3)
Dermatology	16 (81.3)	16 (81.3)
Ophthalmology	20 (90.0)	20 (85.0)
Obstetrics and Gynecology	24 (87.5)	24 (79.2)
Oncology and Hematology	30 (86.2)	30 (90.0)
Other (Environmental)	113 (82.5)	113 (80.5)

Error Type Analysis

In Table 3, the type of error made by the Custom ChatGPT-4 and Default ChatGPT-4 was evaluated. There was no significant difference between Custom ChatGPT-4 and Default ChatGPT-4 for logical error (75.2% vs 80.5%), informational error (12.0% vs 13.6%), or other (12.8% vs 5.9%), with P=.41, P=.87, and P=.11, respectively.

Table . Assessment of the type of error conducted in two language models.

Error type	Custom ChatGPT-4 (n, %)	Default ChatGPT-4 (n, %)
Logical error	88 (75.2)	95 (80.5)
Informational error	14 (12.0)	16 (13.6)
Other	15 (12.8)	7 (5.9)
Total	117 (100)	118 (100)

Probability of Achieving a Passing Score

The passing probability of each ChatGPT model as predicted by the Rosh Review according to the individual ChatGPT performance was compared to the true performance of emergency medicine residents who wrote the ABEM in 2023. The newest ChatGPT models, ChatGPT-4 had a 99% chance of passing in both the Custom and Default versions. These were higher than the 85% probability of the default ChatGPT-3.5 version to pass and the 88% overall pass rate for the human counterparts. Notably, the human counterparts outperformed the ChatGPT-3.5 model.

Discussion

Principal Findings

A prominent characteristic highlighted through the development of ChatGPT is its capacity to grasp the context and key details that are pertinent to the discussed subject. Our study demonstrates that this capability is also applicable within the medical field by evaluating three versions of ChatGPT with the same data set. We found that both the custom and default models are highly likely capable of passing the ABEM written examination. This is supported by the Rosh Review [28], which

XSL•FO
RenderX

had a predictive measure of passing the examination with the probability of passing at 98.8% accuracy; the Rosh Review found that both models had a 99% probability of passing. However, ChatGPT-3.5 had an 85% probability of passing. This prediction suggests that the enhancements made for the custom-modified version did not significantly improve accuracy over the default version of ChatGPT-4 and also shows that advancements made between ChatGPT versions have potential applications in the medical field. These findings imply that the core capabilities of ChatGPT-4 are already sufficiently advanced for tasks such as aiding in emergency medicine board examination preparation. Furthermore, the recorded national average pass rate for first-time test takers is 91%, with the 2023 pass rate being 88% [29], suggesting that ChatGPT-4 has an improved performance while ChatGPT-3.5 is less equipped compared to humans.

In addition, our results illustrate that both models had consistent performance across various medical disciplines and highlight the versatility of ChatGPT as an educational tool. This versatility is particularly relevant in the context of emergency medicine, where a broad spectrum of knowledge is required, and suggests that AI can offer comprehensive support across diverse subject areas. Additionally, the integration of an Anki deck into a ChatGPT-4 model could help identify the specific flashcards and topics that the learners should focus on, an area for future research.

Comparison of Error Types and Response Length

The custom and default models had a similar level of drawing incorrect conclusions and omitting important components of questions, both of which hint at areas for improvement in both models. The high percentage of logical errors, compared to the other two errors, indicates that language models may not be particularly well suited in deductive reasoning [30]. It may be possible to address this by careful prompt engineering [31], for instance, instructing the model to follow a hierarchy of information sources to deliver the most reliable answers consistently. This is an area that could be the subject of further research.

Additionally, the response length analysis revealed that longer responses do not necessarily correlate with increased accuracy. Prompt engineering could be used to enhance the ease of learning by outlining a preferred explanation format. This finding has practical implications for the design of AI-driven study tools, suggesting that brevity, combined with accuracy, could enhance the efficiency of study sessions and information retention for learners. In contrast, it could be argued that longer responses reflect more comprehensive explanations. Future studies and particularly a qualitative analysis could be done to interrogate these hypotheses.

Effect of Custom Training on Performance

The results underscore the rapid advancements in AI technology, particularly in natural language processing and knowledge retrieval, which have significant implications for medical education. The observed improvements from version 3.5 to the more recent iterations of ChatGPT reflect a trajectory in AI development that could increasingly support complex learning needs. This evolution underscores the potential of AI to become an increasingly valuable asset in educational settings [6,19], offering up-to-date knowledge and adaptive learning paths on balance with a general cautious optimism among medical professionals [32]. Despite the lack of observed benefit from custom modifications in this context, the findings highlight the critical role of up-to-date AI models in enhancing learning outcomes. Furthermore, the results illustrate that the untrained ChatGPT-4 has a higher likelihood of passing compared to human test takers, who extensively prepared for the board examinations, suggesting that, even without custom modifications, ChatGPT-4 has sufficient accuracy to serve as a customizable tutor.

Overall, while the investigation revealed no significant difference in performance accuracy between the custom-modified and default versions of ChatGPT-4, both showed considerable improvement over the older 3.5 version. These findings prompt a re-evaluation of the presumed advantage of tailoring AI through specific educational content, suggesting that the core capabilities of advanced AI models might already be sufficiently robust for some less highly subspecialized educational applications. Additionally, these findings promote investigation into future upcoming ChatGPT models to evaluate if their advancements have accelerated benefit in the medical field.

When evaluating the reason for the Custom model not being significantly better than the Default model, we must consider that the Default version has already been trained on sufficiently similar data that the information provided did not contribute anything new to the knowledge base. The need for AI to be trained on up-to-date data is well established [33]. A previous study has hypothesized that training the model on static knowledge could potentially be a limiting factor [5], the reason for this being that online resources can be constantly updated with the latest guidelines and treatments. Basing training on a well-maintained dynamic knowledge source such as UpToDate® (Wolters Kluwer) could potentially provide more useful outcomes. It seems that general medicine knowledge has been well incorporated into the training material for the ChatGPT-4 model, and this can explain the similar performance between the two versions of ChatGPT-4 we tested. However, for more niche and subspecialized fields, there may exist a more pronounced benefit, and this is something future works could explore.

This study reaffirmed the potential of AI, particularly ChatGPT-4, as a powerful tool in medical education [6,34], capable of supporting learners in high-stakes examination preparation without the need for specialized enhancements. It highlighted the importance of leveraging the inherent capabilities of advanced AI models and provided a foundation for further research into effective integration strategies in educational settings. As AI continues to evolve, its role in education is likely to expand, offering opportunities to enrich learning experiences and access to knowledge.

Limitations

While this study provides valuable insights, it is not without limitations. The scope was restricted to emergency medicine,

XSL•FO
RenderX

limiting the generalizability of the findings to other fields of medicine or education. Future research could explore the application of AI in different specialties to assess its versatility and effectiveness further.

Additionally, the study's design focused on the efficacy of AI in answering board examination questions, which may not fully capture the nuances of applying that knowledge in clinical practice [35]. Further studies could investigate the impact of AI-assisted learning on clinical skills and decision-making processes [36,37]. The results of this study are not generalizable to the use of AI in contexts of medical education beyond the use case described for examination preparation.

The study's limitations suggest caution in generalizing the findings to other disciplines or educational objectives. Future research could broaden the scope to include diverse medical specialties and different types of educational content to verify the applicability of these results more widely.

Conclusion

This study reaffirmed the potential of AI, particularly ChatGPT-4, as a powerful tool in medical education, capable of supporting learners in high-stakes examination preparation without the need for specialized enhancements. It highlighted the importance of leveraging the inherent capabilities of advanced AI models and provided a foundation for further research into effective integration strategies in educational settings. This could be accomplished by determining if linking ChatGPT to a dynamic and reliable data source provides benefits, focusing in on highly subspecialized fields with static information sources, and ultimately comparing evaluation and management plans generated by AI to physician counterparts. As AI continues to evolve, its role in education and potentially clinical practice is likely to expand, offering opportunities to enrich learning experiences and access to knowledge.

Authors' Contributions

MP and SHK contributed to the conceptual design, data collection, data analysis, and drafting of the manuscript. MP and SHK are equal contributors. Abstract

Background: Acute marijuana intoxication can impair motor skills and cognitive functions such as attention and information processing. However, traditional tests, like blood, urine, and saliva, fail to accurately detect acute marijuana intoxication in real time.

Objective: This study aims to explore whether integrating smartphone-based sensors with readily accessible wearable activity trackers, like Fitbit, can enhance the detection of acute marijuana intoxication in naturalistic settings. No previous research has investigated the effectiveness of passive sensing technologies for enhancing algorithm accuracy or enhancing the interpretability of digital phenotyping through explainable artificial intelligence in real-life scenarios. This approach aims to provide insights into how individuals interact with digital devices during algorithmic decision-making, particularly for detecting moderate to intensive marijuana intoxication in real-world contexts.

Methods: Sensor data from smartphones and Fitbits, along with self-reported marijuana use, were collected from 33 young adults over a 30-day period using the experience sampling method. Participants rated their level of intoxication on a scale from 1 to 10 within 15 minutes of consuming marijuana and during 3 daily semirandom prompts. The ratings were categorized as not intoxicated (0), low (1-3), and moderate to intense intoxication (4-10). The study analyzed the performance of models using mobile phone data only, Fitbit data only, and a combination of both (MobiFit) in detecting acute marijuana intoxication.

Results: The eXtreme Gradient Boosting Machine classifier showed that the MobiFit model, which combines mobile phone and wearable device data, achieved 99% accuracy (area under the curve=0.99; F_1-score=0.85) in detecting acute marijuana intoxication in natural environments. The F_1-score indicated significant improvements in sensitivity and specificity for the combined MobiFit model compared to using mobile or Fitbit data alone. Explainable artificial intelligence revealed that moderate to intense self-reported marijuana intoxication was associated with specific smartphone and Fitbit metrics, including elevated minimum heart rate, reduced macromovement, and increased noise energy around participants.

Conclusions: This study demonstrates the potential of using smartphone sensors and wearable devices for interpretable, transparent, and unobtrusive monitoring of acute marijuana intoxication in daily life. Advanced algorithmic decision-making provides valuable insight into behavioral, physiological, and environmental factors that could support timely interventions to

XSL•FO

reduce marijuana-related harm. Future real-world applications of these algorithms should be evaluated in collaboration with clinical experts to enhance their practicality and effectiveness.

Introduction

Background

Acute effects of marijuana use impair motor skills and cognitive functions, such as attention and information processing [1-3], leading to adverse outcomes like poor academic and work performance, as well as an increased risk of motor vehicle crashes and fatal collisions [2,4]. Delta-9 tetrahydrocannabinol (THC), the principal psychoactive constituent of marijuana, binds to brain receptors, inducing a feeling of “euphoria” or being “high” [5]. Given the risks associated with THC-induced impairment, there is a critical need to detect episodes of marijuana intoxication in real time in the natural environment.

Several studies have explored the use of phone sensors or wearable devices to detect acute marijuana consumption. For example, a laboratory study with 10 participants used smartphone sensors (accelerometer, gyroscope) to detect acute marijuana use (3% or 7% THC vs placebo) and found that gait analysis with a support vector machine model achieved 92% accuracy (F_1-score=0.93) [6]. Another study (n=1) developed an electrochemical biosensor ring that detected salivary THC (minimum of 0.5 µM) and blood alcohol levels (minimum of 0.2 mM) within three minutes [7]. However, these studies were conducted in controlled environments, highlighting the need for research on using smartphone and wearable sensors to detect acute marijuana use in nonlaboratory, natural settings.

Detecting marijuana use in daily life could enable Just-In-Time interventions to reduce harm, such as avoiding driving while intoxicated [8]. However, challenges exist in detecting acute marijuana-related intoxication [9]. THC could be detected in an individual’s blood or urine for several days after consumption depending on factors such as recency, frequency, and chronicity of use [10]. Thus, a person who tests positive for THC might not be intoxicated or impaired at the time of testing [10]. Existing testing methods (eg, blood, urine, saliva, and breath) are not suitable for real-time detection, as THC can remain detectable in the body for days after consumption, which does not necessarily indicate current impairment [10].

To address these limitations, our recent study [11] used passive sensing via smartphones, coupled with self-reported intoxication, to detect marijuana use with 90% accuracy, using sensor-derived data from mobile phones alongside temporal variables, including time of day and day of week. Building on these findings [11], this study explores the use of wearable devices (eg, Fitbit) to enhance detection capabilities by incorporating physiological indicators, thereby improving the accuracy and immediacy of identifying marijuana effects in natural environments.

Wearable device–reported heart rate (HR) was examined as a potential physiological indicator of acute marijuana intoxication, based on laboratory studies, showing a dose-dependent increase in resting HR shortly after smoking or vaping marijuana [12-14]. Specifically, laboratory research reports that within 2-3 minutes of smoking marijuana, there is an acute increase (20%-60% dose-dependent) in resting HR [13], which might represent a “physiological signal” of the onset of a marijuana smoking episode. HR peaks 10-15 minutes after reaching maximum THC levels, followed by a rapid decline [12-14]. While tolerance to this effect may develop (eg, from a mean increase of 44.6 to 6.6 beats per minute (bpm) after 18-20 days of use) with chronic use, [12-14]. The acute HR increases have been validated in laboratory settings but have remained unexplored in real-world contexts. This study examines using off-the-shelf wearable devices, such as Fitbit, to detect acute HR increases as a physiological signal potentially correlated with self-reported marijuana intoxication.

Research Objectives and Contributions

While laboratory studies have established the link between HR changes and marijuana intoxication [12-14], its applicability in real-world scenarios is unexplored. To address this gap, we propose that combining wearable device data with smartphone sensors could improve algorithms for detecting marijuana intoxication in real-life settings. To enhance the interpretability of our algorithms and provide insights for just-in-time adaptive interventions, we incorporated explainable artificial intelligence (XAI) into our machine-learning pipeline. XAI helps clarify the role of digital biomarkers associated with self-reported marijuana intoxication in natural environments.

This study aims to determine whether data from smartphones (eg, accelerometer and GPS) and wearable devices (eg, Fitbit) can detect self-reported marijuana intoxication (“feeling high”) in the natural environment, a topic not previously investigated. Two hypotheses drive this research: (1) the novel MobiFit model, which combines smartphones and Fitbit data will outperform models that use only one data source in detecting self-reported intoxication; (2) HR and daily behavioral data (eg, step count) from Fitbit are important features for detecting self-reported marijuana intoxication. If either hypothesis is validated, it indicates the value of integrating wearable device data into daily life monitoring.

This study evaluates the performance of sensor-based models using (1) only smartphone sensors, (2) only Fitbit data, and (3)

XSL•FO
RenderX

the combined MobiFit model. We also used XAI to enhance understanding of key digital features from both smartphone sensors and Fitbit data associated with self-reported marijuana intoxication. Identifying smartphone-based sensors and Fitbit features that accurately detect self-reported marijuana intoxication in natural environments could ultimately trigger just-in-time interventions.

This study presents a comprehensive approach toward using mobile and wearable technology for detecting self-reported acute marijuana intoxication in real-life settings, emphasizing interpretability and transparency through XAI. This study demonstrates the potential of integrating smart devices with advanced analytical techniques to improve detection accuracy and support timely interventions based on detected intoxication levels.

Methods

Recruitment and Participants

A total of 57 participants aged 18-24 years were recruited through flyers, advertisements, and local communities. Eligibility criteria were (1) using marijuana at least twice a week, (2) owning a personal mobile phone, (3) not currently seeking treatment for substance abuse, (4) no self-reported history of psychosis, and (5) not taking any medication or using any medical device (eg, pacemaker) that could affect HR. Of the 57 participants, 24 participants were excluded from the analysis due to missing data (eg, no HR data and no mobile sensor data).

The final analysis focused on 33 participants aged 18-24 years, with an average age of 19.64 (SD 1.77) years. Among these, 23 participants identified as White, 4 participants as Black, and 6 participants as other race or ethnicity. The average age of first marijuana use was 16.48 (SD 1.84, range 13-22) years, and the average age of regular marijuana use was 17.03 (SD 1.72) years. In this subset, 24% (n=8) reported daily marijuana use, 9% (n=3) reported using it 5-6 times per week, and 67% (n=22) reported using it 2-4 times per week. Notably, 97% (n=32) of participants primarily used iOS smartphones, with only 3% (n=1) using Android devices.

Ethical Considerations

This naturalistic, observational follow-along study was approved by the university's institutional review board (Stevens 2020-008 [23-COAS3], Rutgers Pro2019002365). In line with similar Institutional Review Board–approved observational studies [15], all participants were informed about local medical and mental health resources. The study obtained a National Institutes of Health Certificate of Confidentiality. Written consent was obtained from participants, who were informed about privacy protections and the voluntary nature of their participation [16]. The research staff explained the types of data to be collected, the duration of data collection, and the purpose of the study.

Study Design

Participants completed a baseline laboratory assessment including interviews, questionnaires, and cognitive testing. They downloaded study apps from the App Store or Google Play Store to their smartphones. Research staff trained participants on how to use the apps and the study provided Fitbit Charge 2 for data collection. The AWARE mobile app [17] delivered experience sampling method (ESM) questions on marijuana use. Participants wore the Fitbit Charge 2 wristband to collect data on HR, physical activity (eg, step count), and sleep (eg, time, duration, and quality; see Table S2 in Multimedia Appendix 1 for Fitbit variables). The study collected continuous sensor data from smartphones and Fitbit devices, along with self-reported data on marijuana intoxication, for up to 30 days. A 30-day period was chosen to ensure sufficient data, given the study's inclusion criteria of frequent marijuana use. At the end of the study, participants completed a debriefing interview about their experience.

Participants were compensated for their time and effort, receiving US $75 for completing the baseline assessment, and US $25 for the debriefing interview. They earned US $10 for each day on which they completed more than 75% of data collection (eg, Fitbit and ESM).

Mobile Sensing Framework and Applications for Data Collection

AWARE App

AWARE is a mobile sensing framework [17] that passively and continuously collects data from smartphone sensors. This data can be used to infer human behavior patterns using various sensors: location (eg, distance traveled and circadian rhythm), physical movements (eg, acceleration and activity), device usage (eg, unlock, charge, keypress, and app usage), social patterns (eg, communication and conversations), and environmental context (eg, Wi-Fi, Bluetooth, sound or ambient noise, and light). The app, developed to track participants' natural behaviors in real-life settings, runs in the background 24/7 and collects sensor data with associated metadata, such as time stamps and communication logs. The data is transferred to a secure MySQL database owned and operated by the research team.

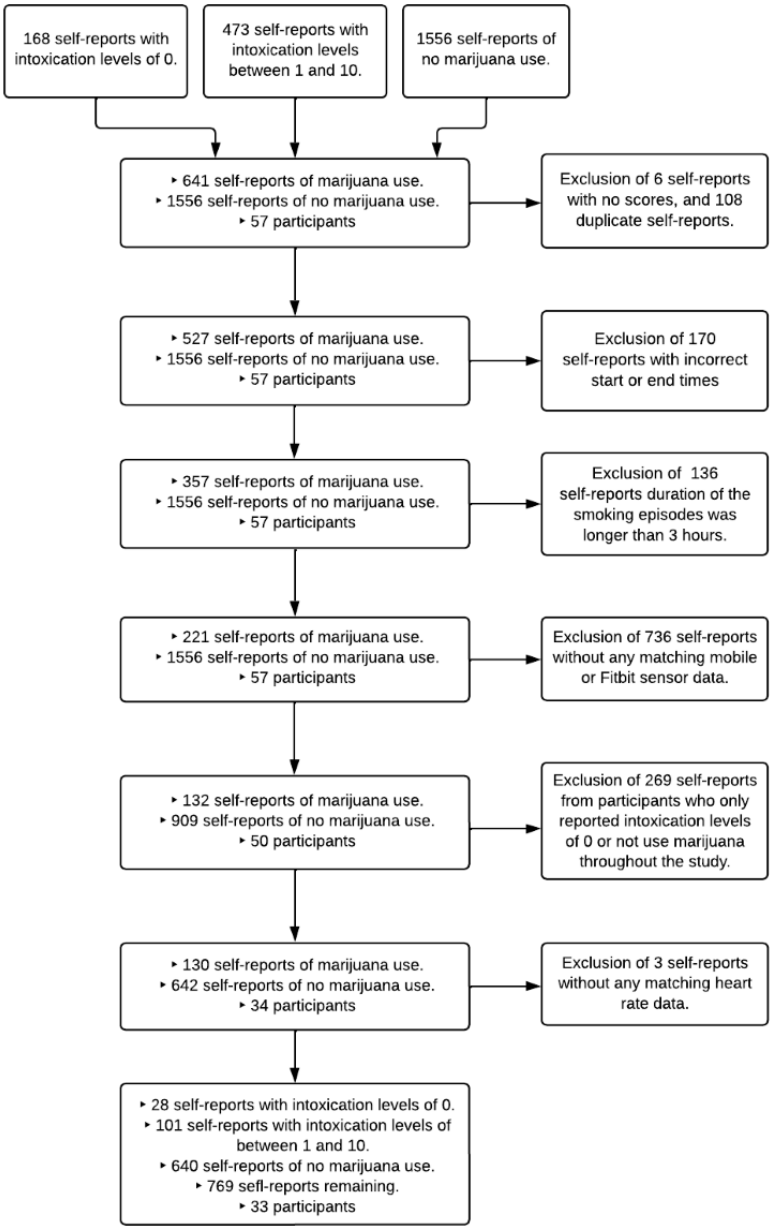
ESM

The mobile app also captured self-reports of marijuana use by participants. Two types of surveys were used [18]. Participants manually reported marijuana use within 15 minutes of consumption, detailing the amount used, mode of consumption, and the people whom the participant consumed marijuana with. They also rated their subjective intoxication on a scale from 0 (none) to 10 (a lot) [19]. Two hours later, the app prompted participants to complete an end-session survey indicating when intoxication symptoms subsided. In addition, fixed-time surveys were delivered daily at 10 AM, 3 PM, and 8 PM to collect information on the participants' daily lives, including time since last marijuana use, cravings, mood, and feelings (eg, relaxed, anxious, and sad), and other substance use (eg, alcohol and tobacco). Survey response windows were open for 5 hours to accommodate participants' schedules.

Fitbit Charge 2

Participants were provided with Fitbit Charge 2 devices and asked to wear them as much as possible. Fitbit collected

XSL•FO
RenderX



physiological data (eg, HR), activity data (eg, step count), and sleep. The study hypothesized that HR and behavioral data could signal episodes of acute marijuana intoxication. Fitbit data were retrieved from the Fitbit server at the end of the study using the Fitbit application programming interface.

Preparing Self-Report and Fitbit Data for Analysis

An episode of self-reported subjective marijuana intoxication was defined based on the ESM item: "How high are you feeling right now?" rated from 0 to 10 (0=not high to 10=a lot) [18,19]. To include episodes in the analysis, both start and end times had to be reported to calculate duration and label the sensor data. To capture behaviors without marijuana use, 1556 reports where participants answered "no" to the question "Did you smoke marijuana since the last report?" during afternoon (n=1151) and evening (n=950) surveys were labeled as "0" for the subjective rating of marijuana intoxication.

From all participants, we received 641 self-reports (mean 9.86, SD 8.49; median 7, IQR 4-13) and 1556 with no marijuana use reports (Figure 1). Out of 641 reports, 168 reports had a subjective intoxication rating of 0 and 10, and 6 reports had no rating. After excluding 6 reports without ratings and 108 duplicate reports, 527 samples remained. Reports with missing start and end times, or implausible episode durations (eg, longer than 3 hours) were excluded based on laboratory research indicating that smoked or vaped marijuana effects last less than 3 hours [20]. A total of 136 self-reports were excluded for exceeding this duration, leaving 1556 reports where no marijuana use was recorded [20].

Figure 1. Flowchart of participants and the data included in the analyses.

For model building, episodes without mobile sensor data (n=72) were excluded, leaving 221 marijuana self-reports. Furthermore, episodes without Fitbit sensor data (n=17) were excluded, leaving 50 participants. These participants provided 132

XSL•FO
RenderX

marijuana use self-reports and 909 “no marijuana use” reports. We analyzed reports from each participant, excluding those who only reported not using marijuana or had a rating of 0 for subjective intoxication, leaving a total of 642 with no marijuana use report or who reported 0 subjective intoxications when using marijuana and 34 people. Finally, to prevent participants from using Fitbit incorrectly, we excluded users without HR data, leaving a total of 33 people, who provided a total of 769 events: 640 “no marijuana use” reports and 129 marijuana use self-reports.

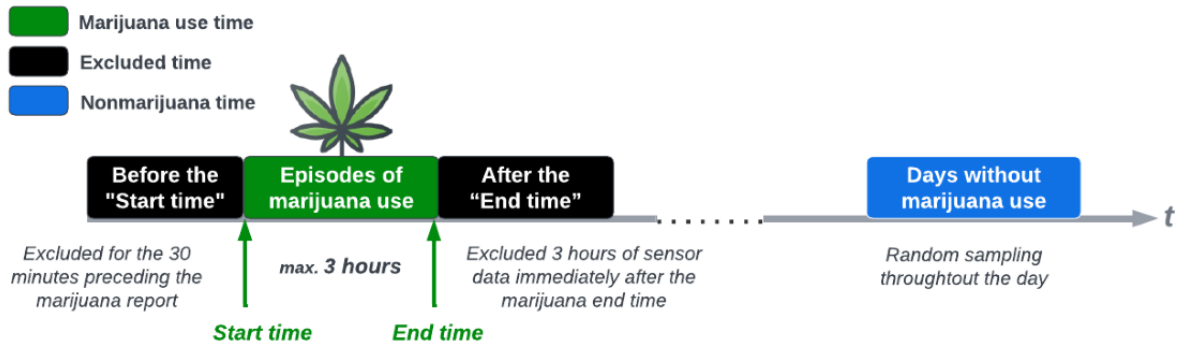
Extracting Smartphone and Fitbit Sensor Features

Following previous studies, we extracted audio features to detect social interactions [21,22] potentially associated with marijuana use. Audio features were extracted using the conversation plug-in, which detects whether a person was engaged in a conversation. Raw audio signals are converted to amplitude using the Euclidean norm [23], which categorizes ambient levels into silence, noise, voice, and unknown [24]. We also computed device use features, such as smartphone unlock minutes and the duration of device interaction sessions. In addition to audio features, we extracted GPS features to examine movement patterns related to marijuana use [25-28]. These included the radius of gyration, time at a location cluster, total distance traveled, number of clusters within a 5-minute window, acceleration, and phone angles. Environmental features, such as the number of Bluetooth devices detected, the most frequently contacted Wi-Fi access point, and light features (eg, average [avg], and maximum [max] lux) were also extracted. For most features, we calculated the minimum (min), max, avg, median (med), and SD. Further details on smartphone features can be found in Multimedia Appendix 1.

We used a 5-minute time window for extracting sensor feature statistics, as laboratory studies show a dose-dependent acute in resting HR within 2-3 minutes of marijuana use. Using larger time intervals could include data not related to marijuana use, given the average reported marijuana session duration is 75 (SD 46.2) minutes.

Raw data for HR, sleep, and steps were extracted from Fitbit. We first obtained per-minute HR and step count data using the Fitbit application programming interface. To exclude outliers, we refined data selection to omit instances where HR was below 40 bpm, as recommended by the American Heart Association [29,30]. We extracted feature statistics such as avg, SD, min, med, and max HR within a 5-minute window to explore the relationship between HR and marijuana intoxication levels (“moderate-intensive,” “low,” and “none”). Resting HR was defined as HR data collected when the participant was sedentary (ie, no steps taken) for more than 5 minutes. To further analyze HR patterns related to marijuana intoxication, we examined the degree of peakedness (kurtosis) and asymmetry (skewness) in HR data, as these features may reveal physiological changes associated with marijuana intoxication [31]. For more details, refer to Table S2 in Multimedia Appendix 2.

Ground Truth and Labeling Sensor Data



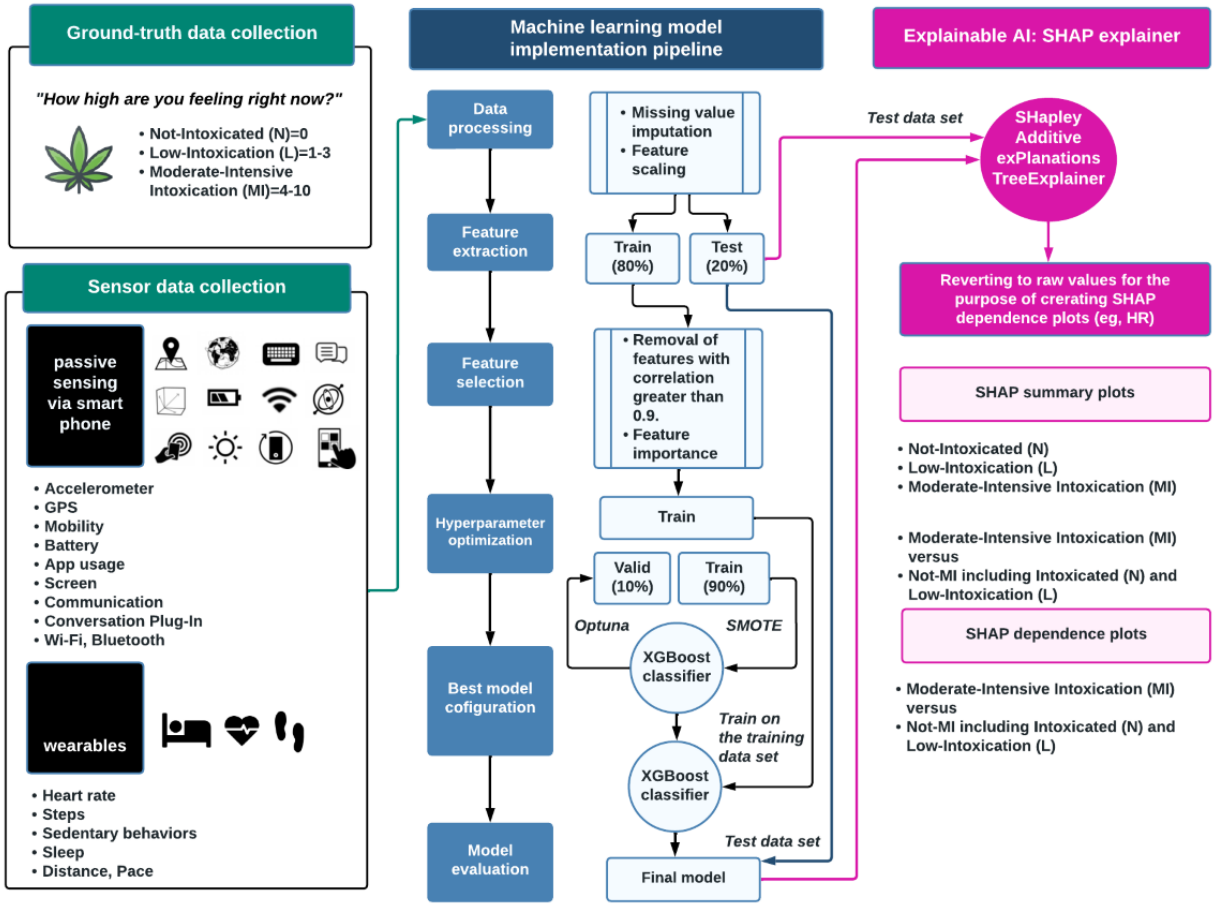
To accurately label the collected sensor data, we defined the duration of marijuana use episodes as those equal to or less than 3 hours, based on reported start and end times. We excluded 3 hours of sensor data following the reported end time to account for the continued effects of marijuana, even when participants reported a subjective intoxication level of 0. For example, if marijuana use was reported from 6 PM to 6:30 PM, data from 6:30 PM to 9:30 PM were excluded to account for residual effects. We also excluded data from 30 minutes before the reported start time to account for potential delays in self-reporting, based on pilot study findings that delays could range from 5 to 15 minutes. To collect nonmarijuana data, we randomly sampled sensor data from days when participants did not use marijuana (ie, nonmarijuana days). These samples were labeled using morning, afternoon, and evening surveys in which participants reported “no” to the ESM item “Did you smoke marijuana since the last report?” and indicated that the last use was more than 5 hours before the ESM time stamp (Figure 2).

We aimed to capture acute intoxication versus nonuse, classifying intoxication levels into three categories: 0 as “not intoxicated,” 1-3 as “low intoxication,” and 4-10 as “moderate-intensive intoxication” (MI). In total, we labeled 32,722 sensor stream samples (5-minute windows) as “not intoxicated” (154 from self-initiated survey coded as 0 high, and 32,586 from time-based self-reports), 423 samples as “low intoxication” (ratings between 1 and 3) and 772 samples as “moderate-intensive” (ratings between 4 and 10, with 10 indicating “a lot”).

Data from smartphones and Fitbit resulted in two datasets of different sizes. To ensure consistency, we down-sampled the smartphone dataset to include only samples overlapping with Fitbit data during the same time frames. This resulted in three datasets: (1) eXtreme Gradient Boosting (XGBoost)-Mobile: mobile phone only, (2) XGBoost-Fitbit: Fitbit-only, and (3) XGBoost-MobiFit: combined mobile and Fitbit data. The rationale for choosing Machine Learning (ML) models is detailed in Multimedia Appendix 3 and model comparison with different classifiers can be found in Multimedia Appendix 4.

XSL•FO
RenderX

Figure 2. Marijuana use episodes and labeling principle.



ML Pipeline

Feature Selection

We began data analysis by randomly partitioning the labeled sensor data into training (80%) and test (20% holdout) datasets. As shown in Figure 3, we first calculated Pearson correlation coefficients between features in the training dataset to identify highly covariant feature pairs (correlation coefficients >0.9) [32]. We then systematically removed one feature from each pair to reduce redundancy and improve model performance by retaining the most relevant and independent features. Next, we selected statistically significant features with a Gini coefficient importance [33] greater than 0.005. Details can be found in Multimedia Appendix 2.

Figure 3. Study overview. AI: artificial intelligence; HR: heart rate; SHAP: Shapley Additive exPlanations; SMOTE: Synthetic Minority Over-Sampling Technique; XGBoost: eXtreme Gradient Boosting Machine.

XSL•FO
RenderX

Hyper-Parameter Tuning and Cross-Validation

As shown in Figure 3, during hyper-parameter tuning in the training dataset, we used cross-validation to randomly leave 10% of the samples out, training the model on the remaining 90% and testing on the withheld 10%. We used the Synthetic Minority Over-Sampling Technique [34] to ensure equal representation across all classes. We further optimized model performance with a Bayesian-optimization-driven method called Optuna [35] to select the best combination of hyperparameters and 10-fold cross-validation on models with Optuna-optimized hyperparameters.

For the final model evaluation, we used the reserved test data (20% unseen data, as shown in Figure 3). The model was evaluated on predictions made on the test data. Finally, as shown in Figure 3 (right column), we conducted an XAI analysis to better understand the decision-making process of our final predictive model. We generated SHapley Additive exPlanations (SHAP) on the unseen test data to ensure our findings were explainable for data the model had not seen.

Model Evaluation Metrics

We evaluated model performance using F_1-score, recall, and precision, and selecting the best model based on the F_1-score [36]. Low precision indicates too many false positives (ie, detecting intoxication when there is none), here we would mistakenly intervene or notify the participant. Low recall indicates too many false negatives (ie, not detecting intoxication when it occurs), potentially leading to unsafe behaviors such as impaired driving. Therefore, while we prioritize the F_1-score, we also consider precision and recall.

Given our imbalanced samples, we used the area under the curve (AUC) metric, which provides a robust evaluation across all classification thresholds and is resilient to class imbalance.

XAI: Interpretation Approaches for Black-Box ML Models

To enhance algorithmic transparency, we used SHAP, a widely used interpretability method for ML models [37,38]. SHAP explains how specific data features influence model predictions, providing insights into the model's decision-making process. We identified the top 30 most significant features associated with marijuana intoxication reports, including their importance scores and visual summaries calculated by SHAP (see "Key Features Contributing to Model Performance" under the Results section). XGboost was selected due to its superior performance compared to other classifiers. The use of tree SHAP in this context reduces the computation time for SHAP values from exponential to polynomial [37].

Results

Timing, Duration, and Rating of Subjective Marijuana Intoxication

During the 30-day period, participants averaged 14 (SD 8.59) days of active participation. A total of 129 ESM self-initiated reports of marijuana use met the criteria for inclusion in the analysis: 101 reports of subjective marijuana intoxication (feeling high rated 1-10 out of 10) and 28 reports of feeling not high (0). Events not involving marijuana use were assigned a high rating of 0.

Tables 1 and 2 show the distribution of self-reported subjective marijuana intoxication across participants. Most episodes of intoxication (n=75) lasted between 30 minutes and 3 hours, with 54 episodes lasting up to 30 minutes (Table 1). Marijuana use was most often reported between 10 PM and 11 PM (n=24). Table 2 shows the distribution of ESM responses throughout the day. The average response latency to an ESM prompt expired. Most self-initiated reports of marijuana use occurred in the evenings: 14% (n=18) between 6 PM and 9 PM, and 39% (n=50) between 9 PM and midnight. On average, young adults rated their feeling of being high at 3.63 (SD 2.72) out of 10 when using marijuana (Table 3).

Model Comparison: Mobile Only, Fitbit Only, and Mobile and Fitbit Integration

The first part of our analysis aimed to determine whether smartphone sensor features alone could be used for real-time detection of subjective marijuana intoxication and whether adding Fitbit data would improve model performance, justifying the added complexity of Fitbit data collection. We compared three ML models using the XGBoost classifier: (1) smartphone sensors only (XGBoost-Mobile), (2) Fitbit features only (XGBoost-Fitbit), and (3) a combined model using smartphone and Fitbit features (XGBoost-MobiFit).

Among the 3 models tested, the XGBoost-MobiFit model, which integrates smartphone and Fitbit data, had the best performance, achieving 99% accuracy, 92% precision, 79% recall, 85% F_1-score, and 99% AUC on the test dataset (Figure 4 and Table 4). These metrics indicate the XGBoost-MobiFit model's superior ability to accurately identify MI compared to low-intoxication and not-intoxicated states. While the XGBoost-Fitbit performed reasonably well, it did not match the performance of the XGBoost-MobiFit model in detecting marijuana intoxication. XGBoost-Fitbit achieved accuracy of 98%, 79% precision, 70% recall, 74% F_1-score, and 97% AUC. These results suggest that using only Fitbit data may not be as effective as combining it with smartphone sensor data for detecting subjective marijuana intoxication. Based on these findings, the added burden of wearing and charging the Fitbit device seems justified in future deployments. The combined model (XGBoost-MobiFit) demonstrated improved performance in detecting subjective marijuana intoxication compared to using smartphone or Fitbit data alone.

Combining Fitbit data with mobile data resulted in a significant improvement over the Fitbit-only model. The mobile-only model achieved an AUC of 96%, an F_1-score of 72%, a recall of 75%, and a precision of 70%. These results indicate that including Fitbit data adds value beyond what can be achieved with smartphone-based sensor data alone, as evidenced by a 13% improvement in F_1-score.

In summary, three key findings emerged: the XGBoost-Mobile model had the lowest performance (F_1-score=0.72, recall=0.75, precision=0.70); the XGBoost-Fitbit model (F_1-score=0.74, recall=0.70, precision=0.79) generally performed lower than the combined model; and the XGBoost-MobiFit model was the best performer with an F_1-score of 0.85, recall of 0.79, and precision of 0.92. As highlighted earlier, high precision and recall are critical so we focused on the F_1-score to identify the best-performing model. The model comparison with different classifiers is provided in Multimedia Appendix 4.

Figure 4. Model comparison to detect acute marijuana intoxication "low-intoxicated" (rating=1-3) versus "moderate-intensive intoxicated" (rating=4-10) versus "not-intoxicated" (rating=0). XGBoost-MobiFit: phone sensors and Fitbit (AUC=0.99; accuracy=0.99; left), XGBoost-Mobile: smartphone-based sensors (samples overlapping with Fitbit; AUC=0.96; accuracy=0.97; middle) and XGBoost-Fitbit: Fitbit only (AUC=0.97; accuracy=0.98; right). AUC: area under the curve; ROC: receiver-operating characteristic curve; XGBoost: eXtreme gradient boosting.

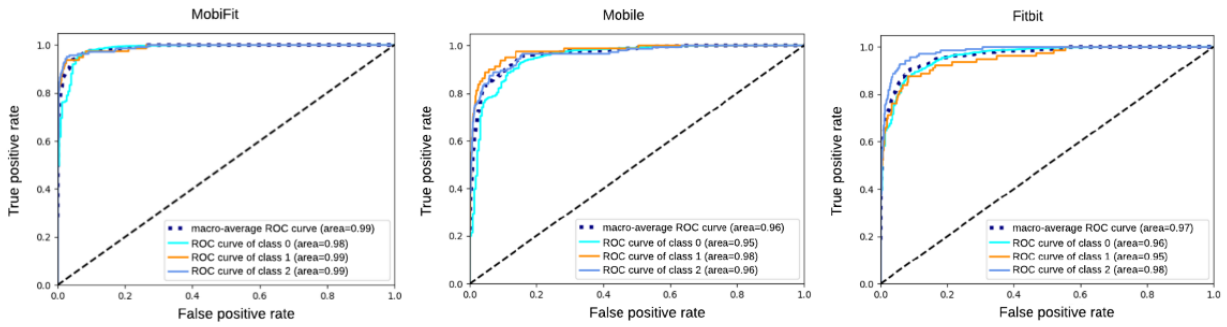

Table 4. Comparison of three XGBoost models using features selected in detecting moderate-intensive marijuana intoxication, low-intoxication, and not-intoxicated classes on the test dataset.

Machine learning model	AUC[a]	F_1-score	Recall	Precision	Accuracy

Understanding Model Performance in Detecting the Risk State of "Moderate and Intensive Marijuana Intoxication"

For predicting the MI class alone, the MobiFit model outperformed the mobile and Fitbit-only models, exhibiting a substantial improvement in the F_1-score of 20% and 18%, respectively (Table 5). This improvement in F_1-score highlights the benefits of integrating data from both devices: enhanced precision and recall for the MI class compared to the not-intoxicated (N) and low-intoxicated (L) classes (Table 6). The XGBoost-Mobile model exhibited a notably high false negative rate for instances labeled as "not-intoxicated," often misclassifying them as "moderate-intensive intoxicated."

XSL•FO
RenderX

However, it showed better accuracy in distinguishing "low-intoxicated" instances. In contrast, the XGBoost MobiFit model demonstrated a higher true positive rate compared to the other models, accurately identifying 76% of MI samples among the total samples belonging to that class. While the XGBoost-Mobile and Fitbit models achieved recall rates of 61% and 63% in predicting MI, they incorrectly predicted 56 and 53 out of 143 actual MI samples as other classes. In comparison, the best-performing MobiFit model achieved 108 true positives out of the 143 actual MI samples. The higher precision of the MobiFit model further supports its superior performance, though there remains room for improvement as it missed 35 samples, as shown in Table 6.

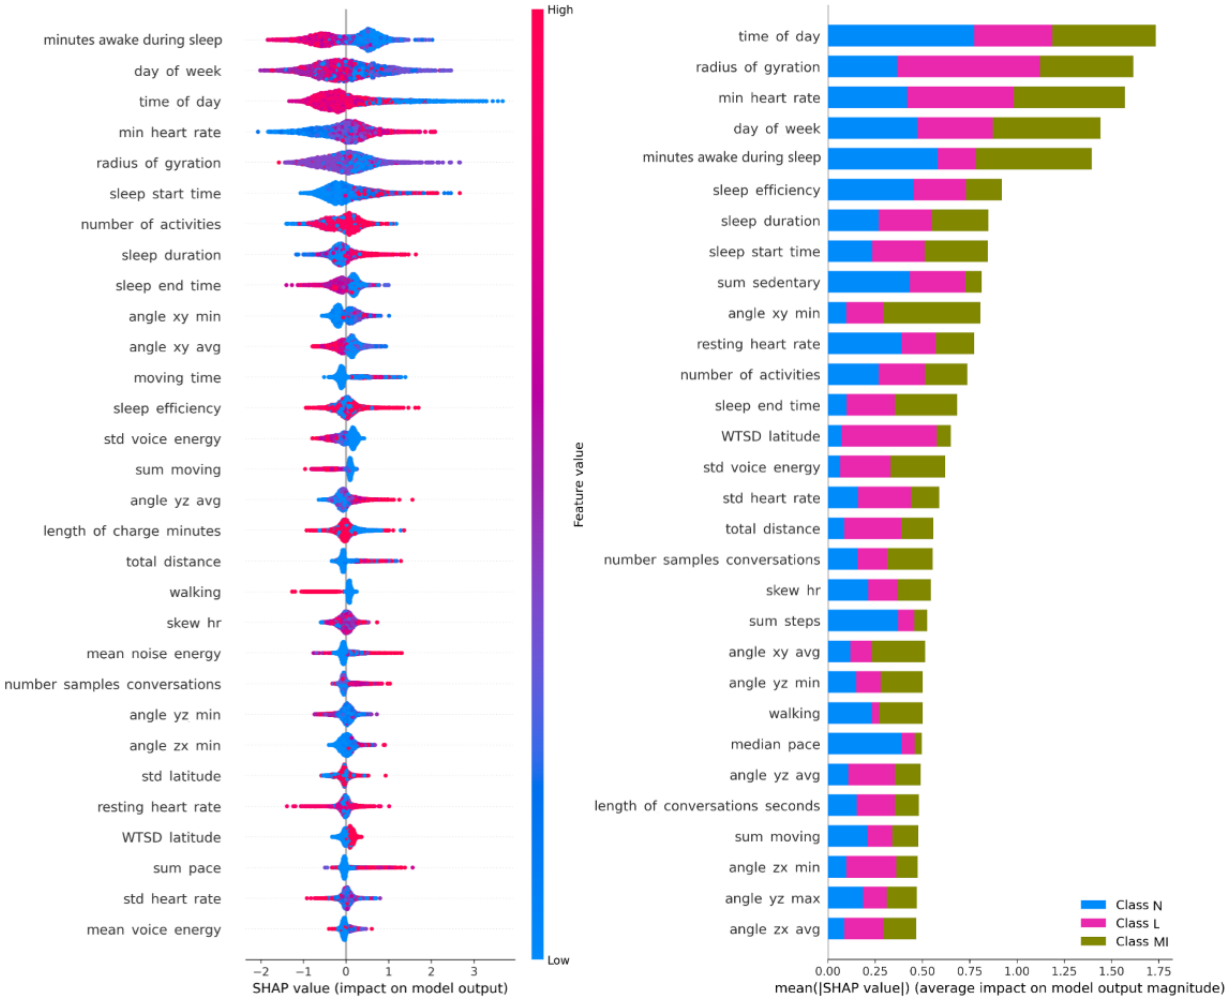
Key Features Contributing to Model Performance

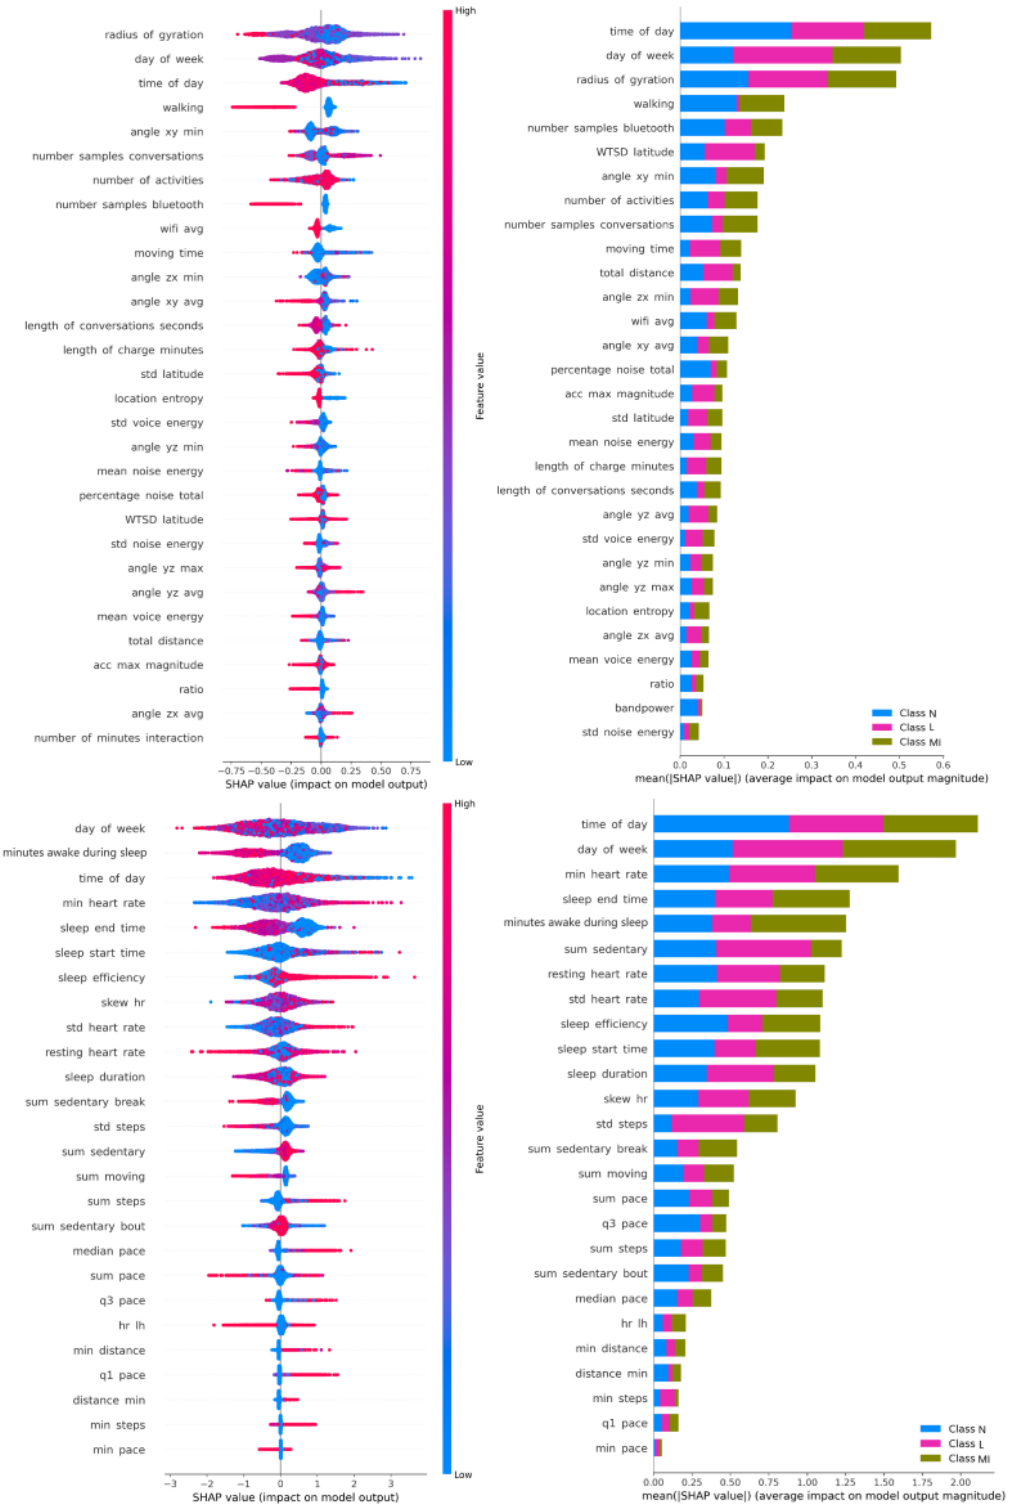
Overview



To explore the algorithms' performance in predicting the MI class, we used SHAP summary visualizations [37,38] to identify patterns of acute marijuana intoxication. We determined the key features contributing significantly to the model's predictions based on mean absolute SHAP values across all instances, with a focus on the MI class.

Figures 5 and 6 present the SHAP visualizations. In Figure 5, the length of each bar on the left indicates the feature's contribution to the model, with longer bars signifying a stronger influence on the outcome. The SHAP summary plots on the right of Figure 5 illustrate how features influence the MI prediction class, with the strongest influence at the top. The

XSL•FO
RenderX



color shading indicates the direction of the feature's effect, with blue for low values, purple for median values, and red for high values. Plots extending to the left indicate a negative contribution to the prediction, while those extending to the right positively contribute to MI predictions.

Figure 5. Explanations generated by SHAP summary plot. Impact of features on best performing XGBoost-MobiFit model (left) and binary model output identifying moderate-intensive intoxication (MI; SHAP>0) from nonmoderate-intensive intoxication (N and L) classes (SHAP<0; right). HR: heart rate. SHAP: SHapley Additive exPlanations; WTSD: weighted stationary latitude and longitude standard deviation; XGBoost: eXtreme Gradient Boosting.

Figure 6. Explanations generated by SHAP summary plot. Impact of features on XGBoost-Mobile model (top left) and binary model output identifying MI (SHAP>0) from nonmoderate-intensive intoxication (N and L) classes (SHAP<0; top right), impact of features on XGBoost-Fitbit model (bottom left) and binary model output identifying MI (SHAP>0) from nonmoderate-intensive intoxication (N and L) classes (SHAP<0; bottom right). MI: moderate-intensive intoxication; SHAP: SHapley Additive exPlanations; WTSD: weighted stationary latitude and longitude standard deviation; XGBoost: eXtreme Gradient Boosting.

Impact of Average Key Features on Model Output Magnitude

The top five influential features in detecting the three classifications (Figure 5, left) and affecting the MI outputs (Figure 5, right) included time of day, radius of gyration, minimum HR, day of the week, and minutes awake during sleep. Among physical activities and physiological signals, a diverse range of features extracted from various sensors, including those beyond time-based attributes from both mobile and Fitbit combined sensors, was chosen as the top 30 crucial elements for distinguishing between not-intoxicated (N), low-intoxication

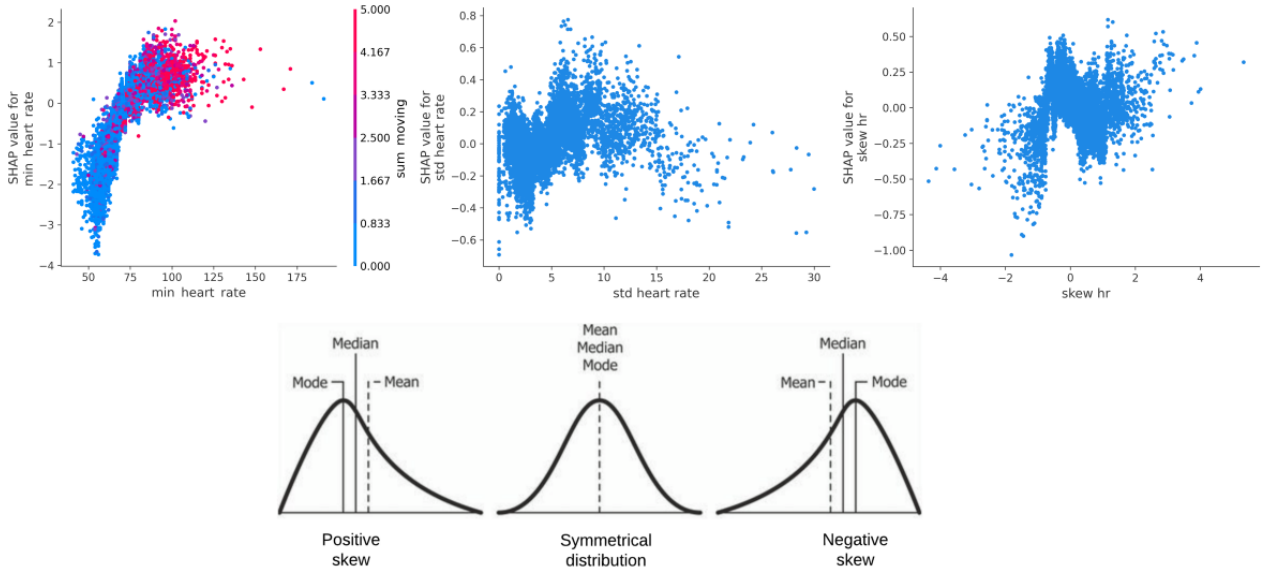
XSL•FO
RenderX

(L), and MI. The SHAP value, signifying the average impact magnitude on the model's output, played a pivotal role in this determination (Figure 5, left).

Impact of Unique Key Features on Mobile and Fitbit Model Outputs

Similar to the best-performing MobiFit model, the Mobile model (Figure 6) highlighted key features with overlapping impacts on the model's outcomes. The only exception was in specific movement and environmental context features, as shown in the top left and right graphs of Figure 6. However, the Fitbit model showed a more significant impact on HR features, with all four HR features ranking within the top 10 for all three classes (shown in the bottom-left graph in Figure 6), and for the MI classes compared to the non-MI classes (bottom-right graph in Figure 6).

Key Features Explaining MI



Overview

To specifically examine the influence of key features on the "risk" state of MI, we present comprehensive details for each key feature within the model.

A partial dependence plot (PDP) in Figure 7 illustrates the overall relationship between a feature and the outcome. The vertical axis represents SHAP values, signifying the effect of the chosen feature on predictions, while the horizontal axis represents actual feature values across instances. Each point represents an instance's feature value and its corresponding SHAP value. An upward PDP slope indicates a positive impact of the feature on MI prediction, while a downward slope indicates a negative impact. The surface on the PDP plot (eg, min HR and sum of moving minutes in Figure 7, top left) shows the combined impact of the two features on MI predictions, with greater values corresponding to increased prediction values.

In the following section, we introduce the key features contributing to MI, including elevated and fluctuating HR, reduced large-scale movement patterns, increased ambient noise and voice energy, and extended sleep patterns.

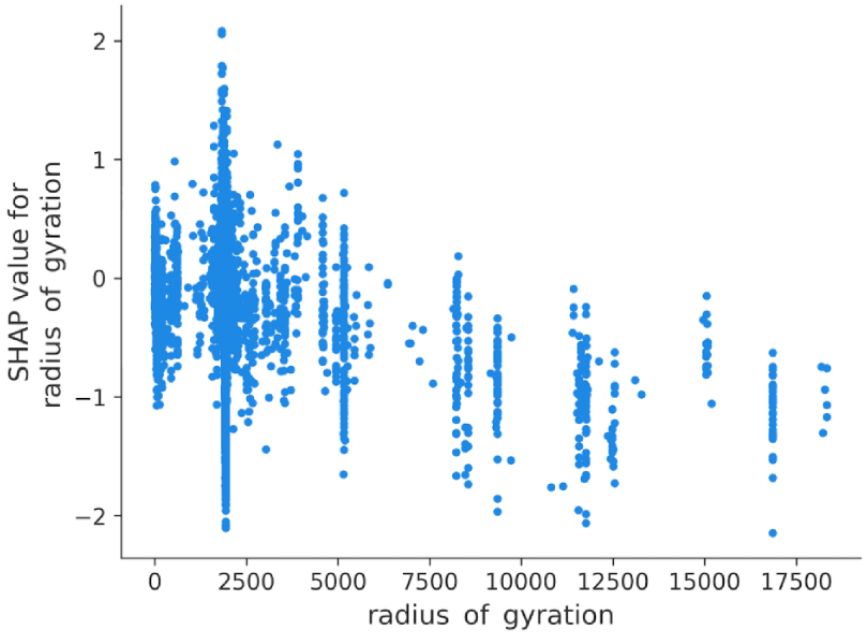
Figure 7. Interaction effects of total minutes spent moving on minimum HR values (top left), SD (top middle), and skewness (top right) of HR, and an explanation of skewness [39] (bottom). HR: heart rate; SHAP: SHapley Additive exPlanations.

Elevated and Fluctuating HRs

We investigated the impact of recent physical activity (measured as the sum of minutes spent moving based on Fitbit data) on HR in relation to self-reported marijuana intoxication using a PDP. The SHAP values for minimum HRs showed significant elevation, with an average increase from approximately 80 bpm to peaks of 90 bpm and reaching up to 100 bpm (ranging from 60 to 120 bpm, with a few data points exceeding 120 bpm). These elevated HRs corresponded to moderate-intensive self-reported marijuana intoxication (SHAP value>0) in young adults compared to other classes (not- and low-intoxicated).

The SHAP values clearly indicate *a* positive increase in minimum HR associated with a higher likelihood of self-reported MI, irrespective of the impact of the sum of minutes spent moving. The total movement time during self-reported MI influenced the rise in minimum HR, as shown in Figure 7 (top left), where the red values represent a maximum of 5 minutes of movement (our analysis uses 5-minute windows). While HR can fluctuate due to various factors, including physical activity, substance use (eg, alcohol), caffeine, meals, and mental state (eg, stress and anxiety), further research is needed to explore these additional influences.

In brief, patterns for the SD of HRs exhibited fluctuations, but, in general, showed an increase when young adults reported MI (Figure 7, top middle). Negative skewness (indicating a "left-skewed" distribution) in HR was consistently associated with MI. This skewness suggests that there were more HR data



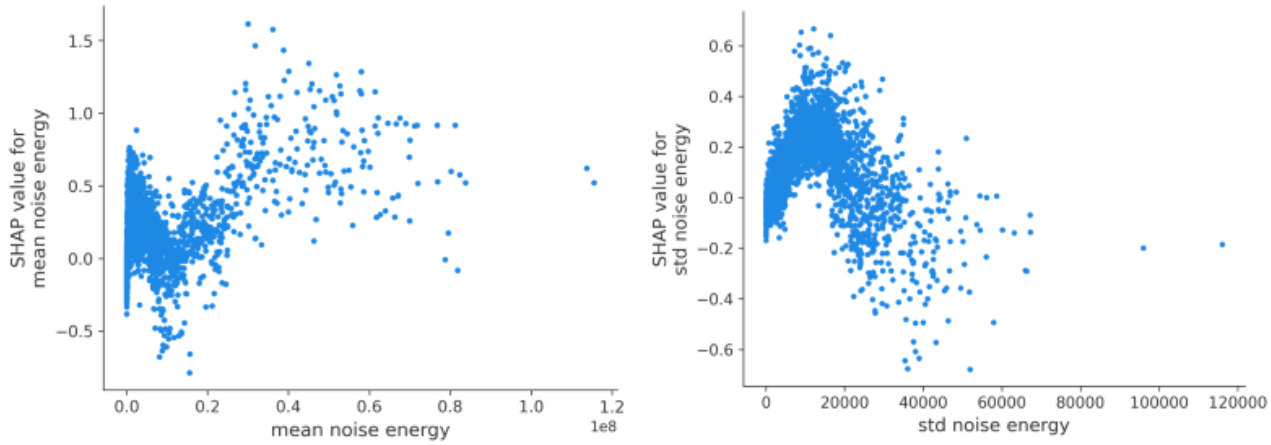
XSL•FO
RenderX

points on the right side of the mean (indicating that the median was greater than the mean), leading to a distribution stretched toward higher HR values (Figure 7, top right).

Decreased Large-Scale Movements

During MI, individuals showed a tendency for limited large-scale movement, often restricted to a radius of approximately 5 km. Notably, instances where the radius of gyration exceeded approximately 10 km were not associated with MI. This finding suggests that when young adults reported MI (rated 4-10), they were less inclined to engage in extensive travel (Figure 8). However, they still demonstrated movement within an average radius of 5 km.

Figure 8. Influence of radius of gyration (unit: meters). SHAP: SHapley Additive exPlanations.



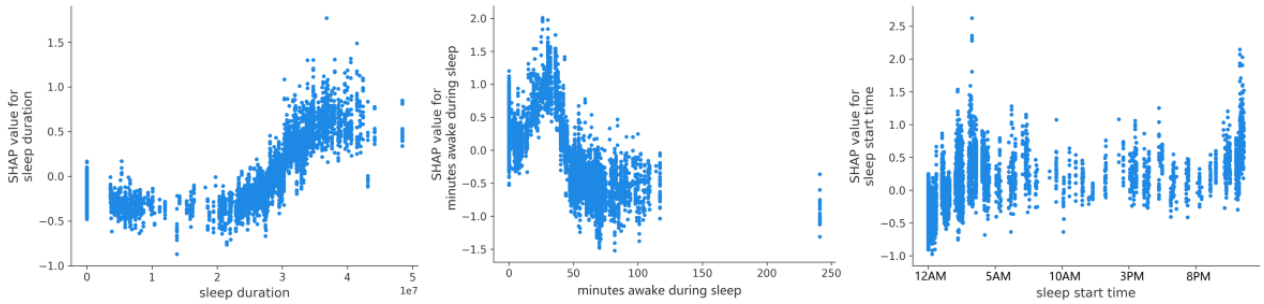
Elevated Surrounding Noise Energy

Interestingly, while the variance in environmental noise energy increased (with data points deviating further from the mean), the average noise energy decreased, though it exhibited an overall upward trend (Figure 9, left). Instances of MI were associated with increased noise variability (calculated based on the amplitude of audio samples), followed by a subsequent reduction (Figure 9, right).

Analyzing ambient sounds provides insights into the environmental context where individuals reporting MI might be located. This could include situations such as marijuana smoking, socializing with friends, or engaging with media like television or music. Although GPS-generated features were the primary indicators, MI may or may not be directly linked to specific locations such as shared social spaces (eg, lounges) or entertaining venues (eg, bars, pubs, or clubs). Nevertheless, it remains plausible that young adults reporting MI may choose to stay in noisy environments.

Figure 9. Influence of mean (left) and SD (right) noise energy (unit: Joule). SHAP: SHapley Additive exPlanations.

XSL•FO
RenderX



Prolonged Sleep Patterns

Distinct sleep patterns were linked to episodes of self-reported MI. Individuals who reported MI demonstrated extended sleep durations, spanning approximately 8 to 11 hours (Figure 10, left) the day before self-reported intoxication. In contrast, instances with low or no reported intoxication generally corresponded to healthy sleep durations, averaging around 6-7 hours, with some patterns as short as 2 hours.

There was also a positive correlation between the duration of minutes awake after falling asleep and self-reported MI, particularly when the period involved less than 50 minutes of wakefulness. However, an increase in extended minutes awake after falling asleep (if >50 minutes, extending beyond approximately an hour) did not show any significant association with a likelihood of MI (Figure 10, middle). Regarding sleep start times, the data indicated peaks at both 11 PM and early morning hours, with a rise in sleep start times continuing until around 4 AM (Figure 10, right).

In summary, elevated minimum HR values were clearly linked to a higher likelihood of self-reported MI. However, we observed that GPS-travel patterns (macromovements) did not appear to increase during self-reported marijuana intoxication. Interestingly, extended sleep hours and minutes awake during sleep [40] the day before self-reported marijuana intoxication were associated with MI.

Figure 10. Total sleep duration (left), minutes awake during sleep (middle), and sleep start time (right). SHAP: SHapley Additive exPlanations.

Additional Analyses for Real-World Feasibility

To enhance the practicality of our ML model in real-world settings, we conducted supplementary analyses to evaluate our top-performing model, the XGBoost-MobiFit model, under different scenarios. These scenarios involved: (1) excluding GPS-derived travel data due to potential privacy concerns or GPS deactivation; (2) excluding sleep data in cases where users did not provide sleep information; and (3) excluding both GPS-derived travel and sleep data. This approach aims to explore the feasibility of offering more flexible data collection options, potentially addressing privacy concerns and incomplete data issues.

In brief, excluding GPS-derived features (XGBoost-MobiFit-GPS excluded) resulted in a 15% decrease in the F_1-score compared to the best model, with a 10% reduction in sensitivity (recall). Excluding sleep data (XGBoost-MobiFit-Sleep excluded) led to a 24% decrease in the F_1-score compared to the best model. When both GPS and sleep features were excluded (XGBoost-MobiFit-GPS-Sleep excluded), the model experienced a 16% reduction in F_1-score and showed the lowest recall for identifying self-reported MI classes compared to the best-performing model. Please refer to Multimedia Appendix 5 for a detailed description of the additional analyses and results.

Discussion

Overview

The ability to detect subjective reports of acute marijuana intoxication in natural environments using mobile sensors has the potential to enable just-in-time interventions [41] to reduce marijuana-related harms. To the best of our knowledge, this is the first study that demonstrates the impact of integrating smartphone-based and wearable sensor features on the enhancement of the performance and interpretability of algorithms in detecting acute marijuana intoxication in naturalistic environments.

As hypothesized, we found that the XGB-MobiFit model, which combined smartphone sensor data with Fitbit features outperformed models that used only mobile or only Fitbit data. By integrating sensors from both smartphones and wearable devices, our best-performing algorithm balances specificity and sensitivity on unseen samples, enabling interpretable, transparent, and unobtrusive detection of acute subjective marijuana intoxication in natural environments. This opens up opportunities for real-time monitoring in everyday settings and the implementation of just-in-time adaptive interventions.

XAI visualizations supported our second hypothesis, highlighting HR, GPS, and physical movement data as key features that contributed to self-reported marijuana intoxication predictions. These findings were observed beyond the influences of simply applying time of day and day of the week features (ranked 1st and 4th, respectively), as validated in [11], particularly during instances of self-reported subjective marijuana intoxication in naturalistic environments.

Interpretable Behavioral and Physiological Signals of Marijuana Intoxication in Real-World Settings

To explain the results of the black-box ML models to detect marijuana intoxication in everyday settings, our study integrated sensors from smartphones and a wearable device, identified key sensor features, and used XAI to facilitate the interpretation of model results. The findings are consistent with prior research

XSL•FO
RenderX

conducted in controlled laboratory settings, which consistently found an acute increase in resting HR following marijuana use [12-14]. Our results suggest the potential for HR with behavioral factors to detect marijuana intoxication "outside of laboratory settings" using off-the-shelf devices in naturalistic environments. While many factors can affect HR in daily life, this study yielded significant HR features and insights from the elevated HR patterns during self-reported acute marijuana intoxication. Future research could explore associations between HR and other physiological and behavioral indicators of marijuana use, such as respiration, to better capture marijuana intoxication in natural environments [42].

The use of XAI visualization could help increase transparency and accountability when conducted as part of a substance use detection system [43, 44]. It is promising to use XAI as it enables researchers and clinicians to understand how algorithms arrive at decisions and identify key behavioral and physiological attributes, providing opportunities to improve detection accuracy and enhance trust in the algorithm over time.

Real-Time Detection and Intervention Potential

Compared to an average 30-minute marijuana episode, the 5-minute window used in the best-performing model is small enough to predict marijuana intoxication in near real-time. Detecting marijuana intoxication in near real-time promotes just-in-time intervention, which serves as a crucial first step toward reducing possible marijuana-related harm in a timely manner.

Our best detection model is unlikely to misclassify a "high" state as not high, which demonstrates the potential for using our detection algorithm with unseen data in real-world contexts. On the unseen test set, we obtained 85% precision (92% precision for 3 classes) in specifically identifying self-reported moderate-intensive marijuana intoxication. Passive sensing using smartphone-based sensors has been investigated in the context of alcohol intoxication [25,26,43], and here we extend this research to self-reported marijuana intoxication [11] beyond smartphone-based sensors, which could ultimately be useful for JIT interventions [41] to reduce marijuana-related harm. The value to society and individuals of reducing marijuana-related harm is clear. If individuals choose to use such a personal detection system, they will need to keep their phone charged and with them when using marijuana and wear a device (eg, Fitbit) and keep it charged as well.

For real-time modeling using the XGBoost algorithm, deploying the estimated model onto a computing device is an indispensable phase. We envisage two primary deployment scenarios: first, local assessments can be generated by deploying the model directly onto users' devices, such as smartphones. This approach ensures seamless functionality even without an internet connection but requires adequate storage and computational capacity. Second, cloud-based computation can be used. While this approach relies on a stable internet connection, it effectively offloads the computational burden from the user's device. Real-world applications introduce pragmatic considerations such as battery longevity, which could be affected by the model's continuous operation, and user privacy during data transmission and generation of model results.

Therefore, a comprehensive assessment of the model's feasibility in real-time operational settings is important. Our proposed generalized model, designed to operate across a diverse demographic spectrum rather than relying on individual-specific (idiographic) models, offers advantages in terms of scalability and practicality.

Privacy Considerations and User-Centric Configuration Choices

To highlight the benefits of combining sensor features from both smartphone and wearable devices while addressing potential privacy concerns, particularly related to location data, we aim to offer participants additional configuration choices rather than study withdrawal. For example, participants can deactivate GPS sensors if desired. This is demonstrated by our testing of the best-performing model, XGBoost-MobiFit, where we excluded location features. The analysis revealed a 15% (XGBoost-MobiFit-GPS excluded) decrease in F_1-score from the best model. As proposed by Bae et al [43], collecting GPS data and using rounded GPS data extraction (ie, less precise location data) could be a viable approach. This avoids using raw latitude and longitude, which may contain sensitive information on specific locations. Researchers and clinicians could consider providing alternative options instead of completely disabling GPS, as GPS data contributes to the model's accuracy.

Moreover, to assess the efficacy of our top-performing model, we conducted tests after excluding sleep-related features (Multimedia Appendix 5). The analysis revealed a 24% (XGBoost-MobiFit-Sleep excluded) decrease in the F_1-score compared to the best model's performance. While participants may benefit from the option to disable sensors when necessary, it is important to note that this could potentially decrease the model's ability to detect marijuana intoxication.

By building a system that prioritizes privacy and user autonomy, we can provide a valuable tool to reduce marijuana-related harm to individuals and society. Ultimately, each person will have to decide for themselves whether the benefits of a detection and intervention system outweigh the tradeoffs in minimizing possible marijuana-related harms to themselves and the broader community.

Limitations and Future Work

The first limitation of this study is relying on self-reporting as the ground truth, which may be subjective. This study extends prior ESM work, which codes self-reported marijuana use as yes or no [45], by asking participants to rate marijuana intoxication from 0 to 10, which may be subject to recall or other biases in reporting. The broad categorization might overlook nuanced differences within three categories: low-intoxication (1-3), moderate-intensive marijuana intoxication (4-10), and not-high (0), which could affect the accuracy of the classifiers. Future analyses examining the performance of mobile and wearable sensors against different thresholds for a subjective marijuana intoxication outcome could be valuable.

XSL•FO
RenderX

Another limitation was the size, diversity, and duration of the participants in the study. Since the participants were all young adults, the finding may not be generalizable to a broader age group. In addition, the level of compliance (63%) in completing the morning, afternoon, and evening surveys is relatively low. Thus, it is unclear whether all episodes of marijuana use were reported by participants, which could limit model performance. However, since there is no real-time accessible biological testing method at the time of publication, validating self-reported data with the current method still represents the best alternative. The current findings warrant future replication in a larger and more diverse group of participants over a longer period to address the limitations and validate the findings.

In addition, our model performed best when tested on the same participants it was trained on (with no overlap between training and testing data). While this has a valid use case, it assumes that we can always collect labeled training data for participants for whom we would like to apply the model. By applying more testing data, using more sophisticated sensor features, and better model tuning, future models could improve generalization over unseen testing participants. The HR data only holds significance when examined together with activity data. An acute increase in HR by itself is nonspecific and may not be associated with marijuana use or intoxication. False alarms triggered by the algorithm could erode trust in an automated system, whereas low sensitivity to actual marijuana use could result in marijuana-related harm. Therefore, it is important to investigate the interplay between human activities associated with marijuana intoxication and physiological signals in a larger population, and how these interactions can contribute to intervention delivery in real-world contexts.

Finally, it is crucial to acknowledge that the potential impact of polysubstance use on the interpretation of physiological signals associated with self-reported cannabis intoxication was not included. While ESM is used to collect information on the use of other substances, our analysis did not account for the effects of polysubstance use due to the limited scope of the study. The presence of polysubstance use could potentially confound the physiological signals attributed to marijuana. This may lead to inaccuracies in our algorithm, particularly in distinguishing between marijuana intoxication and the effects of other substances. Thus, while our study provides valuable insights into self-reported marijuana intoxication, it has limitations in addressing the full spectrum of real-world polysubstance use. Future research should include developing algorithms that can differentiate between the physiological signals associated with different substances, including polysubstance use.

Conclusions

Our study demonstrates that integrating features from smartphone-based sensors and wearable devices significantly improves the detection of self-reported marijuana intoxication in natural environments among young adults. The XGBoost-MobiFit model, which combines data from both smartphone sensors and wearable devices, achieved an F_1-score of 0.85 in detecting moderate to intensive self-reported marijuana intoxication, outperforming models that relied solely on smartphone sensors. The results suggest that incorporating wearable device data enhances the XGBoost model's performance by 13%, justifying the additional complexity of using wearable devices among young adults.

Key features contributing to the detection of self-reported "MI" included an acute increase in HR (measured by Fitbit), macromovement indicators (derived from GPS data), and prolonged sleep patterns the night before self-reported marijuana intoxication (measured by Fitbit).

Future research should focus on refining the algorithms that integrate smartphone and Fitbit sensor data in larger, more diverse samples. In addition, exploring how these algorithms, informed by XAI, can support the development of just-in-time interventions for clinicians is essential. Such interventions could offer context-adaptive, personalized strategies to minimize potential marijuana-related harms, such as intoxicated driving, therefore reducing the frequency and severity of acute marijuana-related incidents among young adults.

Acknowledgments

This study was supported by the National Institute on Drug Abuse (R21 DA043181/U01 DA056472), the Stevens Startup grant, and the Provost scholarship.

Authors' Contributions

SWB, TC, and AKD contributed to the design of the study and data collection. SWB, TZ, AKD, and RI processed the data, and SWB and TZ analyzed the data and developed the computational and explainable models. SWB drafted the initial manuscript, which was edited by TC, TZ, and AKD, and approved by all authors.

Abstract

Background: Living kidney donation (LKD), where individuals donate one kidney while alive, plays a critical role in increasing the number of kidneys available for those experiencing kidney failure. Previous studies show that many generous people are interested in becoming living donors; however, a huge gap exists between the number of patients on the waiting list and the number of living donors yearly.

Objective: To bridge this gap, we aimed to investigate how to identify potential living donors from discussions on public social media forums so that educational interventions could later be directed to them.

Methods: Using Reddit forums as an example, this study described the classification of Reddit content shared about LKD into three classes: (1) present (presently dealing with LKD personally), (2) past (dealt with LKD personally in the past), and (3) other (LKD general comments). An evaluation was conducted comparing a fine-tuned distilled version of the Bidirectional Encoder Representations from Transformers (BERT) model with inference using GPT-3.5 (ChatGPT). To systematically evaluate ChatGPT's sensitivity to distinguishing between the 3 prompt categories, we used a comprehensive prompt engineering strategy encompassing a full factorial analysis in 48 runs. A novel prompt engineering approach, dialogue until classification consensus, was introduced to simulate a deliberation between 2 domain experts until a consensus on classification was achieved.

Results: BERT and GPT-3.5 exhibited classification accuracies of approximately 75% and 78%, respectively. Recognizing the inherent ambiguity between classes, a post hoc analysis of incorrect predictions revealed sensible reasoning and acceptable errors in the predictive models. Considering these acceptable mismatched predictions, the accuracy improved to 89.3% for BERT and 90.7% for GPT-3.5.

Conclusions: Large language models, such as GPT-3.5, are highly capable of detecting and categorizing LKD-targeted content on social media forums. They are sensitive to instructions, and the introduced dialogue until classification consensus method exhibited superior performance over stand-alone reasoning, highlighting the merit in advancing prompt engineering methodologies. The models can produce appropriate contextual reasoning, even when final conclusions differ from their human counterparts.

Introduction

Background

Kidney transplantation is the gold standard treatment for patients with end-stage renal disease [1] and can be much more cost-effective than dialysis [2]. Record numbers of transplants have taken place in recent years, but a shortage of donors continues to exist despite the recent increase [3]. Currently, the median wait time for a transplant is approximately 4 years in the United States, and approximately 5000 patients die every year while being on the transplant waiting list [4]. Living donor kidney transplantation (LDKT) generally provides better outcomes than deceased donor transplants but requires that a potential living donor be made aware that they can donate to a specific patient with end-stage renal disease and offer to do so. Racial or ethnic minorities and patients of lower socioeconomic status are less likely to pursue and have living donors donate on their behalf [5,6].

National attitudes about LDKT are generally positive, although many do not know what a living donor undergoes when donating a kidney [7-10]. Recommendations to increase the living donor pool include reaching out more broadly to locate generous individuals motivated by social good to engage more individuals in considering living donation [11]. In addition, research suggests that disseminating education and information about living donation to broader audiences, beyond transplant centers, might increase the numbers of potential donors and recipients pursuing living donation [12,13]. However, identifying individuals dealing with kidney disease and considering whether to pursue LDKT or donate kidneys in their own lives can be difficult, especially when they have not started medical evaluation at a transplant center.

Locating individuals through social media forums discussing living kidney donation (LKD), such as those on Reddit or Twitter (the work herein was done before the platform being rebranded as X), maybe a way to identify individuals who are actively deciding whether to pursue LDKT or LKD outside of transplant centers [14]. While there are many different types of questions and comments related to LKD shared on the web, some people share their personal experiences and even invite people to "ask me anything." These findings motivated our main hypothesis that potential living donors can be identified from social media communities engaged in general discussions about LKD. In addition, understanding the personal experiences shared on these platforms can provide valuable insights into potential donors' needs and decision-making, enabling education and media campaigns to be better tailored for them.

The large volume and high complexity of unstructured natural language require an effective and efficient method that can automate the identification of people sharing personal experiences with LKD. Fortunately, recent advances in natural language processing (NLP), particularly the transformer mechanism [15-19], enable the automatic understanding of personal experiences that were shared on the web social platforms. This study aimed to evaluate the transformer-based techniques to categorize these experiences on Reddit (Reddit, Inc). Specifically, we aimed to evaluate and compare (1) the one-shot classification model Bidirectional Encoder Representations from Transformers (BERT) [19], which required that we fine-tune the model using 1268 well-labeled samples, and (2) the zero-shot classification model ChatGPT (OpenAI), which required no fine-tuning for classification purposes. Comprehensive discussions on transformer-based models can be found in the study by Acheampong et al [20]. Much has been written about the capabilities and limitations of ChatGPT specifically [21]; however, we investigated the importance of prompt engineering when interfacing with it and other generative models applied to the field of organ donation for the first time.

Overview of Prompt Engineering

Prompt engineering has been defined as "the means by which LLMs are programmed via prompts" [22]. Reynolds and McDonell [23] framed the objective of prompt engineering as a discipline that seeks to answer the question, "What prompt will result in the intended behavior and *only* the intended behavior?" Historically, the best practice has been to give a small number of examples of how the task is to be done, known as few-shot prompting. Ray [21] suggested that for large language models (LLMs), few-shot prompting is better thought of as "locating an already-learned task rather than meta-learning." The implication is that the LLMs are large and robust enough that the models are inherently capable of completing NLP tasks, but their scale of capability may require using examples to "activate" the right parameters that will carry out the desired task in the prescribed manner.

However, this flexibility should also be understood as having dangers because LLMs can be "jailbroken." Jailbreaking LLMs is the practice of using prompt engineering to work around the boundaries imposed by the developers, such as OpenAI [24]. The practice of "red-teaming" is used by developers to identify weaknesses in the desired boundaries and adjust the model so that it is more defensible against previous vulnerabilities [25,26]. What is simultaneously exciting and problematic about this is that many techniques used to jailbreak LLMs are the same as those used for their most helpful, intended uses, that is, many of the same methods that allow us to get the best performance from an LLM can be the same ones that are used to bypass the safeguards. Table 1 provides an overview of prompt engineering methods derived primarily from the study by White et al [22].

XSL•FO
RenderX

Table 1. Overview of prompt engineering methods proposed by White et al [22].

Method	Purpose	Example prompts for LKD[a]
Few-shot prompting	Provide examples that illustrate how the task is to be completed	"Here is an example of a risk analysis from a living kidney donation scenario: [EXAMPLE]. Now, please provide a risk analysis for the following scenario."
Meta-language creation	Create a shorthand notation, abbreviated language, or set of standard rules	"For this conversation, 'LKD' refers to living kidney donation, 'DT' refers to donor testing and 'RC' refers to recipient compatibility. Using this shorthand, describe the typical process of LKD."
Flipped interaction	The LLM[b] will ask questions to obtain the information	"I'm working on an algorithm to match donors with recipients in living kidney donation. What information do you need from me to help design this algorithm?"
Persona	Assign a persona to the LLM, usually that of an expert	"Pretend you are a leading surgeon specializing in living kidney donation. Provide your expert opinion on the latest surgical techniques."
Prompt refinement	Ensure that the LLM suggests better or more refined prompts	"I need to write code to analyze the success rates of different kidney matching algorithms. Could you suggest a more refined question or specific details you need to assist me?"
Alternative approaches	Ensure that the LLM offers alternative ways of accomplishing the task	"Describe three different methods for assessing donor-recipient compatibility in living kidney donation."
Cognitive verifier	Subdivide a question into additional questions for a better answer	"To understand the ethical considerations in living kidney donation, what additional questions should I ask you to provide a comprehensive analysis?"
Fact checklist	Mitigate model hallucination by listing the facts	"After explaining the current trends in living kidney donation, list the facts or data sources you used in your response."
Template	Ensure that the LLM's output follows a precise template	"Please answer in the following format: 'Living kidney donation is beneficial because [REASON 1], [REASON 2], and [REASON 3]'."
Gameplay	Create a game around a given topic	"Let's play a matching game. I will describe a recipient, and you suggest a suitable donor from the provided pool based on living kidney donation criteria."
Reflection (chain of thought [25])	Explain the rationale behind the given answers	"Explain the process of donor selection in living kidney donation in a step-by-step manner, detailing the reasoning behind each step."
Refusal breaker	Help users rephrase a question when they are refused an answer	"If you cannot provide personal patient data in living kidney donation, please guide me on how to rephrase my questions to obtain general information."
Context manager	Enable users to specify or remove context	"When discussing living kidney donation statistics, please consider only data from the last five years in the European region."
Recipe	Provide a sequence of steps given some partially provided ingredients	"I have patient medical records, compatibility testing results, and surgical schedules. Provide a sequence of steps to create an optimal living kidney donation matching algorithm."

[a]LKD: living kidney donation.

[b]LLM: large language model.

Reflection and chain of thought reasoning, in particular, have garnered much attention due to their powerful results, creating what is already becoming a niche corner of research [27,28]. At the time of writing this paper and to the best of our knowledge, the 2 most recent and powerful of these improvements are the methods known as self-consistency [29] and the tree of thoughts [30]. The former uses majority voting from multiple replications, and the latter takes an ensemble approach to the chain of thought reasoning and allows LLMs to consider multiple different reasoning paths and to perform self-evaluation on choices. Other methods naturally exist beyond what is contained in this study because of the unbounded human imagination, which makes the domain of prompt engineering quite an exciting frontier. Interested readers may find the website [31] to be a useful resource, with new relevant articles being added to its repository regularly.

While prompt engineering in the context of LKD has not yet entered the literature, some work has emerged in the context of health care. Prompt engineering and generative artificial intelligence broadly are of particular interest in the medical domain as the generation of health information is still of unknown quality. A few researchers have emphasized the importance of medical professionals using LLMs skillfully and in a way that produces reliable information [32,33]. It has been shown that the reliability of GPT-4 (OpenAI) is inconsistent when answering medical questions, and the authors call for prompt engineering techniques to improve its performance [34]. Similarly, other authors have experimented with ChatGPT on calculation-based United States Medical Licensing Examination questions using 3 different prompting strategies, although they found that the prompt itself had only a small effect on answer accuracy [35]. Other research examined using prompt

XSL•FO
RenderX

engineering in generating health messages [36] and even medical image segmentation [37].

Social Media and LKD

Recent years have witnessed a burgeoning interest in studying dialogue on social media regarding important health care issues, such as vaccination [38] and LKD. Henderson [39] highlighted the use of platforms such as Facebook and Twitter to identify potential living donors while noting that formal research efforts are in their early stages. Analyzing social media content, including organ donation posts on the Chinese social media site Weibo, has unearthed key themes such as "organ donation behaviors," "statistical descriptions of organ donation," and "meaningfulness of donation" [40]. In one study, a notable 53% of potential living donors who self-referred for donor evaluation reported that they learned about a patient's need for a donor on social media [41,42], while specialized tools such as the "DONOR" app have enabled expansion of social media marketing about living donation between potential donors and patients with kidney diseases [43]. Research efforts include measuring organ donation awareness through Twitter digital markers [44], surveying readiness of patients who are undergoing a transplant to use social media for education [45], and using Twitter for living donor profile classification [46].

Interventions to increase living donation have used mobile health technologies to manage donor follow-up [47], delivered targeted advertising to specific ethnic groups [48,49], and assessed organ donation awareness across the United States using Twitter data [50]. Best practices for promoting LKD through social media, such as delivering content to specific community demographics in targeted and interactive modes, have been proposed [51]; live transplant broadcasts on Twitter have occurred [52]; and the analysis of public Facebook pages of potential living donors [53] has enhanced insights into donor identification and donation interest. Recent studies highlighted the importance of tailored messaging over generic communication for better audience engagement [54,55].

These investigations underscore social media's potential in augmenting donation awareness and facilitation, emphasizing the necessity for robust methods to discern and support individuals disseminating LKD-related content. A recent study by Garcia Valencia et al [56] has shown that ChatGPT can simplify medical information, making it easier to read and understand by many diverse groups. This can be a vital aid for promoting fairness in access to donation information from official sources. However, with the availability of *public* dialogue in forums also comes the need to thematically understand it. There is variation in both the content being shared and the user sharing it. The growing body of research demonstrates the potential of social media to impact awareness, intention to donate, and the facilitation of living kidney transplants. Therefore, it is necessary to have reliable methods whereby people who explicitly create and share content related to LKD can be automatically identified and understood for appropriate education and support. With this background, our research seeks to assess whether a classification system can be devised to discern individuals at varying stages of decision-making about becoming a living kidney donor. It also explores which of the contemporary NLP models are most apt for automating this classification, namely a fine-tuned distilled version of the BERT (DistilBERT) model (hereafter referred to as BERT for simplicity, unless greater specificity is merited) or ChatGPT. Furthermore, regarding ChatGPT, it examines how prompt engineering—namely, making adjustments to model instructions about the reasoning approach, examples, temperature, and class descriptions— influences its predictive efficacy for this application.

By answering these research questions, this study aimed to build a foundation for a sophisticated classification system in which it is possible to automatically categorize large amounts of social media communication about living donations using these tools. The study also aspires to gain a more in-depth insight into how individuals communicate and express themselves regarding LKD on various social media platforms. Using cutting-edge NLP technologies, our goal is to develop a streamlined, automated process for pinpointing curious, motivated potential donors who have not yet presented to the transplant center so that educational interventions could later be directed to them.

Methods

Data Labeling, Preparation, and Quality Assurance

We used a dataset of 2689 Reddit posts related to LKD from our previous work [14], which were published between January 2010 and April 2021. We also collected 603 Reddit posts from April 2021 to April 2023, for a combined total of 3292 posts from 2591 users. We scraped the posts with the open-source tool pushshift.io using keywords related to LKD, such as "kidney donor," "kidney transplant," "kidney donated," "kidney donate," "kidney years ago," "kidney need," "kidney stranger," and "kidney willing donate." Other search terms could have been included; however, as presented in Table 2, a considerable portion of collected data were not related to personal experiences, and we concluded that additional search terms would primarily expand the noise and add little value.

XSL•FO
RenderX

Table 2. Distribution and description of Reddit (Reddit, Inc) classes.

Merged class categories and class categories	Description	Example post
Present (n=540, 26.9%)		
Present direct (n=363, 21.5%)	The user has *current firsthand experience* with something personally related to kidney disease, kidney failure, living kidney donation, or transplantation (eg, the user with kidney disease or kidney failure, is on dialysis, is seeking a kidney, is exploring donation, or is undergoing evaluation for donation or transplantation).	"A friend of mine is in need of a kidney. My first instinct is to offer one of mine. I have Googled and read LOTS of info. What would you do? Have you donated a kidney? What am I missing?"
Present indirect (n=177, 5.4%)	The user has *current secondhand experience* related to living kidney transplantation (eg, they *know someone* who is currently experiencing kidney failure, on dialysis, seeking a kidney, or preparing to donate a kidney).	"I need help finding a kidney for my dad."
Past (n=222, 6.8%)		
Past direct (n=168, 5.1%)	The user has *past firsthand experience* related to living kidney transplantation (eg, kidney failure, dialysis, kidney recipient or donor).	"Eight years ago today, I donated a kidney to a friend. Ask me anything."
Past indirect (n=58, 1.8%)	The user has *past secondhand experience* related to living kidney transplantation (eg, they *know someone* who experienced kidney failure, was on dialysis, received a kidney, donated a kidney, underwent evaluation for donation, or participated in the donation process (perhaps in a supporting role).	"Picture of my dad and the woman who donated a kidney to save his life."
Other (n=2530, 76.8%)		
General commentary or hypothetical (n=159, 4.8%)	The user is giving a *general opinion* on the topic, asking a *hypothetical question*, or contributing to discussion about an *imagined scenario*.	"If you donate a kidney, then later your only one starts to fail, would you be put on a higher priority?"
News or noise (n=2371, 72%)	The user is either sharing a *news article or headline* related to kidney donation that may be pertinent but *not personal*, or it is *simply irrelevant*.	"A man donated his kidney to his wife of 51 years after finding out he's her perfect match."

We selected Reddit as our data source because it provided the greatest portion of comments that were related to personal experiences rather than discussions of policies and sharing news stories. Reddit was the only place where we found posts from actual living donors inviting people to an "ask me anything" session, sparking highly personal discussions [14].

Under the guidance of LKD domain experts, after reviewing 100 example posts, we created 2 class sets, one with 6 classes (class categories) and the other with 3 classes (merged categories), to automate the process of identifying firsthand experiences with living donation (Table 2). These classes were iteratively defined and improved through multiple discussions with a team of 6 people who performed the manual annotation. Certain posts had sufficient ambiguity to make an explicit ruling impossible. For example, it was not always clear what constituted the boundary between a past and present experience (eg, how much time should have passed since the transplant?) or whether the general transplant mentioned in a post came from a living or deceased donor. Furthermore, long and verbose posts with brief mentions of personal experiences with donation posed a challenge because the brief (although important) mentions of LKD were easy to miss. Individual annotators were found to exhibit varying classification tendencies or use their own "rules of thumb" to expedite the often tedious process.

The granularity between these 6 fine-grained classes proved quite difficult for the models to correctly capture during initial experiments (resulting in accuracies <50%), so the posts were consolidated into the 3 coarse-grained categories: present (n=540, 42.59% of posts), past (n=222, 17.51% of posts), and other (n=506, 39.91% of posts randomly sampled from news or noise and general commentary or hypothetical categories) for 1268 samples that were used for training the BERT model. A randomly selected subset of 100 from each of the 3 classes was used for prompting with ChatGPT. The decision was made to aggregate general commentary and hypothetical posts with news or noise to ensure a more precise focus on personal experiences.

Acknowledging the potential data quality risks [57], we meticulously evaluated incorrect predictions from both BERT and ChatGPT after the analysis. The incorrectly predicted samples were tagged as either acceptable errors (reasonable, if not perfectly aligned predictions), unacceptable errors (flawed or evidently incorrect reasoning), more accurate than the original human label, or instances where both human and model erred. We later reported these using the notation of *LLM human*, *LLM<human*, *LLM>human*, and *both error*, respectively, for both models.

Ethical Considerations

This study was granted an exemption from The University of Louisville Institutional Review Board (review number 22.0458). While there could be ethical concerns about consent and storage of health-related data, every Reddit user is entirely anonymous, ensuring that nothing we find can be directly traced to an individual. In addition, the comments and posts themselves are all very public; some websites may have minimal requirements, such as logging in or being a member of a "closed" group before the content can be observed; however, this is not the case for any of the data we collected. For data sources where such anonymity is not guaranteed, it is imperative to ensure that users consent to the study of their created content and that any identifying information be removed or obscured.

Modeling

We compared 2 transformer-based models for our classification task: a fine-tuned BERT model and a prompt-engineered ChatGPT model. We used the 3.5 Turbo version of ChatGPT via the OpenAI application programming interface and conducted a full factorial analysis of various prompt components to identify the best features. The DistilBERT model was fine-tuned from a pretrained Hugging Face (Hugging Face, Inc) model. Furthermore, we noted that many new models have emerged, both proprietary and open source, after our experiments were completed. Post hoc experiments indicate that our findings are consistent with newer models.

BERT Analysis

The DistilBert tokenizer from Hugging Face was used to tokenize the text data from Reddit, and both input IDs and attention masks were generated to structure the text inputs for the model. A custom model was designed around DistilBERT. The architecture included the pretrained DistilBERT model, followed by 3 fully connected layers with 768, 256, and 128 units, respectively. These were followed by an output layer with 3 units corresponding to the number of classes. Batch normalization and rectified linear unit activation functions were applied, and dropout was set at 10%.

The focal loss was used as the loss function, which is designed to address the class imbalance by downweighting the loss assigned to well-classified examples [58]. It was parameterized with an α factor for controlling the weight and a γ factor for focusing on hard examples. The model was trained using the AdamW optimizer [59], with the learning rate and weight decay optimized by the open-source Optuna hyperparameter tuning library. The dataset was split into training and validation sets using stratified 5-fold cross-validation, with class weights computed to manage class imbalance, and the model was trained for 3 epochs, following the recommended fine-tuning procedures [19]. The metrics used for validation are defined subsequently.

Accuracy is the ratio of correctly predicted instances to the total instances.

Precision is the ratio of correctly predicted positive observations to the total predicted positives.

Recall (sensitivity) is the ratio of correctly predicted positive observations to all observations in actual class.

F_1-score is the harmonic mean of precision and recall.

In equations 1 to 4, *TP*, *TN*, *FP*, and *FN* are the numbers of true positive, true negative, false positive, and false negative values, respectively.

The Optuna library was used to perform hyperparameter optimization, which uses a Bayesian optimization method known as the Tree-structured Parzen Estimator [60]. A search space was defined for the learning rate (ranging from 0.00003 to 0.0003) and weight decay (ranging from 0.0001-0.001). A total of 100 trials were conducted to find the best set of hyperparameters based on the F_1-score.

Dialogue Until Classification Consensus

We introduced a text classification tool for LLMs termed "dialogue until classification consensus" (DUCC). Given the absence of a formal taxonomy for prompt engineering methods, we aligned DUCC's presentation with the pattern widely adopted in software development, which includes a name and classification, intent and context, motivation, structure and key ideas, example implementation, and consequences (Textbox 1). White et al [22] constructed the following categories of prompting patterns: input semantics, output customization, error identification, prompt improvement, interaction, and context control.

XSL•FO
RenderX

Textbox 1. Prompting patterns for "dialogue until classification consensus" (DUCC).

Name and classification

DUCC primarily falls under output customization, although it shares elements from other pattern categories, notably error identification and interaction.

Intent and context

DUCC assigns a persona of at least 2 domain experts to the large language model, instructing them to discuss a text sample until a consensus on its classification or answer selection is reached from a set of options. This setup aims to automate explicit reasoning and reflection through a simulated dialogue, expecting to resemble the effects of distribution-oriented methods, such as self-consistency, without requiring multiple sample replications.

Motivation

Complex classification tasks, especially within niche domains, such as personal living kidney donation experiences, often present labeling challenges. DUCC simulates expert discussions for decision-making while aiming to standardize output formats for classification tasks.

Structure and key ideas

Experts 1 and 2, specialized in [DOMAIN], are to discuss the text sample until an agreed classification or answer is reached.

The final label should be clear with no disagreements, formatted as: "classification: Label."

Additional identities or traits can be attributed to the experts to infuse specific perspectives into the discussion. We have observed that unless a singular label selection is emphasized, the model might assign multiple labels in challenging scenarios.

Example implementation

"Expert 1 and Expert 2, you are both experts in living kidney donation, and you've been tasked with analyzing and classifying a Reddit post that should be related to living kidney donation. You should discuss the post until you come to an agreement for a single classification. If the post is not related to living kidney donation, it needs to be labeled 'Other'. The classifications are defined as follows:

- Present: The user is describing a current or ongoing personal experience with living kidney donation
- Past: The user is describing a past personal experience with living kidney donation.
- Other: The user isn't discussing a personal experience with living kidney donation or isn't discussing living kidney donation at all.

Discuss until you reach a consensus, showing your reasoning. The final label should be clear, and there should be no disagreement. Output your agreed label in this format: {'classification': 'your agreed label'}.

Here's an example of how this should be done:

- Post: 'Are you a kidney donor? How was the recovery process and how are you doing now?'
- Expert 1: 'I think the appropriate label is Present, because the user is asking questions and seems to want information to help them with a current decision about living kidney donation.'
- Expert 2: 'I think the appropriate label is Past because the user wants to know about past personal experiences from others.'
- Expert 1: 'I see your point about bringing up the past, but since we are interested in assigning a label to the user who wrote the post, we should keep our focus on the author's perspective. If we knew what the replies were, we could label those users as Past, but we are only looking at this user for now.'
- Expert 2: 'You're correct, we should be focused on this user rather than possible answers from others. Even though there are elements of both, we have to pick one and only one label, so let's go with Present.'
- Final Label: "'classification': 'Present.'"

Consequences

DUCC prompts large language models to reason through multiple perspectives, ensuring a singular, consistently formatted label, simplifying extraction. The example implementation is crucial as it demonstrates the desired dialogue structure, aiding the model in handling nuanced classifications. However, DUCC may exhibit biases when numerous classes are present, potentially leaning toward the exemplified label. To mitigate token use, especially in lengthy examples, using DUCC when defining the system instead of individual prompts is advisable. For instance, in the OpenAI application programming interface, modifying the "content" section of the "system" role with the entire provided example instead of the default content can better define the system's nature.

Sensitivity Analysis of Prompting

Overview

For our experimentation using ChatGPT to categorize personal experiences, we conducted a study applying a full factorial design with 4 factors (summarized subsequently), which resulted in 48 experimental runs. We must first acknowledge that the nature of prompting is such that there were an infinite number of ways we could write the prompt and parameters that could be chosen. It is well known that examples that illustrate the solutions can influence performance (known as "few-shot" prompting) [61], so we examined the number of examples and the type of examples that might produce bias as well as the parameters provided subsequently.

XSL•FO
RenderX

Use of the DUCC Method (2 Settings)

In addition to the DUCC method described earlier, the alternative was to prompt a single expert to make a classification decision, with the instruction to "Examine the evidence for each class option step by step. The final label should be clear." In this case, the model attempts to identify any evidence that suggests the sample should be assigned to each class and weighs the evidence to draw a conclusion.

Number of Examples Used (4 Settings)

We selected either 1 example or 3 examples. For 3 examples, 1 example was used for each class (present, past, and other). For the single example setting, we performed an experiment with each class once to evaluate whether it produced a bias in the predicted class.

Definition of "Past" (2 Settings)

Observing a tendency for underprediction in the "Past" label, we considered 2 definitions for the class. The first was a short and concise definition: "The user is describing a past personal experience with living kidney donation." The second was a longer, more descriptive definition: "The user is referring to a past personal experience with LKD. This may be presented in the context of a present tense story, but if the event of LKD was lived previously, the post should be labeled past."

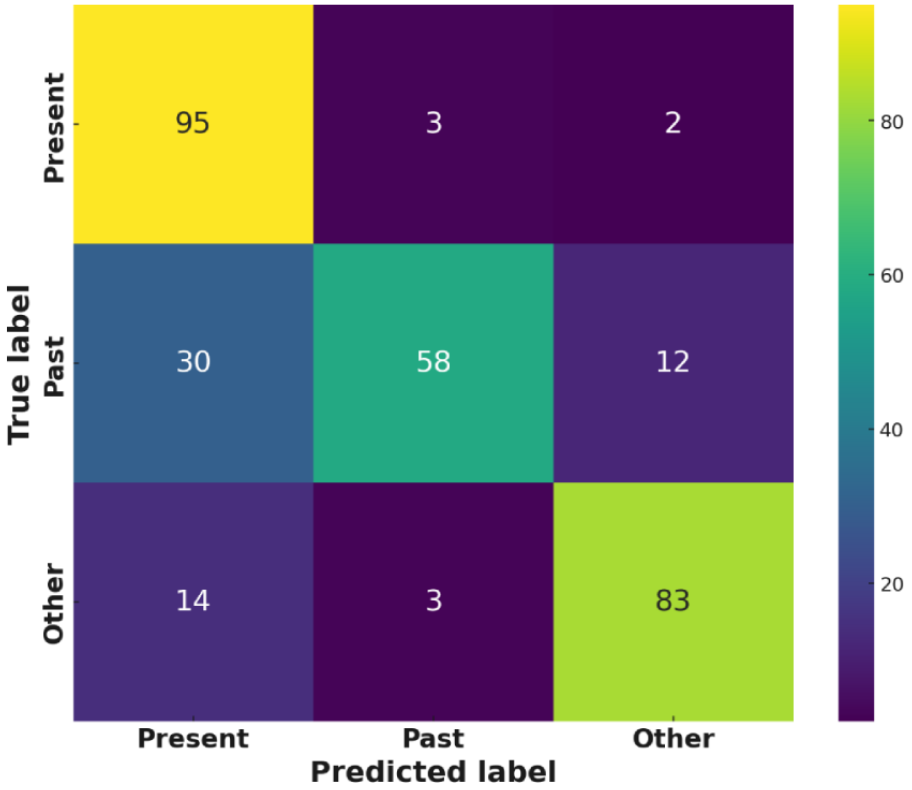
Temperature Settings (3 Settings)

Experimentation spanned temperature values of 0, 0.15, and 0.3, investigating the tradeoff between output variability and consistency. The settings were guided by OpenAI documentation, emphasizing lower values for consistency and higher values for diversifying outputs [62].

Given the cost implications of OpenAI application programming interface calls, an initial assessment was carried out to determine the necessity for replicating each setting. We performed 30 replications of a fixed parameter setting and found no substantial effect within replications for any metric. Thus, the experimentation proceeded with a singular sample for each parameter setting.

Results

Overview



In this section, we present the results of the BERT model first and then the results of ChatGPT. We present the performance metrics, confusion matrices, and assessment of incorrect predictions. For ChatGPT, we also present the results of an ANOVA on the various factors used in the experimentation.

BERT Results

In >100 trials, the best BERT model performed with an accuracy of 75.1% and an F_1-score of 78.2% on the validation data during training. The best parameters were a learning rate of 0.000131687 and a weight decay of 0.000791. The confusion matrix for the predictions on the test data is presented in Figure 1, showing reasonably good performance but with a tendency to erroneously predict the Other label on both past and present labels.

The classification report provided in Table 3 shows that the BERT model significantly underpredicts past labels, partly due to the smaller sample size, and also because of the ambiguity that can arise when a reference to a past experience is nested within an ongoing story.

Figure 1. Confusion matrix for the best Bidirectional Encoder Representations from Transformers model.

XSL•FO
RenderX

Table 3. Classification report.

	Precision	Recall	F_1-score	Support
Present	0.88	0.82	0.85	101
Past	0.66	0.52	0.58	44
Other	0.75	0.86	0.80	108
Weighted average	0.79	0.79	0.78	253

ChatGPT Results

The best ChatGPT prompt produced an accuracy and F_1-score of 78.67% and 78.17%, respectively (surprisingly, this F_1-score is identical to that of BERT). This was achieved using the DUCC method, a single example of a present class post, a temperature of 0, and the shorter definition of the past class (refer to the Dialogue Until Classification Consensus section). Full experimentation results are provided in the Multimedia Appendix 1. The next 3 columns show the percentage of predictions for that class, and the remaining 3 columns show the evaluation metrics.

The confusion matrix for ChatGPT performance is presented in Figure 2, which shows again that past class samples were underpredicted and that both other and past class samples were overpredicted to be present class, suggesting a bias toward present classifications.

Figure 2. Confusion matrix for the best ChatGPT prompt.

The results of the ANOVA are presented in Table 4, which shows that the number and type of examples used is the most significant factor, followed by the method. We observe that the examples and method factors were the only statistically significant factors.

Given that there were 3 df within the examples setting, we sought to better understand the difference between the example settings using a Tukey test, with results provided in Table 5. We observed that when our example belonged to the "past" class the model performed better than when the example came from the "other" class. But using an example from the "past" class resulted in poorer performance compared to using 3 examples (one from each class) and using an example from the "present" class. Interestingly, the "past" sample was underpredicted in every setting except when using 3 examples and the evidence method. Interestingly, samples belonging to the "past" class were underpredicted in every setting except when using 3 examples and the evidence method. Although this setting (3 examples; evidence method) does not demonstrate the same underprediction bias as other settings, it does not give better accuracy overall.

XSL•FO

1, other	1, present	0.0078	.92	–0.0249	0.0405	False
1, other	3	–0.0017	.99	–0.0344	0.031	False
1, past	1, present	0.0953	<.001	0.0626	0.128	True
1, past	3	0.0858	<.001	0.0531	0.1185	True
1, present	3	–0.0094	.87	–0.0421	0.0233	False

Discussion

Principal Findings

Our experimentation has found that BERT and ChatGPT perform comparably for the classification of different living kidney donor experiences. Because BERT is completely dependent on the available training data, ChatGPT can be used with a somewhat higher degree of precision via prompt engineering, as shown by our use of the novel DUCC method. Our full factorial experimentation identified the best settings to use for our engineered prompt. In this section, we will discuss the predictions that were made incorrectly and consider future work and ethical considerations.

Examination of Incorrect Predictions

As noted in the Data Labeling, Preparation, and Quality Assurance section, there is an inherent risk of data quality that arises from the dataset in question. Unlike standardized benchmarks, which often have explicit “ground truth” labels, our task is fraught with nuance. Despite our extensive efforts to ensure data quality, the given label is not always clear. As such, we have provided a more detailed examination of the instances where the models made predictions that diverged from the given labels.

BERT and GPT-3.5 produced 21.3% (54/253) and 21.3% (64/300) incorrect predictions, respectively. It should be recalled that the difference in the denominator values is because BERT requires a split test set, whereas, with GPT-3.5, we can use a larger inference-only set. We assessed the quality of these incorrect predictions not only to see how “close” they were to the mark but also to determine whether any human errors had been made in labeling the incorrect predictions. As provided in Table 6 for BERT, we observe that 27 prompts were incorrectly labeled either because of an acceptable error where a clear prediction is difficult to make (perhaps due to the ambiguity of what constitutes the difference between the past and present samples) or where BERT made a better prediction than the original human label. Treating these 27 predictions as being acceptable or correct brings the total number of correct predictions from 199 (78.7%) of 253 to 226 (89.3%) of 253, which elevates the predictive accuracy considerably to 89.3%. In these tables, examples are written “as they are” from the original posts, including typos and terminology that may be unique to Reddit.

XSL•FO
RenderX

Table 6. Analysis of incorrect predictions from Bidirectional Encoder Representations from Transformers (BERT; n=54).

Error type	Incorrect predictions, n (%)	Example post	Reason
Unacceptable error (BERT<human)	22 (41)	"Required testing to be a living Kidney donor where I live - these are the tests I took before becoming a living kidney donor almost 2 yrs ago everything has gone great for me and the recipient happy to answer any questions."	BERT predicted the "other" label, but the user clearly states that he or she was a previous living donor.
Acceptable error (BERT human)	12 (22)	"Hey Mum, it's been a year since what was supposed to be a life changing kidney transplant that took a turn for the worst. I love you so much and think about you every day xxx"	BERT predicted the "other" label, which could be appropriate if it was a deceased donor transplant. We predicted the "past" label.
Human error (BERT>human)	15 (27)	"Me 26F with my Dad 58 he needs a kidney and I feel pressured to donate one. [removed]"	We predicted the "other" label because of the (removed) tag at the end of the post, which commonly appears in unusable posts. BERT predicted the "present" label, which is the more appropriate label.
Both erred	5 (9)	"I used to like her but I found out that she did not even acknowledge her kidney donor... Just referring to her as a person I know it seems pretty ungrateful [removed]"	This is someone's opinion about a celebrity who famously received a kidney transplant from her friend. It is not a personal experience at all, but the human label was "present," and the BERT label was "past."

From our analysis of the incorrect predictions on GPT-3.5 (Table 7), we observed that 26 (40%) of the 64 errors were acceptable.

As mentioned earlier, we had previously observed that many "past" posts were labeled as "present" because many of the posts were in a present tense context. The best setting used the shorter definition of past, which does not teach the model to treat past experiences nested in present accounts as the past class, so this is to be expected. Anytime both the human and predicted labels were wrong, the post was almost always ambiguous regarding whether it was about living or deceased donation. The experiences being described could have been a living donation, but there is not enough information to determine that for certain.

Regarding BERT, we may allow ourselves to consider the 26 acceptable errors and 10 human errors as being correctly predicted, changing the total number of correct predictions from 236 (78.7%) of 300 to 272 (90.7%) of 300 for an "actual" predictive accuracy of 90.7%. While still imperfect, this shows considerable reliability when using these methods on nuanced language tasks.

The implications of this examination are threefold: (1) sometimes human annotations go wrong, even with clear instructions; (2) these powerful models are capable of correctly catching things that humans miss (due to decision fatigue or similar cognitive difficulties); and (3) the models can be largely trusted to give sensible reasoning, even if the final conclusions differ from that of a human counterpart.

XSL•FO
RenderX

Table 7. Analysis of incorrect predictions from ChatGPT (n=64).

Error type	Incorrect predictions, n (%)	Example post	Reason
Unacceptable error (ChatGPT<human)	21 (33)	"relationships My (36F) estranged sister (43F) donated a kidney to me. I just heard that she died (for a different reason). I'm very confused. [removed]"	The simulated experts reasoned that the focus of the post was on grief rather than LKD[a] and labeled it as "other." The human label was given as "past" because the user mentions a sister who donated her kidney some time ago.
Acceptable error (ChatGPT human)	26 (41)	"Successfully donated a kidney to my sister whos been fighting Lupus."	This could be easily interpreted as either a "present" (ChatGPT) or a "past" (human) label, given that there is no explicit reference to time. It could go either way, but it is still clearly related to a personal experience with LKD.
Human error (ChatGPT > human)	10 (16)	"I (30F) had heart and kidney transplant. Ask Me Anything (AMA)."	The simulated experts concluded that this should be labeled "other" when the human label had been given as "past." ChatGPT made a more correct conclusion because this may have been from a deceased donor rather than a living donor. We would need more information to be certain, so it should be an "other" label.
Both erred	7 (11)	"I am A double kidney transplant recipient! AMA! I am a 28 year old white male, I've had two renal transplants over the course of my lifetime. I've been on dialysis. I've been in and out of hospital my entire life. I think it's interesting, but there's only one way to find out! Ask Me Anything."	The human-given label for this was "past" because of the previous transplant experiences, and the reasoning provided by ChatGPT concluded that the label should be "present" because the user mentions dialysis and being in and out of the hospital. Both were incorrect because there is not enough evidence that either of the transplants was from living donors, and thus, it should be labeled "other."

[a]LKD: living kidney donation.

Limitations and Future Work

BERT and ChatGPT have both proven effective in classifying personal accounts of LKD on platforms such as Reddit, achieving approximately 80% accuracy, which increases to about 90% when considering acceptable errors, marking a step forward in using web-based data for LKD research. These models could potentially automate the screening of new content for further scrutiny, thereby aiding donor support initiatives, particularly in education and community outreach. Despite the promising results, the complexity of the subject matter complicates the task of making perfect predictions. Our initial attempts to use fine-grained classifications led to suboptimal results, requiring us to use coarse-grained categories. Regarding costs, BERT's open-source nature and the flexibility to fine-tune make it an appealing choice. In contrast, ChatGPT excels in providing understandable reasoning for its decisions.

A review of errors indicated that ChatGPT generally understood the context well, although there were instances where the reasoning was off the mark, highlighting the importance of clear, prompt instructions. Interestingly, there were instances where the LLMs' reasoning surpassed ours, especially in delineating the "past" and "present" boundary, thereby suggesting a potential for iterative prompt enhancements informed by LLM reasoning. However, the quest for prompt optimization (or "promptization," if you will) may present an unending journey, as the allure of "just one more experiment" to elevate performance is always present. Drawing a line on performance as "good enough" is crucial, which may be attained through automated processes, as explored in some recent and exciting studies [63-69]. Future work will leverage these powerful new methodologies to both improve performance on our coarse-grained 3-class schema as well as achieve superior performance on the fine-grained 6-class schema that was unattainable with the present methods.

The performance of both models is significantly constrained by the size of the available data. While thousands of Reddit posts related to LKD are accessible, only a fraction pertains to personal experiences. The performance consistency across different data folds for BERT and across different sample sizes for ChatGPT highlights the need for larger datasets to better gauge each model's robustness.

A core challenge lies in the task's inherent demand for a singular label, which often oversimplifies the nuanced narratives in internet posts. Future endeavors could explore more elaborate information extraction techniques, leveraging LLMs such as ChatGPT to answer multiple queries or even construct knowledge graphs per post. Although ensuring uniform and usable output formats remains a hurdle, our work underscores ChatGPT's proficiency in deriving insightful inferences from the text. Our findings concerning the influence of few-shot learning examples on output bias also suggest the need for

XSL•FO
RenderX

deeper investigation into the interplay between example selection and model performance.

With reliable automation methods that can identify when a person is describing a personal experience with LKD, future work will extend the reach to additional media platforms, each of which has its own system for reaching users via advertising. There will certainly be potential biases in accessing educational information about living donations based on the characteristics of audiences most likely to post on each platform. To not exacerbate disparities, one must examine the generalizability of the profiles across multiple platforms and ensure the dissemination of information across platforms that reach diverse audiences and non-English speakers. An examination of access to most audience members, particularly the underserved, is warranted to ensure that all communities are reached equitably.

Utility of Results

By identifying these unique user classifications, tailored educational interventions for different profiles could be designed. First, for those most actively considering living donation, there could be social media campaigns built and targeted to specific users to invite them to learn more about living donation. These users can be referred to a trusted site, which includes education materials and an opportunity to register to begin donor medical evaluation at a nearby transplant center [41,42]. For individuals discussing their concerns about the costs involved with becoming a living donor, referrals to websites that discuss the ways to apply for grants to cover the out-of-pocket costs and lost wages could be valuable in their decision-making [70].

Second, for donors and families identified to have completed donations, campaigns inviting them to share their experiences on a living donor storytelling website [8,9] might result in more real-life stories being captured from diverse individuals to increase awareness of living donations for the national public. Stories are particularly valuable for educating learners with low health literacy or those for whom English is not their primary language about the possibilities of living donation [71].

Finally, it will be very important to work with experts in marketing and campaign design to plan social media campaigns that are motivating and helpful for patients and their families at different points along their donation journey. Identifying motivated learners from platforms such as Reddit, delivering content to them about living donation, and assessing its impact on learning more or pursuing donation are our next planned steps.

The proposed profiles may incorrectly identify a person's interest or stage of pursuit of donation, making any educational information sent to them irrelevant. In contrast, users could also be made uncomfortable if the education being provided matches their needs perfectly, indicating that their data are being scrutinized. Users can always disregard nonrelevant content; however, it will be important in the design of new campaigns not to assume with too much certainty that all learners are correctly identified. Respect for users is an ethical tenet that must always be considered in designing the campaigns and communicating how we found that they might be considering living donations as we move forward.

Conclusions

Much of the previous health care–related research about LLMs has been centered on their reliability in producing quality medical information. In contrast, we endeavor to extract individual-level information from the internet that can be used to inform health care providers. Consequently, there is little comparison that can be made to previous work other than to say that the reliability of the models is subject to the instructions they are given. However, our experimental results do illustrate that when using examples as part of the prompt (few-shot), bias toward the class of the given examples can affect performance. We have also shown that simulating a dialogue between 2 experts is more effective than using stand-alone reasoning.

This study takes a significant step in applying advanced NLP methods to the field of LKD, focusing on automating the detection of personal LKD experiences in online content. Both BERT and ChatGPT proved effective for this task, each with its own advantages and disadvantages. Our new DUCC method outperformed traditional reasoning approaches, emphasizing the importance of further work on improving prompt design. The study also highlights the need for automated prompt creation to reduce the time and effort currently required for manual testing, making NLP applications in the LKD field more efficient and impactful.

Abstract

Background: In the contemporary realm of health care, laboratory tests stand as cornerstone components, driving the advancement of precision medicine. These tests offer intricate insights into a variety of medical conditions, thereby facilitating diagnosis, prognosis, and treatments. However, the accessibility of certain tests is hindered by factors such as high costs, a shortage of specialized personnel, or geographic disparities, posing obstacles to achieving equitable health care. For example, an echocardiogram is a type of laboratory test that is extremely important and not easily accessible. The increasing demand for echocardiograms underscores the imperative for more efficient scheduling protocols. Despite this pressing need, limited research has been conducted in this area.

Objective: The study aims to develop an interpretable machine learning model for determining the urgency of patients requiring echocardiograms, thereby aiding in the prioritization of scheduling procedures. Furthermore, this study aims to glean insights into the pivotal attributes influencing the prioritization of echocardiogram appointments, leveraging the high interpretability of the machine learning model.

Methods: Empirical and predictive analyses have been conducted to assess the urgency of patients based on a large real-world echocardiogram appointment dataset (ie, 34,293 appointments) sourced from electronic health records encompassing administrative information, referral diagnosis, and underlying patient conditions. We used a state-of-the-art interpretable machine learning algorithm, the optimal sparse decision tree (OSDT), renowned for its high accuracy and interpretability, to investigate the attributes pertinent to echocardiogram appointments.

Results: The method demonstrated satisfactory performance (F_1-score=36.18% with an improvement of 1.7% and F_2-score=28.18% with an improvement of 0.79% by the best-performing baseline model) in comparison to the best-performing baseline model. Moreover, due to its high interpretability, the results provide valuable medical insights regarding the identification of urgent patients for tests through the extraction of decision rules from the OSDT model.

Conclusions: The method demonstrated state-of-the-art predictive performance, affirming its effectiveness. Furthermore, we validate the decision rules derived from the OSDT model by comparing them with established medical knowledge. These interpretable results (eg, attribute importance and decision rules from the OSDT model) underscore the potential of our approach in prioritizing patient urgency for echocardiogram appointments and can be extended to prioritize other laboratory test appointments using electronic health record data.

Introduction

Background

In the present medical landscape, the intricate interplay between innovative techniques has expanded the horizons of medical knowledge and opened avenues for unprecedented precision in patient care. The increasingly sophisticated laboratory tests play a crucial role in this transformative process. Born out of meticulous research and honed by the rigors of scientific scrutiny, these tests provide clinicians with a multifaceted toolkit to decipher the intricacies of illnesses, capturing the nuances of each condition, guiding medical professionals toward evidence-based interventions, and empowering medical professionals to tailor treatments with personalized precision.

However, a pivotal factor to take into consideration is the limited availability of certain state-of-the-art laboratory tests, as they often involve intricate equipment and elaborate protocols. This is evident from their expensive nature, the scarcity of skilled medical professionals capable of operating these laboratories, and the limited accessibility across different regions or during specific time frames [1]. As a result, the transformative potential of these laboratory tests is mitigated by the practical challenges they pose in terms of affordability [2]. The potential significant advantages of laboratory tests, coupled with their limited availability, render them a scarce resource, resulting in many patients having to endure wait times for access to laboratory tests. Consequently, predicting and prioritizing which patients require testing has emerged as an important research problem.

The rise of health IT and the subsequent influx of electronic health record (EHR) data, combined with the power of machine learning, offers new opportunities to revolutionize the prioritization of medical laboratory tests [3]. By delving into vast amounts of historical patient information, machine learning algorithms can discern intricate patterns and correlations that might otherwise elude human observation. The predictive outcomes generated by machine learning algorithms can contribute to refining testing protocols, enabling medical practitioners to make data-driven decisions regarding the prioritization and scheduling of laboratory tests based on patient information. In this study, we aim to elucidate methods for evaluating patients' urgency for tests, seeking to refine the allocation of scarce laboratory tests by harnessing the power of machine learning and analyzing historical EHRs. Specifically, we aim to contribute by applying an optimal sparse decision tree (OSDT) to a new domain—predicting the urgency of medical laboratory tests, using echocardiograms as a case study. Based on our literature review, OSDT stands out as one of the most suitable methods for achieving both optimal performance and interpretability in predicting the urgency of patients requiring echocardiograms. Our ultimate objective is to ensure prompt access for patients with the most critical needs.

Related Work

Echocardiogram and Patient Prioritization Techniques

An echocardiogram is one the most cost-effective means for screening cardiac anatomy, uses ultrasound to evaluate the cardiac structures, and provides critical information for medical providers [4]. It functions as a crucial precursor to a detailed diagnosis, capable of screening cardiac anatomy and providing essential information for assessing cardiovascular conditions such as murmurs, stenosis, and regurgitation. Additionally, it plays a crucial role in diagnosing valvular morphology and uncovering the root causes of valve diseases [5]. A comprehensive echocardiographic assessment can provide both diagnostic and prognostic information, thus facilitating risk stratification and establishing baseline data for future evaluations [5].

The echocardiogram, although immensely valuable, is not always easily attainable due to the increasing demand for the test. For example, there has been an observed increase in the prevalence of rheumatic heart disease, which stands as the most predominant form of valvular heart disease and impacts approximately 41 million individuals in developing countries [6]. In recent years, there has been a notable escalation in the demand for pediatric cardiology services, leading to documented workloads that have exhibited a substantial upsurge of up to 51% over the past decades [7]. Furthermore, there has been an increase in the prevalence of children with asymptomatic murmurs who necessitate evaluation through echocardiogram [8]. The increasing demands pose challenges to echocardiogram laboratories in resource management, requiring medical institutions to establish more effective scheduling protocols to prioritize patients in critical need of echocardiogram lab appointments.

Patient prioritization techniques can be broadly classified into scoring systems and machine learning classification–based systems [9]. Scoring systems, particularly those using regression techniques, have gained prominence for their ability to allocate medical resources. These systems heavily rely on the expertise of medical professionals to assign priority scores to patients. Examples include the Salisbury priority scoring system, allowing surgeons to assign relative priorities, and the Italian waiting time prioritization system, which reallocates outpatient referrals based on clinical priorities prescribed by general practitioners [9]. These methods, however, exhibit various limitations. First, there may be inherent bias (eg, subjective judgments obtained through experience by medical professionals) as these approaches often necessitate input from medical specialists' judgments. A machine learning and data-driven method can serve as a complement to these types of systems. Second, these methods might be tailored for a particular patient prioritization task (eg, surgery or referral), and demand a high level of specialized medical knowledge for their design, making them difficult to generalize to other tasks [10]. Third, certain methods lack transparent decision rules for assessing the significance of input attributes, thereby posing challenges for their practical applications [11]. Machine learning classification-based methods typically rely on a large amount of patients' information (eg, EHRs) to autonomously discern patterns and generate predictions. This process aids in patient prioritization and avoids limitations associated with scoring systems [12]. The existing methods, however, fail to transform the prediction process and outcomes into clear and executable rules, limiting the practical application of these approaches [9]. Moreover, existing studies predominantly center around 5 clinical areas, including cataract

surgery, general surgical procedures, hip and knee replacements, magnetic resonance imaging scanning, and children's mental health using specific predictive attributes and expert systems [13]. There is a crucial need for new methods that apply more broadly to general laboratory test prioritization.

To summarize, our literature review underscores the need for new methods of prioritizing patients, which leverage machine learning and data-driven techniques to complement existing methods, ensure transparency, and have the potential to be generalized to various patient prioritization tasks. Consequently, using extensive patient historical EHRs combined with an interpretable machine learning approach emerges as a potential solution to address these gaps.

Leveraging Machine Learning for Optimizing the Use of Scarce Laboratories Tests

When a large number of patient EHRs, which contain numerous hidden patterns, are available, integrating machine learning into health care practices emerges as a potential solution to address pressing issues such as the continual demand for medical services outpacing available resources. Specifically, machine learning, with its capacity to analyze vast data and discern intricate patterns, empowers health care professionals to make data-driven decisions regarding the allocation of laboratory tests. By developing predictive models using historical EHRs, machine learning models can identify individuals who are more likely to benefit from specific tests, ensuring that scarce resources are allocated where they can yield the greatest impact. Furthermore, such methods ensure critical cases receive prompt attention, leading to expedited diagnoses and interventions [14]. Moreover, the prediction results can potentially streamline the testing process by reducing unnecessary tests [15].

The integration of machine learning techniques to optimize the allocation of limited medical tests and laboratory resources has attracted considerable research attention. Research by Elitzur et al [16] delves into the use of prediction models to allocate medical tests efficiently. The study uses historical patient data to develop models that identify the most suitable candidates for specific tests, thereby enhancing resource allocation and streamlining the testing process. In a similar vein, Marescotti et al [17] investigate the orchestration of laboratory workflows through machine learning-driven prioritization. By considering factors such as clinical urgency and resource availability, their work demonstrates how machine learning algorithms can ensure timely and effective laboratory test processing, contributing to both improved patient care and optimized resource use. Similarly, Zhang et al [18] estimate the probability of requiring mechanical ventilation for in-hospital patients and contribute to the literature by identifying which patients require medical devices (ie, critical medical resources) more urgently.

However, while the potential benefits of machine learning in optimizing resource allocation are evident, challenges remain. A recent study underscores the need for further research and development in the area of machine learning models' interpretability and fairness, ensuring that data-driven decisions in health care maintain transparency [19]. The research gap drives us to use an interpretable and efficient machine learning method for laboratory tests and patient optimization.

Interpretable Machine Learning

Medical research is often at the forefront of technological innovation, with machine learning algorithms being harnessed to analyze vast datasets, predict disease outcomes, and assist in clinical decision-making. However, as these algorithms become increasingly sophisticated, they tend to function as "black boxes," where the reasoning behind their predictions remains obscured. This opacity not only raises concerns about trustworthiness but also impedes the adoption and acceptance of these tools by medical professionals [19].

In medical research, the concept of interpretability holds profound significance. The intricate interplay between cutting-edge technology and human well-being underscores the critical need to not only generate accurate predictions but also to understand the underlying rationale behind those predictions. The complexity of medical data, coupled with the potential life-altering consequences of decisions made based on data and machine learning models, demands a heightened level of transparency and comprehensibility requirements [20].

The interpretability of machine learning models empowers health care providers to understand the factors that led to a specific decision, enabling them to fine-tune treatment strategies according to their medical judgment and the patient's unique circumstances. Consequently, there has been a surge in post hoc techniques for elucidating black box machine learning models in a manner interpretable by humans. The most prominent techniques among these include local, model-agnostic methods that aim to explain individual predictions of a given black box classifier, such as local interpretable model-agnostic Explanation and Shapley additive explanation [21]. Due to their high generalizability, post hoc methods have been used to explain a wide array of machine learning models across various domains. However, previous research has indicated that there are common limitations associated with these post hoc techniques, including local interpretability, sensitivity to perturbations, and difficulties in choosing interpretable surrogate models [21].

In health care, arguably, a more appropriate research direction for using interpretable machine learning is tree-based models because much of the data related to patient prioritization is structured data (eg, tabular EHRs). Tree-based machine learning models can perform comparably to complex models (eg, deep learning models), especially after thorough preprocessing of tabular data [22]. In contrast to post hoc explainable machine learning techniques, tree-based models are logical models that consist of statements involving logical operations, providing clear and interpretable decision rules [22]. This interpretability is highly valuable in health care, as it allows medical professionals to not only make accurate predictions but also understand the underlying factors driving those predictions, enhancing transparency and trust in the decision-making process.

Since our research aims to use historical EHR data for patient prioritization, it is crucial to acknowledge another notable characteristic of patient prioritization-related information: the prevalence of numerous categorical variables (eg, patient demographic information such as gender and age groups). Furthermore, the outcomes of patient prioritization are also

XSL•FO
RenderX

expressed as categorical variables. For example, preventive interventions often involve categorical decisions, such as determining which individuals should undergo selective or indicated interventions or identifying those most likely to benefit from specific treatments [23]. In such scenarios, an efficient tree-based approach tailored to categorical variables is highly valuable. In this study, we focus on a cutting-edge decision tree algorithm–OSDT [24].

A decision tree features a hierarchical structure that is composed of a root node, branches, internal nodes, and leaf nodes in a tree format. Each path from the root node to the leaf node illustrates a rule to partition the data and leads to the final classification. The tree-based method presents a clear pattern for the decision-making process; thus, it is considered a transparent and highly interpretable model [25]. The results of the tree-based models are extremely useful for medical decision-making [26], and the performance of decision tree classifiers is verified by researchers on medical data [27]. Nevertheless, concerns have been raised regarding the suboptimality of decision tree algorithms [24,28]. To address this issue, OSDT has been introduced, aiming to ensure optimal solutions for binary variables in a computationally efficient manner [24].

The OSDT algorithm addresses various limitations observed in prior tree-based methods. Unlike previous approaches that often focused on finding the optimal tree within a fixed number of nodes or limited topology, OSDT tackles these shortcomings by identifying optimal trees through the use of a regularized loss function. This loss function strikes a balance between accuracy and the number of leaves, thereby enhancing the efficiency of the decision tree model. Furthermore, OSDT improves computational efficiency and interpretability by incorporating a series of analytical bounds that effectively reduce the search space while still identifying the optimal tree. By implementing these bounds, the algorithm streamlines the search process, leading to expedited identification of the optimal decision tree structure. Moreover, the OSDT algorithm has undergone mathematical validation, demonstrating its efficacy in constructing optimal trees for structured tabular datasets with attributes having binary values. It establishes its effectiveness in addressing binary classification problems. The algorithm is designed to uphold commendable levels of accuracy and is anticipated to meet the demands of medical prediction tasks with stringent interpretability requirements.

Methods

Study Design

In this study, we conducted empirical and predictive analyses using echocardiogram data extracted from EHRs at a large multispecialty hospital and medical facility. The dataset included administrative details, referral diagnoses, and patient conditions. To explore attributes relevant to echocardiogram prioritization, we used the OSDT algorithm due to its high accuracy and interpretability. We aim to enhance the scheduling of echocardiogram laboratory appointments by enabling the prioritization of patients with urgent needs based on our model's predictions. To be noted, our proposed method is not intended to replace human expertise but to complement it, offering valuable insights that guide practitioners toward informed and patient-centric choices.

Ethical Considerations

The Mayo Clinic Institutional Review Board, based on the authors' submission notes and in accordance with the Code of Federal Regulations, 45 CFR 46.102, deemed that this research did not require IRB review.

Data Collection and Selection

The dataset comprises real-world data from one of the top medical centers in the United States. The data were collected over a 1-year period in 2019, including 34,293 echocardiogram appointments. It consisted of 64 dummy-coded categorical attributes, encompassing various aspects such as patient demographics, medical history, clinical settings (eg, inpatient or outpatient status), past procedures, future scheduled procedures, and diagnose indicators for echocardiogram-justifying signs (eg, heart murmurs, shortness of breath, or chest pain) extracted from the clinical notes and referrals in the EHRs (Table 1).

The dataset exhibited a notable class imbalance issue, particularly evident in the examination of the "MadeBeforeEcho" attribute. This attribute delineates whether the downstream appointment following the echocardiogram occurs before the scheduling date of the echocardiogram appointment (not the actual appointment date). Within the "Y" category, the distribution revealed 84% nonurgent cases and 16% urgent cases. Conversely, in the "N" category, the distribution portrayed 58% nonurgent cases and 42% urgent cases. This observation underscored a substantial prevalence of nonurgent cases within the "MadeBeforeEcho" attribute. Furthermore, a similar pattern of imbalance is discerned when analyzing attributes such as "ReferredType" and "SurgeryYN." These attributes also exhibit a significant majority of cases concentrated within 1 category, indicating the need for careful consideration of class distribution in subsequent predictions.

The response variable is determined by calculating the number of days between the date the echocardiogram appointment was generated in the system and the actual appointment date. According to medical policy, appointments are classified as urgent (ie, the response variable) if the number of days is 2 or less, and nonurgent otherwise.

It is important to note that the features categorized under the "Future Scheduled Process" were derived based on the date the echocardiogram appointment is generated in the system, rather than the actual appointment date (Figure 1). This approach ensures that the model uses only the information available up to the point of echocardiogram appointment generation, without incorporating any data beyond this cutoff.

Of note, our dataset is a tabular dataset with attributes and response variables having binary values. Therefore, OSDT is highly suitable for serving this dataset, assisting us in making predictions for patient prioritization.

Problem Formulation: Urgency Prediction Using OSDT

With data , where are M binary attributes and are the response variable, we model an OSDT tree d with a collection of H distinct leaves $d = (p_1,p_2,...,p_H)$. The objective function in this study integrates the misclassification error with a sparsity penalty imposed on the number of leaf nodes, denoted as $R(d,x,y)$. $R(d,x,y) = l(d,x,y) + \lambda H_d$, where $l(d,x,y)$ represents the misclassification error of the tree, which is computed as the fraction of training data with incorrectly predicted labels. In addition, H_d represents the number of leaves in tree d. To regularize the model and discourage larger trees, a regularization term λH_d is introduced, where λ is a hyperparameter controlling the strength of the penalty. A higher value of λ corresponds to a stronger penalty on the size of the tree. This implies that the tree is more likely to be shallower when achieving optimality.

By using OSDT, we aim to improve the overall performance of the classification task while simultaneously upholding a significant level of interpretability, thereby facilitating a comprehensive understanding of the underlying patterns and factors influencing the classification outcomes.

Results

Overview

In this section, we evaluated the proposed method against state-of-the-art machine learning models. We then highlighted attribute importance and provided clear interpretations of derived results within specific patient cohorts for transparency and clarity.

Performance Evaluation

We demonstrated the performance of our OSDT model by comparing it to commonly used machine learning models as baselines, including naive Bayes, generalized linear model, fast large margin, logistic regression, neural network, vanilla decision tree, random forest, gradient boosted trees, and support vector machine. The evaluation metrics used for the binary classification are accuracy, precision, recall, F_1-score, and F_2-score. Accuracy is a metric that quantifies the overall correctness of a machine learning model. It represented the proportion of correct predictions made by the model across all categories or classes. Precision and recall, on the other hand, measured the model's ability to accurately predict a specific category or class. Precision focused on the proportion of true positive predictions relative to all positive predictions made by the model. Recall, also known as sensitivity, gauged the model's capability to correctly detect instances of a specific category. It quantified the proportion of true positive predictions relative to all actual positive instances present in the data. The F_1-score has been widely used in the context of imbalanced classification problems and serves as a prominent metric. It is computed as the harmonic mean of the precision and recall scores, providing a balanced assessment of the model's performance by considering both precision and recall simultaneously. The F_2-score assigns greater weight to recall than precision, proving beneficial when the consequences of false negatives (ie, missed positive cases where patients are in urgent condition but remain unidentified by the model) outweigh those of false positives (ie, incorrectly identified positive cases). All metrics mentioned exhibited a range of values between 0 and 1, whereby a higher value indicated superior performance.

Compared with various baselines, the performance of the OSDT model achieved the highest accuracy, recall, F_1-score, and F_2-score (Table 2). The performance reported is based on 5-fold cross-validation. These results indicated the predictive capability of the OSDT model in our research context, demonstrating the overall performance and effectiveness of the OSDT model.

[a]OSDT: optimal sparse decision tree.

[b]OSDT is an algorithm that makes decisions based on direct constraints rather than generating probability scores. As a result, metrics like the receiver operating characteristic curve, precision and recall curve, and area under curve are not applicable for this method.Although the CIs for SVM and OSDT overlap, it is noteworthy that SVM exhibits a significantly larger SD. This indicates that OSDT is more robust in this scenario, delivering a more stable and reliable performance despite the overlapping intervals.

[c]; β=2.

[d]SVM: support vector machine.

Interpreting Prediction Results

OSDT, as a tree-based model, possesses the notable advantage of providing interpretable prediction results. We conducted an analysis of the decision trees generated using the entire dataset as well as specific patient cohorts. The objective is to extract the most influential rules that demonstrate both high accuracy and coverage, thereby aiming to uncover the underlying factors that drive the urgent decision of echocardiogram appointments.

We first identified several key categories and attributes that significantly influenced the urgency of patients' echocardiogram appointments (Table 3). First, the most important categories included "future scheduled process," pertaining to clinic scheduling policies, and "diagnosis," indicative of patients' health conditions. Second, within the top 12 important attributes, a cluster of attributes related to future scheduled processes emerged as the most prominent. These attributes encompassed scenarios if the next downstream appointment following the echocardiogram was scheduled prior to the echocardiogram appointment (ie, "MadeBeforeEcho"), instances where the next appointment did not pertain to the cardiovascular department (ie, "NextDepartment"), cases where no subsequent appointment was scheduled after the echocardiogram appointment (ie, "NextLength_None"), and situations where the time gap between the echo appointment and the subsequent one was less than a day ("NextLength_1"). The absence of a downstream appointment before the echocardiogram could be attributed to the clinic's practice of tailoring subsequent appointments based on the results of the echocardiogram. Consequently, it became imperative for medical providers to accord priority to the echocardiogram appointments of these patients, as the results would furnish vital evidence for guiding appropriate follow-up care and future steps. Third, attributes related to diagnoses assumed the second tier of importance, particularly whether patients exhibited respiratory and cardiac symptoms (ie, "R") or had documented cardiovascular conditions (ie, "I"). Patients diagnosed with heart-related issues, such as heart murmurs, shortness of breath, and chest pain, typically require expedited access to echocardiography results to determine the next course of action. Fourth, clinical setting attributes and demographic information are also important to patient prioritization. In the context of inpatients, health care providers tended to assign earlier echocardiogram appointment slots as part of a strategy to reduce the length of hospital stays. Additionally, when prioritizing patients with heart conditions, individuals referred by cardiologists received preferential treatment in terms of scheduling. Furthermore, the medical facility providing the data adopted a proactive approach by expediting echocardiogram appointments for out-of-state patients, aiming to minimize their duration of stay. This proactive stance facilitated timely evaluation and management, thereby contributing to a more efficient allocation of resources and an enhanced patient experience. Among medical history attributes, the presence of fluid and electrolyte disorders (ie, "FluidsLytes") emerged within the top 12, which underscored the strong correlation between fluid and electrolyte disorders and heart failure, further emphasizing its relevance in patient prioritization [29].

These results underscore the significance of admission and policy-related information in determining the urgency of echocardiogram appointments. They reflected the complexities of the scheduling process and highlighted the need for tailored appointment allocation strategies based on patients' referral status and downstream appointment requirements.

We subsequently focus on a specific patient cohort for further analysis. The "MadeBeforeEcho" attribute clearly emerged as

XSL•FO
RenderX

exceptionally significant among the dataset's attributes. It was noteworthy to highlight that, based on the data, there were no urgent cases when the "MadeBeforeEcho" variable was marked as "N." Consequently, we conducted an investigation specifically focusing on patients whose subsequent downstream appointment was scheduled before the date the echocardiogram appointment was generated in the system. This subset of the patient cohort served as an illustrative example of how decision trees could provide a high degree of interpretability in the context of patient prioritization (Figure 2). Upon scrutiny of the subdecision tree for this cohort depicted, several noteworthy observations emerged. Primarily, it became evident that the most crucial attribute for this cohort is "R," signifying whether the patient presents with respiratory and cardiac symptoms, which served as the root node of the subtree. The pathway leading to categorizing a patient case as urgent depended on multiple conditions: the patient exhibited respiratory and cardiac symptoms, had an appointment scheduled within the cardiology department, hailed from out of state, and had a subsequent appointment scheduled following the echocardiogram. In contrast, patients without respiratory and cardiac symptoms tended toward classification as nonurgent. This tendency toward nonurgency was particularly pronounced in cases lacking a scheduled appointment subsequent to the echocardiogram.

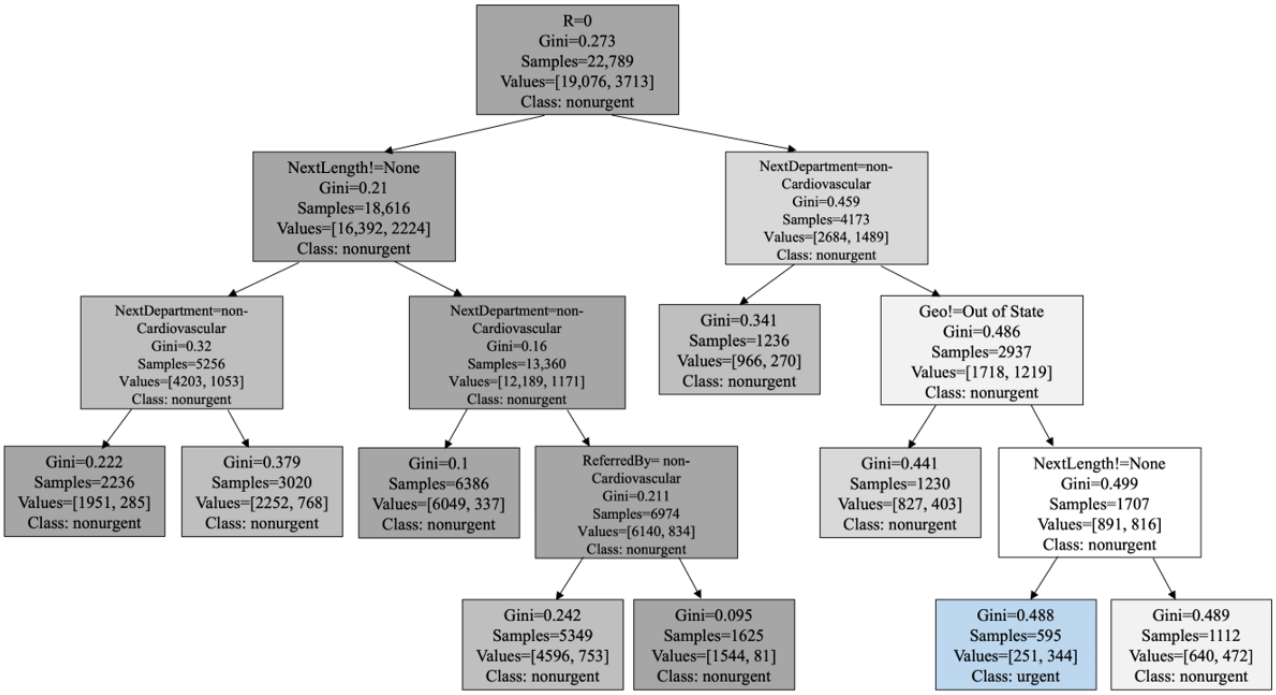
Table 3. Attribute importance and category importance[a].

Category and attribute	Meanings	Attribute importance
Future scheduled process (importance=0.0369)		
MadeBeforeEcho	Whether the next downstream appointment after echocardiogram is made before the date the echocardiogram appointment was generated in the system or not.	0.0279
NextDepartment	The department in which the appointment happened after the date the echocardiogram appointment was generated in the system.	0.0049
NextLength_None	No following appointment scheduled after the date the echocardiogram appointment was generated in the system.	0.0035
NextLength_1	The number of days from the date the echocardiogram appointment was generated in the system to its following appointment is less than 1 day.	0.0006
Diagnoses (importance=0.0154)		
R	If have murmur, hypoxemia, shortness, SOB[b], breath, shock, dyspnea, chest pain, troponin, syncope, electrocardiogram, extremity, mass, swelling, and edema.	0.0147
I	If have heart failure, coronary artery, cardiac arrest, STEMI[c], stroke, cardia, hypertension, endocarditis, NSTEMI[d], PEA[e] arrest, AFib[f], pulmonary embolism, pulmonary hypertension, and vegetation.	0.0007
Demographic (importance=0.0369)		
Geo_Out of State	Patient is from out of state.	0.0029
Geo_Town	Patient is from the local town.	0.0013
AGE_19-55	Age between 19 and 55 years.	0.0011
Clinical settings (importance=0.0053)		
ReferredType	Referred type-inpatient or outpatient.	0.0047
ReferredBy_CV	The specialty that patient referred by is cardiovascular disease department.	0.0006
FluidsLytes (medical history; importance=0.0021)	If have fluid and electrolyte disorders	0.0021

[a]The relative importance scores of the attribute category and individual attributes are determined by the Gini index of the optimal sparse decision tree. The feature importance values are relative importance values and do not have a fixed absolute range. We presented only the most important features.

[b]SOB: shortness of breath.

[c]STEMI: ST-elevation myocardial infarction.



[d]NSTEMI: non–ST-elevation myocardial infarction.

[e]PEA: pulseless electrical activity.

[f]AFib: atrial fibrillation.

Figure 2. The OSDT for patients whose next downstream appointment after the echocardiogram is scheduled before the date the echocardiogram appointment was generated in the system. OSDT: optimal sparse decision tree. λ=0.0008; accuracy: 83.69%.

Analyses on Diverse Patient Cohorts

In order to enhance the validity of the decision trees and gain more valuable medical insights, we conducted more analyses on smaller patient cohorts. Specifically, we focus on patients who have no next downstream appointment after echocardiogram and are categorized as inpatients. Furthermore, we narrowed down the patient cohort based on specific medical history and presented a compilation of rules extracted from the decision tree (Table 4).

A decision rule was defined as the pathway from the root of a decision tree to a leaf node . The accuracy and coverage of a decision rule served as critical metrics for evaluating its effectiveness and applicability. Accuracy, denoting the capacity of a decision rule to effectively forecast the outcome of interest, was quantified as the proportion of records that fulfill both the rule's precondition and its consequent within the precondition. This metric was computed as , where "number of Correct Predictions" denoted the count of instances where the decision rule accurately anticipated the desired outcome and "Total number of Instances" represented the entire dataset or the set of instances under consideration, which elucidated how accuracy measures the precision of a decision rule in making predictions based on its specified conditions and its congruence with actual outcomes within the dataset. Coverage, on the other hand, measured the proportion of cases or individuals to which the decision rule could be applied. It could be calculated as . It signified the generalizability and practical scope of the rule in real-world scenarios. A decision rule with high coverage indicates its ability to be applied to a wide range of cases or individuals, thereby increasing its usefulness in practice.

In the context of patients with congestive heart failure (CHF), anemia played a significant role in determining the urgency of echocardiogram appointments (Table 4). Anemia could have detrimental effects on cardiac function through various mechanisms [29]. First, it induces cardiac stress by increasing heart rate and stroke volume. Additionally, anemia could lead to reduced renal blood flow and fluid retention, adding further strain to the heart. Prolonged anemia, regardless of its underlying cause, could contribute to the development of left ventricular hypertrophy, which exacerbates CHF by promoting cardiac cell death through apoptosis. Notably, patients with anemic CHF often exhibited resistance to CHF medications, and numerous studies consistently demonstrated that these individuals have a higher mortality rate compared to patients with non-anemic CHF [30]. Anemia also played a critical role in patients with coagulopathy, as it exacerbated bleeding, which in turn further worsens coagulopathy [30].

For patients with hypothyroidism, fluid and electrolyte disorders served as strong indicators. Hypothyroidism, a prevalent endocrine disorder, was associated with the development of congestive heart failure. Electrolyte disturbances were commonly observed in patients with chronic heart failure [31]. Echocardiogram has been a suitable modality for guiding fluid resuscitation in critically ill individuals. It allowed for the evaluation of fluid responsiveness based on several parameters, such as the left ventricle, aortic outflow, inferior vena cava, and right ventricle [32].

The impact of alcohol consumption on cardiovascular health was multifaceted. Extensive research has demonstrated that the consumption of alcohol at levels surpassing approximately 1 to 2 drinks per day was associated with hypertension [28]. This condition adversely affects the elasticity of arteries, leading to diminished blood and oxygen flow to the heart and consequently contributing to the onset of heart disease [33]. These pathophysiological changes increase the risk of heart disease. Consequently, patients with a history of alcohol abuse and

XSL•FO
RenderX

concomitant hypertension might require an urgent echocardiogram to assess the potential cardiac implications arising from these interconnected conditions.

Patients diagnosed with valvular heart conditions would fall into the urgent category if they also exhibited cardiovascular issues and a history of congestive heart failure. These attributes collectively signaled the presence of potentially serious cardiac problems, indicating a compelling need for an echocardiogram to obtain detailed cardiac information and facilitate accurate diagnoses. In the case of patients grappling with depression, their urgency classification as "urgent" was contingent upon the presence of co-occurring health issues. Extensive research has established a substantial influence of depression on the outcomes of concurrent medical conditions. Consequently, when depression coincided with other health problems, it necessitated an "urgent" classification, acknowledging its significant impact on overall health outcomes [34]. Regarding patients with obesity, an "urgent" classification applied if they additionally exhibited fluid and electrolyte disorders. Research findings have illuminated a connection between overweight or obesity and specific physiological factors, such as lower reactance and hypertonicity. Furthermore, individuals with overweight and those with obesity with lower reactance tended to demonstrate significantly elevated serum sodium levels compared to individuals with a normal weight. These associations underscored the importance of promptly addressing the medical needs of patients with obesity with fluid and electrolyte disorders, warranting an "urgent" classification for their cases [35].

Overall, the decision rules extracted from our analyses aligned closely with medical knowledge, providing reliable insights for identifying urgent echocardiogram appointments for patients. The congruence between the rules and medical understanding not only validated the effectiveness of our model but also highlighted the consistent application of medical principles in the decision-making process. This focused analysis contributed to a better understanding of the OSDT model's validity and offered valuable medical perspectives to enhance the identification of urgent patients' echocardiogram appointments.

Table 4. Decision rules for specific patient cohorts.

Cohort	Rules for a patient to be classified as urgent	Rule accuracy (%)	Rule coverage (%)
CHF[a]	The department in which the appointment happened after the echocardiogram appointment was generated in the system=non-cardiovascular disease, AGE<75, anemia=yes	100	14.20
Coagulopathy	Anemia=Yes	99	53.03
Hypothyroid	Fluid and electrolyte disorders=yes, Whether the patient had a cardiovascular surgery within six months prior to the echocardiogram appointment=no	100	32.91
Alcohol	Hypertension=yes	100	43.75
Valvular	I=1(has cardiovascular conditions), CHF=yes	100	6.36
Depression	Z=1 (has factors influencing health status and contact with health service)	100	24.49
Obesity	Geo!=Town, E=0 (has no nutritional and metabolic diseases), fluid and electrolyte disorders=yes	100	23.75

[a]CHF: congestive heart failure.

Discussion

Overview

The primary objective of our study is to forge an effective tree-based classification machine learning model geared toward prioritizing the allocation of echocardiogram appointments for patients with a heightened need for timely diagnostics. Our long-term goal is to streamline the scheduling process, ensuring that patients' medical requirements are promptly addressed, thereby minimizing delays and optimizing their health care experience. Moreover, our study aspired to delve deeper into the intricate attributes that contribute to the urgency of echocardiogram lab appointments. Recognizing the intricate interplay of medical, logistical, and patient-specific variables, we sought to unravel the complex rules and dynamics that govern appointment prioritization. By harnessing the inherent interpretability of our model, we aim to uncover hidden insights and relationships within a large amount of EHR data, shedding light on the critical determinants that underscore the need for rapid scheduling. The implications of our study extended beyond the realm of predictive modeling. We aimed to empower health care professionals with a powerful tool that not only optimizes resource allocation but also enriches their decision-making process.

Principal Results

The findings demonstrate promising results by accurately predicting the urgency of echocardiogram appointments and providing valuable insights into the critical guidelines applicable to specific patient cohorts. In summary, the study emphasizes two key points: (1) among the various attributes examined, it is observed that admission-related attributes exert a significant influence on the level of urgency for patients' echocardiogram appointments; and (2) the urgency of scheduling echocardiogram appointments can be influenced by the presence of comorbidities that exacerbate patients' conditions. In the case of congestive heart failure, anemia emerges as a significant attribute, highlighting its relevance in contributing to the urgency of echocardiogram appointments. Similarly, coagulopathy is identified as an important attribute for patients with congestive heart failure, further emphasizing the need for prompt

XSL•FO
RenderX

assessment. For patients with hypothyroidism, the presence of fluid and electrolyte disorders serves as a concerning indicator, warranting the prioritization of an echocardiogram. Additionally, hypertension is found to be a critical medical knowledge for patients with a history of alcohol abuse, underscoring the urgency of echocardiogram in this population.

Our work is unique in applying an advanced binary decision tree model that offers inherent interpretability, avoiding the limitations of post hoc techniques like local interpretable model-agnostic Explanation and Shapley additive explanation, such as local interpretability constraints, sensitivity to perturbations, and difficulties in selecting appropriate surrogate models. We extract interpretable rules grounded in medical knowledge, making this the first study to introduce tree-based interpretable machine learning for patient prioritization and the stratification of medical test urgency. Furthermore, the tree-based model allows us to derive rules that are easily understandable to medical professionals. These rules can be assessed for alignment with existing medical knowledge and applied in real-world practice by health care providers.

Limitations

The research has several limitations that could be addressed in future work. First, the accuracy of the prediction model hinges on the quality and completeness of available data; incomplete or missing data may compromise the reliability of predictions. Furthermore, it is essential to recognize that the effectiveness of the model may vary when applied to diverse patient populations or health care settings. This variation can be attributed to the unique attributes and patterns present in the training data, which significantly impact the model's performance. Moreover, the predictions rely on the elapsed days between the appointment scheduling date and the appointment date. Nonurgent patients may inadvertently be grouped with urgent cases due to cancellations and rescheduling of echocardiogram appointments. While this offers a broad indication of urgency, it may overlook critical factors that influence appointment priority. Integrating essential clinical or contextual details, such as the patient's medical history, symptom severity, or health care resource availability, into the model could provide more comprehensive insights.

Conclusions

This research adapts the OSDT algorithm to assess the urgency of patients in need of echocardiograms. The OSDT model demonstrates better performance over alternative machine learning models, highlighting its predictive accuracy and effectiveness. Furthermore, it identifies key attributes and rules governing the prioritization of echocardiogram appointments.

The analysis of decision trees generated by the OSDT model reveals the significance of admission- and policy-related attributes, such as downstream appointment scheduling and patient referral status, in determining appointment urgency. Moreover, the analyses of specific patient cohorts provide medical insights into the role of comorbidities, such as anemia in patients with CHF and coagulopathy, and fluid and electrolyte disorders in patients with hypothyroidism. These insights align with established medical knowledge and enhance the identification of urgent echocardiogram appointments.

In summary, this study facilitates the development of effective scheduling protocols for echocardiogram appointments by harnessing machine learning techniques and integrating medical insights. This approach enhances the overall efficiency and effectiveness of echocardiogram services, ultimately benefiting patient care. The findings can also be generalized to inform the establishment of efficient scheduling protocols and the promotion of equitable access to various other medical laboratory tests.

Abstract

Background: The rapid advancement of deep learning in health care presents significant opportunities for automating complex medical tasks and improving clinical workflows. However, widespread adoption is impeded by data privacy concerns and the necessity for large, diverse datasets across multiple institutions. Federated learning (FL) has emerged as a viable solution, enabling collaborative artificial intelligence model development without sharing individual patient data. To effectively implement FL in health care, robust and secure infrastructures are essential. Developing such federated deep learning frameworks is crucial to harnessing the full potential of artificial intelligence while ensuring patient data privacy and regulatory compliance.

Objective: The objective is to introduce an innovative FL infrastructure called the Personal Health Train (PHT) that includes the procedural, technical, and governance components needed to implement FL on real-world health care data, including training deep learning neural networks. The study aims to apply this federated deep learning infrastructure to the use case of gross tumor volume segmentation on chest computed tomography images of patients with lung cancer and present the results from a proof-of-concept experiment.

Methods: The PHT framework addresses the challenges of data privacy when sharing data, by keeping data close to the source and instead bringing the analysis to the data. Technologically, PHT requires 3 interdependent components: “tracks” (protected communication channels), “trains” (containerized software apps), and “stations” (institutional data repositories), which are supported by the open source “Vantage6” software. The study applies this federated deep learning infrastructure to the use case of gross tumor volume segmentation on chest computed tomography images of patients with lung cancer, with the introduction of an additional component called the secure aggregation server, where the model averaging is done in a trusted and inaccessible environment.

Results: We demonstrated the feasibility of executing deep learning algorithms in a federated manner using PHT and presented the results from a proof-of-concept study. The infrastructure linked 12 hospitals across 8 nations, covering 4 continents, demonstrating the scalability and global reach of the proposed approach. During the execution and training of the deep learning algorithm, no data were shared outside the hospital.

Conclusions: The findings of the proof-of-concept study, as well as the implications and limitations of the infrastructure and the results, are discussed. The application of federated deep learning to unstructured medical imaging data, facilitated by the PHT framework and Vantage6 platform, represents a significant advancement in the field. The proposed infrastructure addresses the

XSL•FO
RenderX

challenges of data privacy and enables collaborative model development, paving the way for the widespread adoption of deep learning–based tools in the medical domain and beyond. The introduction of the secure aggregation server implied that data leakage problems in FL can be prevented by careful design decisions of the infrastructure.

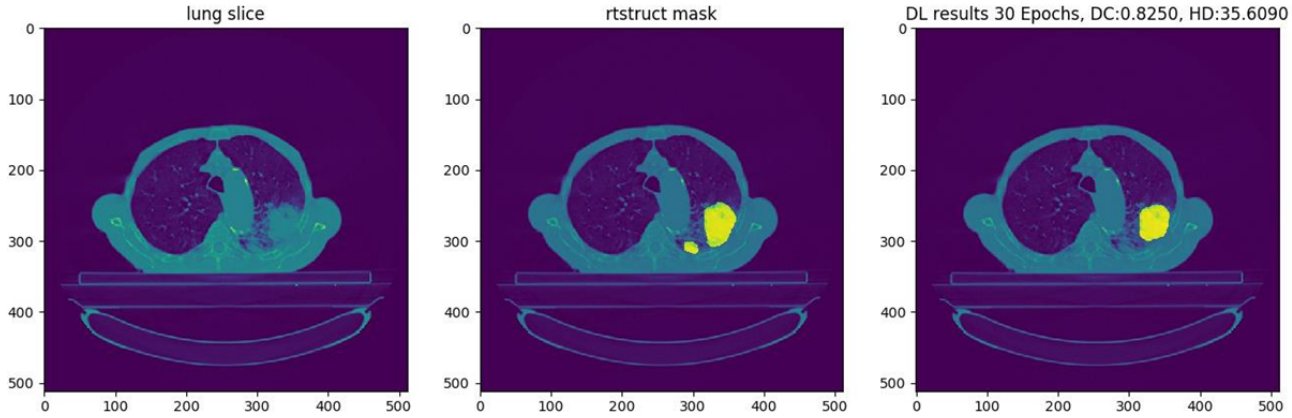
Introduction

Federated learning (FL) allows the collaborative development of artificial intelligence models using large datasets, without the need to share individual patient-level data [1-4]. In FL, partial models trained on separate datasets are shared, but not the data itself, hence a global model is derived from the collective set of partial models. This study introduces an innovative FL framework known as the Personal Health Train (PHT) that includes the procedural, technical, and governance components needed to implement FL on real-world health care data, including the training of deep learning neural networks [5]. The PHT infrastructure is supported by a free and open-source infrastructure known as "priVAcy preserviNg federaTed leArninG infrastructurE for Secure Insight eXchange," that is, Vantage6 [6]. We will describe in detail an architecture for training a deep learning model in a federated way with 12 institutional partners located in different parts of the world.

Sharing patient data between health care institutions is tightly regulated due to concerns about patient confidentiality and the potential for misuse of data. Data protection laws—including the European Union's General Data Protection Regulations; Health Insurance Portability and Accountability Act of 1996 (HIPAA) in the United States; and similar regulations in China, India, Brazil, and many other countries—place strict conditions on the sharing and secondary use of patient data [7]. Incompatibilities between laws and variations in the interpretation of such laws lead to strong reluctance about sharing data across organizational and jurisdictional boundaries [8-10].

To address the challenges of data privacy, a range of approaches have been published in the literature. Differential privacy, homomorphic encryption, and FL comprise a family of applications known as "privacy enhancing technologies" [11-13]. The common goal of privacy-enhancing technologies is to unlock positively impactful societal, economic, and clinical knowledge by analyzing data en masse, while obscuring the identity of study subjects that make up the dataset. Academic institutions are more frequently setting up controlled workspaces (eg, secure research environments [SREs]), where multiple researchers can collaborate on data analysis within a common cloud computing environment, but without allowing access to the data from outside the SRE desktop; however, this assumes that all the data needed have been transferred into the SRE in the first place [14,15]. Similarly, the National Institutes of Health has set up an "Imaging Data Commons" to provide secure access to a large collection of publicly available cancer imaging data colocated with analysis tools and resources [16]. Other researchers have shown that blockchain encryption technology can be used to securely store and share sensitive medical data [17]. Blockchain ensures data integrity by maintaining an audit trail of every transaction, while zero trust principles make sure the medical data are encrypted and only authenticated users and devices interact with the network [18].

From a procedural point of view, the PHT manifesto for FL rules out the sharing of individual patient-level data between institutions, no matter if the patient data have been deidentified or encrypted [19]. The privacy-by-design principle here may be referred to as "safety in numbers," that is, any single individual's data values are obscured, by computing either the descriptive statistics or the partial model, over multiple patients. PHT allows sufficiently adaptable methods of model training, such as iterative numerical approximation (eg, bisection) or federated averaging (FedAvg [20]), and does not mandatorily require model gradients or model residuals, which are well-known avenues of privacy attacks [21-24]. Governance is essential with regards to compliance with privacy legislation and division of intellectual property between collaboration partners. A consortium agreement template for PHT has been made openly accessible [25], which is based on our current consortium ARGOS (artificial intelligence for gross tumor volume segmentation) [26]. Technologically, PHT requires 3 interdependent components to be installed—"tracks" are protected telecommunications channels that connect partner institutions, "trains" are Docker containerized software apps that execute a statistical analysis that all partners have agreed upon, and "stations" are the institutional data repositories that hold the patient data [23]. It is this technological infrastructure—the tracks, trains, and stations—that is supported by the aforementioned Vantage6 software, for which detailed stand-alone documentation exists [27].



The paper proposes a federated deep learning infrastructure based on the PHT manifesto [19], which provides a governance and ethical, legal, and social implications framework for conducting FL studies across geographically diverse data providers. The research aims to showcase a custom FL infrastructure using the open-source Vantage6 platform, detailing its technological foundations and implementation specifics. The paper emphasizes the significance of the implemented custom federation strategy, which maintains a strict separation between intermediate models from both internal and external user access. This approach is crucial for safeguarding the security and privacy of sensitive patient data,

XSL•FO
RenderX

as it prevents potential reverse engineering of intermediate results that could compromise confidentiality. This aggregation strategy is particularly important in the case of deep learning–based studies where multiple iterations of models or gradients are necessary to derive an optimal global model.

To demonstrate the infrastructure's robustness and practical applicability, the study presents a proof-of-concept involving the development of a federated deep learning algorithm based on 2D convolutional neural network (CNN) architecture [28]. This algorithm was implemented to automatically segment gross tumor volume (GTV) from lung computed tomography (CT) images of patients with lung cancer. Figure 1 [29] demonstrates a manual segmentation and deep learning–based segmentation of a tumor in the chest CT image of a patient. The subsequent sections provide a comprehensive account of the precise technical specifications of the infrastructure that links 12 hospitals across 8 nations, covering 5 continents. The algorithm developed learns from the distributed datasets and deploys it using the infrastructure. However, it is important to mention that the choice of the use case is only exemplary in nature, and the infrastructure is equipped to train any kind of deep learning architecture for relevant clinical use cases.

Figure 1. Illustrative result on a hold-out validation slice; the main bulk of the gross tumor volume as determined by the oncologist (middle) has been correctly delineated by the deep learning algorithm (right), but a small tumor mass adjacent and to the lower right of the main gross tumor volume mass has been missed (reproduced from Figure 6 of Chapter 4 of the thesis by Patil [29], which is published under the Taverne License [Article 25fa of the Dutch Copyright Act]).

The research used a deep learning architecture because in recent times the application of deep learning in health care has led to impressive results, specifically in the areas of natural language processing and computer vision (medical image analysis), with the promise for more efficient diagnostics and better predictions of treatment outcomes in future [30-35]. However, for robust generalizability, and to earn clinicians' acceptance, it is essential that artificial intelligence apps are trained on massive volumes of diverse and demographically representative health care data across multiple institutions. Given the barriers to data sharing, this is clearly an area where FL can play a vital role. Many studies have been published that present FL on medical data including federated deep learning [36-40]. However, only a limited number of studies have documented the use of dedicated frameworks and infrastructures in a transparent manner. The adoption of a custom federation strategy or absence of explicit reporting on the used infrastructure is observed in most of the studies. Table 1 summarizes the small number of FL studies that have been published in connection with deep learning investigations related to medical image segmentations to date.

The paper primarily focuses on demonstrating the training and aggregation mechanism of a deep learning architecture within a FL framework. It deliberately avoids delving into the optimization of model performance or clinical accuracy, as these aspects fall outside the paper's scope. Instead of emphasizing the selection of an optimal CNN architecture or aggregation strategy [39], the research concentrates on elucidating the functionality of the FL infrastructure. Existing literature has shown that FL models can achieve performance comparable to centrally trained models [38,41,45-47]. This supports the assumption that, given identical datasets and CNN architectures, a model trained using FL would likely yield similar results to one trained through centralized methods. The paper operates under this premise, prioritizing the explanation of the FL process over demonstrating performance parity with centralized training approaches.

The study highlights 3 key points as follows:

- FL is particularly well suited for deep learning applications, which typically require vast amounts of data. This makes it an ideal showcase for the federated approach.
- When implementing federated deep learning, it is crucial to have a robust infrastructure and use a customized, secure aggregation strategy. These elements are essential for safeguarding the privacy of sensitive patient information.
- FL in real-world medical data is not just a technological challenge; it requires a comprehensive strategy that addresses ethical, legal, governance, and organizational aspects, as highlighted by the PHT manifesto.

Glioblastoma tumor boundary detection [44]	Brain MRI	71 centers

[a]MRI: magnetic resonance imaging.

[b]CT: computed tomography.

The findings of the proof-of-concept study, as well as the implications and limitations of the infrastructure and the results, are discussed. The subsequent section of the paper is structured as follows: the *Methods* section describes the approach taken, followed by the *Results*, which detail the implementation of the infrastructure and a proof-of-concept execution. Finally, the paper concludes with a *Discussion* section.

Methods

Overview

When conducting a federated deep learning study, it is crucial to consider several key perspectives, which include both technical as well as organizational and legal aspects. These key factors have been instrumental in designing the infrastructure architecture used for training the deep learning algorithm. In this section, we discuss the technical details while adhering to an Ethics-Legal-Social Impact framework as laid down by the PHT manifesto. The technical design decisions are based on the following assumptions:

Data Landscape

Understanding the data landscape is crucial in designing and deploying FL algorithms. The technological approaches for handling horizontally partitioned data, where each institution contains nonoverlapping human subjects but the domain of the data (eg, CT images of lung cancer) is the same across different institutions, can differ significantly from those used for vertically partitioned data, where each institution contains the same human subjects but the domain of the data do not overlap (eg, CT scans in one, but socioeconomic metrics in another). Additionally, unstructured data, such as medical images, requires different algorithms and preprocessing techniques compared with structured data. In this paper, the architecture will only focus on CT scans and horizontally partitioned patient data.

Data Preprocessing

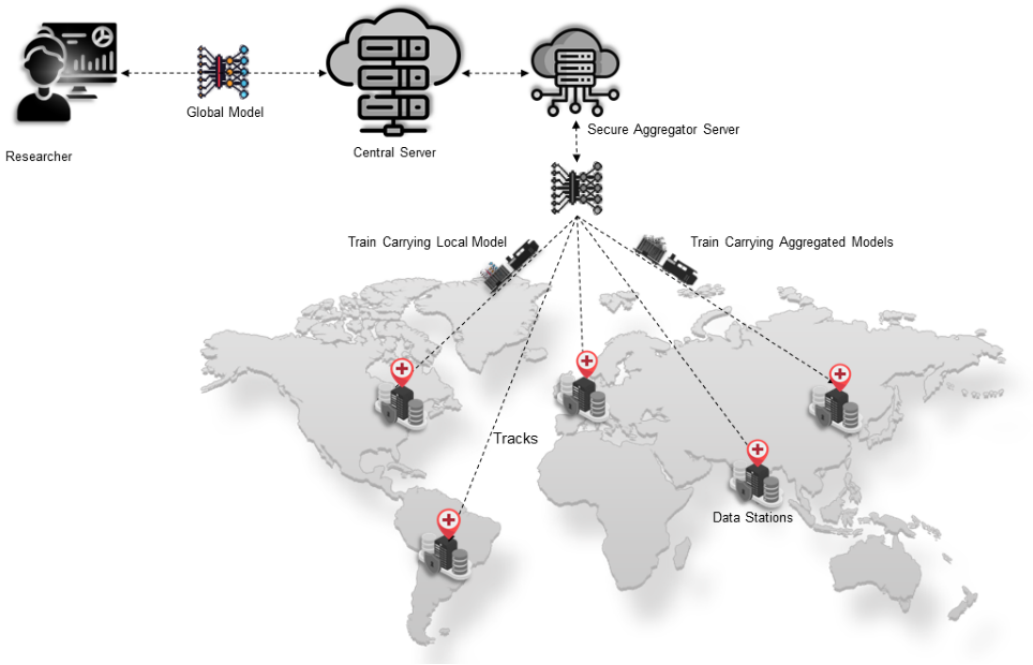
In a horizontally partitioned FL setting, the key preprocessing steps can be standardized and sent to all partner institutions. However, the workflow needs to handle differences in patients, scan settings, and orientations. Anonymization, quality improvements, and DICOM standardization ensure homogeneity and high quality across hospitals. These offline preprocessing steps, applied consistently to the horizontally partitioned data, enabled using the same model across institutions, crucial for the FL study's success.

Network Topology of the FL Infrastructure

The network topology choice for implementing FL can vary from client-server, peer-to-peer, tree-based hierarchical, or hybrid topologies. While peer-to-peer architecture is more cost-effective and offers a high capacity, it has the disadvantages of a lack of security and privacy constraints and a complex troubleshooting process in the event of a failure. The choice of network topology for this study is based on a client-server architecture, offering a single point of control in the form of the central server.

Choice of Model Aggregation Site

For a client-server architecture, the model aggregation can occur either in one of the data providers' machines, the central server, or in a dedicated aggregation server. For this implementation, we opted to use a dedicated aggregation server. The details and benefits of the implementation are discussed in the next section.



Training Strategy

The communication mechanism for transferring weights can be either synchronous, asynchronous, or semisynchronous, and weights can be consolidated using ensemble learning, FedAvg, split learning, weight transfer, or swarm learning. The strategy used for this study is based on a synchronous mechanism using the FedAvg algorithm. This gives a simple approach, where the averaging algorithm waits for all the data centers to transfer the locally trained model before initiating the averaging.

Based on the assumption, Figure 2 depicts the overall architecture of the federated deep learning study presented in the paper. The next section describes the FL Infrastructure in detail.

XSL•FO
RenderX

Figure 2. Overall architecture of ARGOS (artificial intelligence for gross tumor volume segmentation) federated deep learning architecture adapted from Vantage6. The figure depicts a researcher connected to the central server, a secure aggregation server, trains carrying models, connected data stations, and the communicating tracks.

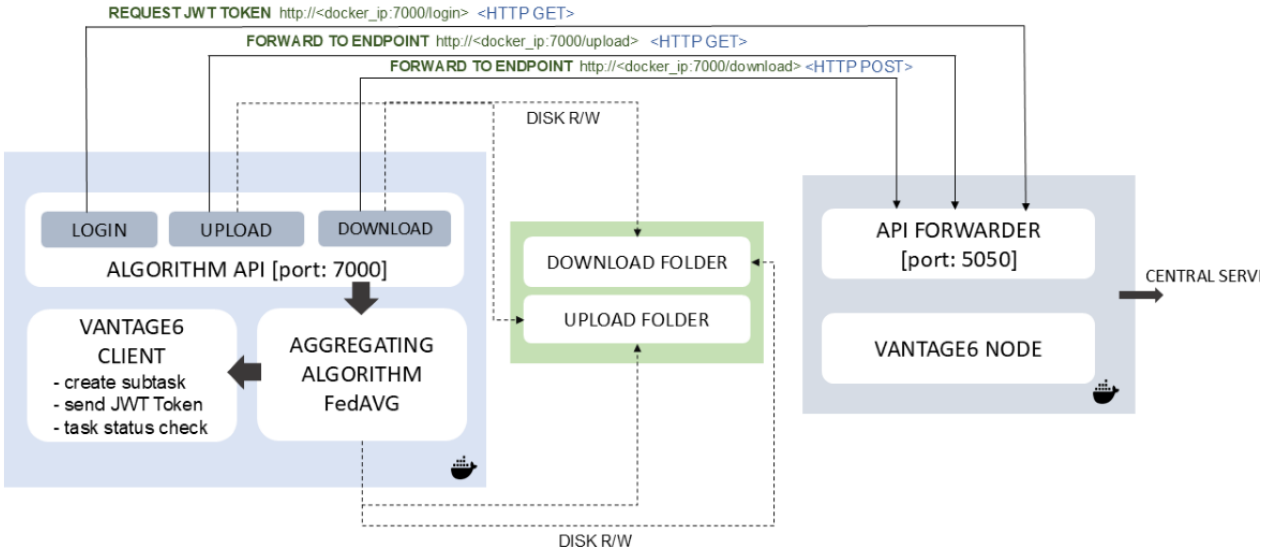
The ARGOS Federated Deep Learning Infrastructure

Overview

In accordance with the PHT principles, the ARGOS infrastructure is comprised of 3 primary categories of components, labeled as the data stations, the trains, and the track. Furthermore, the architectural framework encompasses various roles that map to the level of permissions and access, specifically a track provider, the data providers, and the researcher. The infrastructure implementation can be further categorized into 3 important components: a central coordination server, a secure aggregation server (SAS), and the nodes located at each "data station." In the following sections, we attempt to describe each of these components and the respective stakeholders responsible for maintaining them.

Central Coordinating Server

The central coordination server is located at the highest hierarchical level and serves as an intermediary for message exchange among all other components. The components of the system, including the users, data stations, and SAS, are registered entities that possess well-defined authentication mechanisms within the central server. It is noteworthy that the central acts as a coordinator rather than a computational engine. Its primary function is to store task-specific metadata relevant to the task initiated for training the deep learning algorithm. In the original Vantage6 infrastructure, the central server also stores the intermediate results. In the ARGOS infrastructure, the central server is designed to not store any intermediate results but only the global aggregated model at the end of the entire training process.



Secure Aggregation Server

The SAS refers to a specialized station that contains no data and functions as a consolidator of locally trained models. The aggregator node is specifically designed to possess a Representational State Transfer (REST)–application programming interface (API) termed as the API Forwarder. The API Forwarder is responsible for managing the requests received from the data stations and subsequently routing them to the corresponding active Docker container, running the aggregation algorithm.

To prevent any malicious or unauthorized communication with the aggregator node, each data station is equipped with a JSON Web Token (JWT) that is unique for each iteration. The API Forwarder only accepts communications that are accompanied by a valid JWT. The implementation of this functionality guarantees the protection of infrastructure users and effectively mitigates the risk of unauthorized access to SAS. Figure 3 shows the architecture and execution mechanism for the SAS.

XSL•FO
RenderX

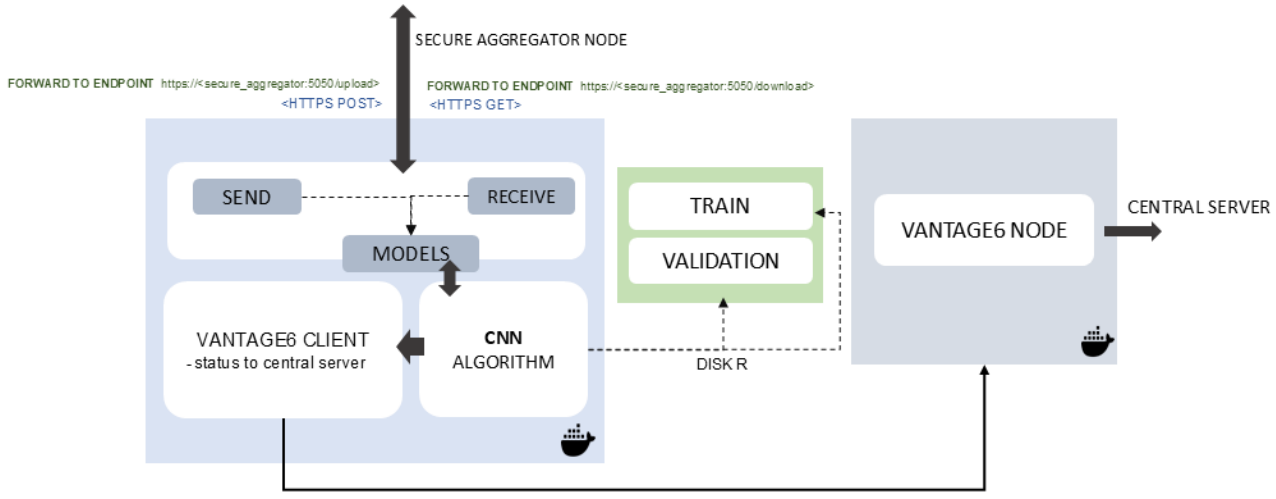


Figure 3. Architecture of the secure aggregation server, showing incoming and outgoing requests from the data station nodes. The upload and download folders are temporary locations used within the running Docker container to store the local and averaged models through disk read or write operations. The API forwarder, running at port 5050 and embedded within the Vantage6 infrastructure, forwards the incoming requests from the data station nodes to the algorithm API running at local port 7000 within the Docker container through HTTP requests. The SAS is hosted behind the firewall of a proxy server, which allows only hypertext transfer protocol secure (HTTPS) communication from the participating nodes. API: application programming interface; FedAvg: federated averaging; JWT: JSON Web Token.

Data Stations

Data stations are devices located within the confines of each hospital's jurisdiction that are not reachable or accessible from external sources other than Vantage6. The data stations communicate with the central server through a pull mechanism. Furthermore, the data stations not only serve as hosts for the infrastructure node but also offer the essential computational resources required for training the deep learning network. The infrastructure node is the software component installed in the data stations that orchestrates the local execution of the model and its communication with the central server and the SAS. Each data station is equipped with at least 1 graphics processing unit (GPU), which enables the execution of CNNs. Preprocessing of the raw CT images was executed locally, using automated preprocessing scripts packaged as Docker containers, and the preprocessed CT images are stored within a file system volume in each station. The CNN Docker is designed and allowed to access the preprocessed images during training. The primary function of the data station is to receive instructions from both the SAS and the central server, perform the computations needed for training the CNN algorithm, and subsequently transmit the model weights back to the respective sources. Figure 4 depicts the architectural layout of the data station and node component of the infrastructure.

Figure 4. Architecture of the data station node component. The node runs the CNN algorithm to learn from the local data. The node further sends and receives model weights from the secure aggregation server. The train and validation folders are persistent locations within the data stations, storing the preprocessed NIFTI images. At the end of each training cycle, the intermediate averaged model is first evaluated on the validation sample. CNN: convolutional neural network; HTTPS: hypertext transfer protocol secure; NIFTI: neuroimaging informatics technology initiative.

XSL•FO
RenderX

Train

The "train" in the form of a Docker image encompasses several components bundled together: an untrained U-Net [48,49], a type of CNN architecture designed for image segmentation tasks for training on local data; the aggregation algorithm used for consolidating the models; and a secondary Python Flask API known as the Algorithm API for facilitating the communication of these models. The Algorithm API is designed to cater to requests from the API Forwarder and is built within the algorithm container. Two levels of API ensured that the node could handle multiple requests and divert to appropriate Docker containers. Furthermore, the first level of API also helps in restricting malicious requests by checking the JWT token signature, so that the models within the master Docker container are protected. Each data station is responsible for training and transmitting the CNN model to the aggregator server. This suggests that the aggregation algorithm exhibits a waiting period during which it ensures that all data stations have effectively transmitted their models to the server before proceeding to the next iterations. The process is executed in an iterative manner until convergence is achieved or the specified number of iterations is attained.

Tracks and Track Provider

The various infrastructure components establish coordination among themselves through the use of secure communication channels commonly referred to as the "tracks." The communication channels are enabled with end-to-end encryption. The responsibility for the maintenance of the infrastructure, including the hosting of the central coordinating server and the specialized SAS, lies with the track provider. The track provider is additionally accountable for the maintenance of the "tracks" and aids the data providers in establishing the local segment of the infrastructure known as the "nodes."

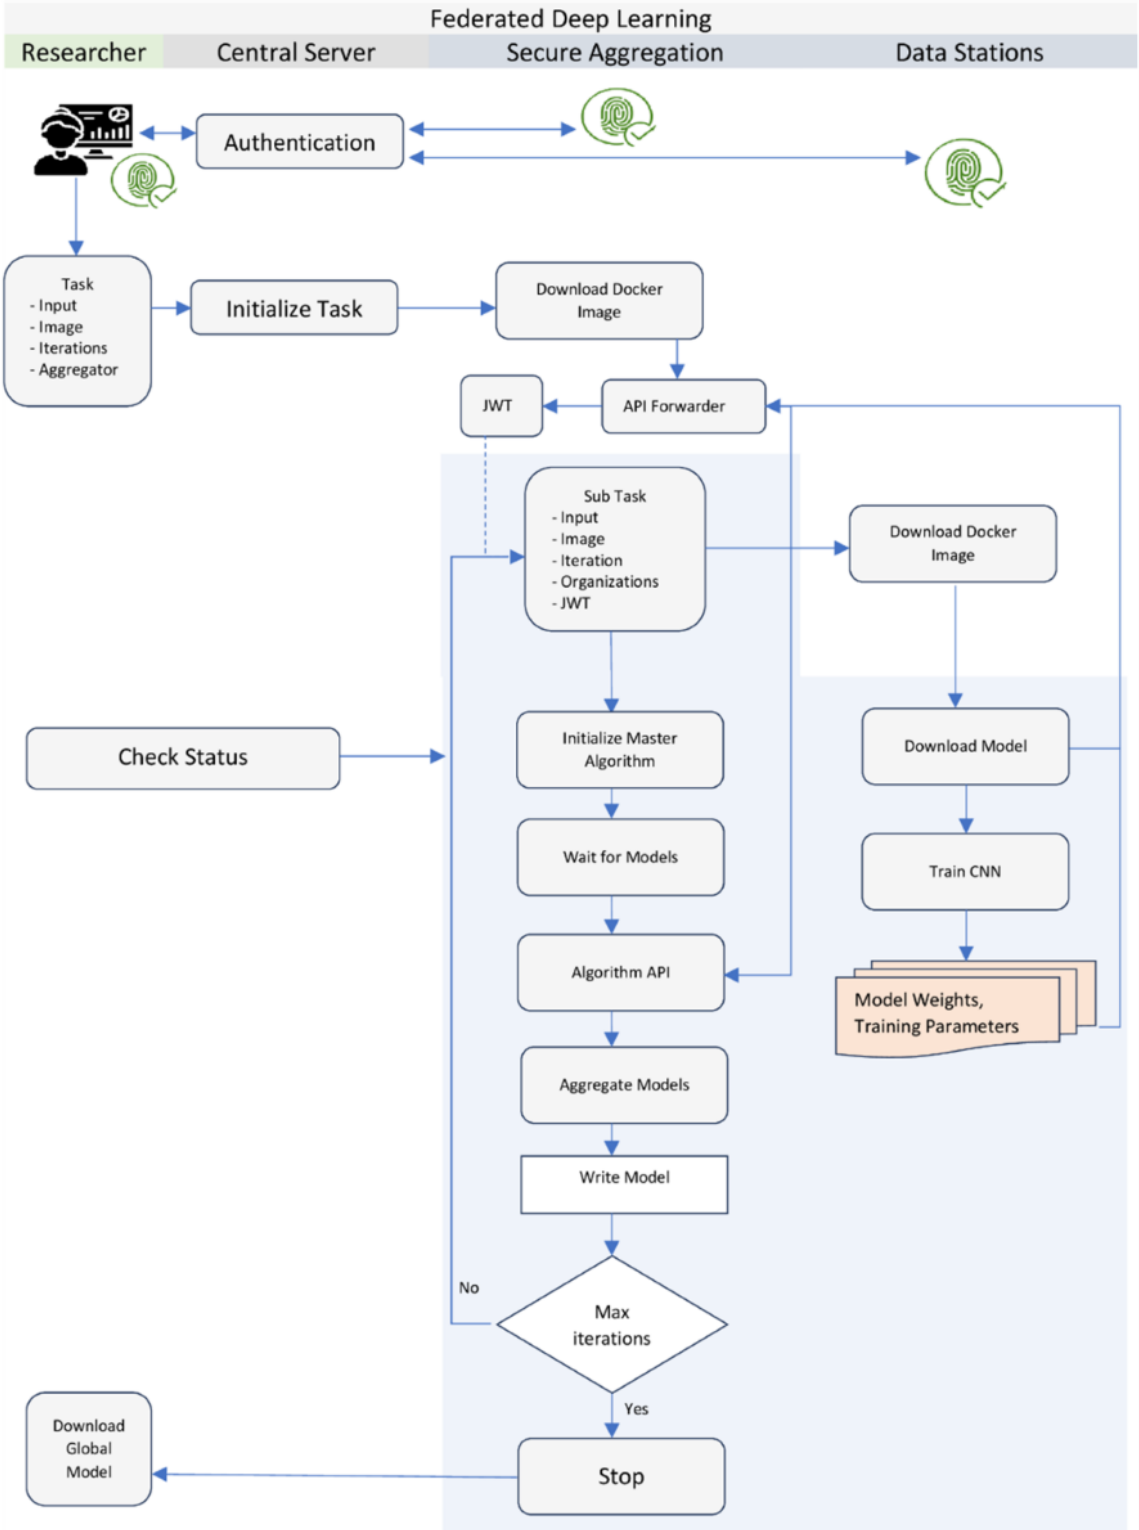
Data Provider

Data providers refer to hospitals and health care organizations that are responsible for curating the pertinent datasets used for training the deep learning network. The responsibility of hosting the data stations within their respective local jurisdiction lies with the data provider. They exercise authority over the data as well as the infrastructure component called the node.

Researcher

The researcher is responsible for activating the deep learning algorithm and engaging in the authentication process with the central coordinating server using a registered username and password. This allows the researcher to establish their identity and gain secure access to the system, with their communication safeguarded through end-to-end encryption. The researcher can then assign tasks to individual nodes, monitor progress, and terminate tasks in the event of failure. Importantly, the researcher's methodology is designed to keep the intermediate outcomes of the iterative deep learning training process inaccessible, ensuring that the ultimate global model can only be obtained upon completion of all training iterations, thereby mitigating the risk of unauthorized access by malicious researchers to the intermediate models and providing a security mechanism against insider attacks.

Training Process



Each of the components described above works in a coordinated manner to accomplish the convergence of the deep learning algorithm. The training process begins with the researcher authenticating with the central server. Upon successful authentication, the researcher specifies the task details, including a prebuilt Docker image, input parameters, number of iterations, and the identity of the SAS. The task is then submitted to the central server, which forwards it to the connected nodes. The SAS is the first to receive the task request. It downloads the specified Docker image from the registry and initiates the master algorithm. The master algorithm orchestrates the training at each data station node through the central server. The central server then forwards a subtask request to all the data stations. Like the SAS, the data nodes download the same Docker image and initiate the node part of the algorithm. The node algorithm runs the learning process on local data for the specified number of epochs. After each training cycle, the node algorithm sends the local model weights to the SAS.

The SAS verifies the JWT signature of each received model and forwards the request to the Algorithm API. The Algorithm API extracts the weight and metadata information of the models. Once the SAS receives all the required locally trained models for that cycle, it initiates the FedAvg algorithm to consolidate the models and create an intermediate averaged model, which is stored locally. This completes the first iteration of the training cycle. For the second and subsequent iterations, the data stations request the SAS to send the intermediate averaged model weights from the previous iteration. The SAS validates these requests and sends the model weights to the data stations, which then use them for further training on their local data. This cycle of training and averaging continues until the model converges or the desired number of iterations is reached.

At the end of the training process, the SAS sends a notification to the researcher indicating the successful completion of the task. The researcher can then download the final global model from the server. It is important to note that during the training iterations, the researcher or other users of the infrastructure do not have access to the intermediate averaged models generated by the SAS. This design choice prevents the possibility of insider attacks and data leakage, as users cannot regenerate patterns from the training data using the intermediate models. Figure 5 shows the diagrammatic representation of the training process spread across the infrastructure components.

XSL•FO
RenderX

Figure 5. Process illustration of federated deep learning training. All entities, including the researcher, the central aggregation server, and the data stations, first authenticate with the central server. The researcher creates a task description and submits the task to the central server, which then forwards the request to the secure aggregation node to start the master task. The master task then sends a request to all data stations to download the algorithm Docker image and start training on the local data. Researchers can monitor the algorithm's execution status on the central server using the "check status" function, which reports whether each iteration is completed or aborted as processed by the secure aggregation server and data stations. At the end of each local training, the data stations send the models to the API forwarder of the secure aggregation node by authenticating against a valid JWT token. The JWT token ensures that no unauthorized data station is able to send or receive models from the secure aggregation server. API: application programming interface; CNN: convolutional neural network; JWT: JSON Web Token.

Code Availability

The federated deep learning infrastructure and the algorithm used in this research are open source and publicly available. The codebase, encompassing the components of the infrastructure, the algorithm, and wrappers for running it in the infrastructure and the researcher notebooks, are all available and deposited on GitHub, a public repository platform, under the Apache 2.0 license. This open access allows the research community to scrutinize and leverage our implementation for further development in the field of FL.

The Vantage6 (version 2.0.0) [27,50] open-source software was customized to cater to the specific requirements for running the deep learning algorithm. The central server (Vantage6 version 2.0.0) and the aggregator server were hosted by Medical Data Works BV in 2 separate cloud machines (Microsoft Azure). At each participating center, the "node" component of the software was installed and setup either on a physical or cloud machine running Ubuntu (version 16.0) or above with an installation of Python, (version 3.7 or above; Python Software Foundation), Docker Desktop (personal edition), and NVIDIA CUDA GPU interface (version 11.0). The source code of the customized "node" [51] and setup instructions [52] are available on respective GitHub repositories. The federated deep learning algorithm was adapted to the infrastructure as Python scripts [53] and wrapped in a Docker container. Separately, the "researcher" notebooks [54] containing python scripts for connecting to the infrastructure and running the algorithms are also available on GitHub. Table 2 provides an outline of the resource requirement and computational cost of the experiment.

Table 2. Resource requirement and computational cost.

End points	Resource requirement		Average execution time (per iteration)
	Software	Hardware	
Central server	• Ubuntu (version 16) and above • Docker Desktop • Python (3.7 or above) • Vantage6 (version 2.0.0)	• 4 CPUsa • 16 GB RAM • 20 GB Disk Space	N/A[b]
Data station	• Ubuntu (version 16) and above • Docker Desktop • Python (3.7 or above) • Vantage6 (version 2.0.0) • CUDA GPU Interface (version 11.0)	• 4 CPUs • 1 GPUc • 16 GB RAM • 40 GB disk space	40 mins
Secure aggregation server	• Ubuntu (version 16) and above • Docker Desktop • Python (3.7 or above) • Vantage6 (version 2.0.0)	• 4 CPUs • 16 GB RAM • 40 GB disk space	60 seconds

[a]CPU: central processing unit.

[b]Not applicable.

[c]GPU: graphics processing unit.

Ethical Considerations

The work was performed independently with the ethics board's approval from each participating institution. Approvals from each of the participating institutions including soft copies of approval have been submitted to the leading partner. The lead partner's institutional review board approval (MAASTRO Clinic, The Netherlands) is "W 20 11 00069" (approved on November 24, 2020). The authors attest that the work was conducted by the ethical standards of the responsible committee on human experimentation (institutional and national) and with the Helsinki Declaration of 1975.

Results

Overview

The study was carried out and concluded in 4 primary stages using an agile approach as follows: planning, design and development, partner recruitment, and execution of federated deep learning. The planning phase of the study, which encompassed a meticulous evaluation and determination of the following inquiries, held equal significance to the description of the clinical issue and data requirements.

- What are the minimum resource requirements for each participating center?
- How to design a safe and robust infrastructure to effectively address the requirements of a federated deep learning study?
- How can a reliable and data-agnostic federated deep learning algorithm be designed?
- What are the operational and logistical challenges associated with conducting a large-scale federated deep learning study?

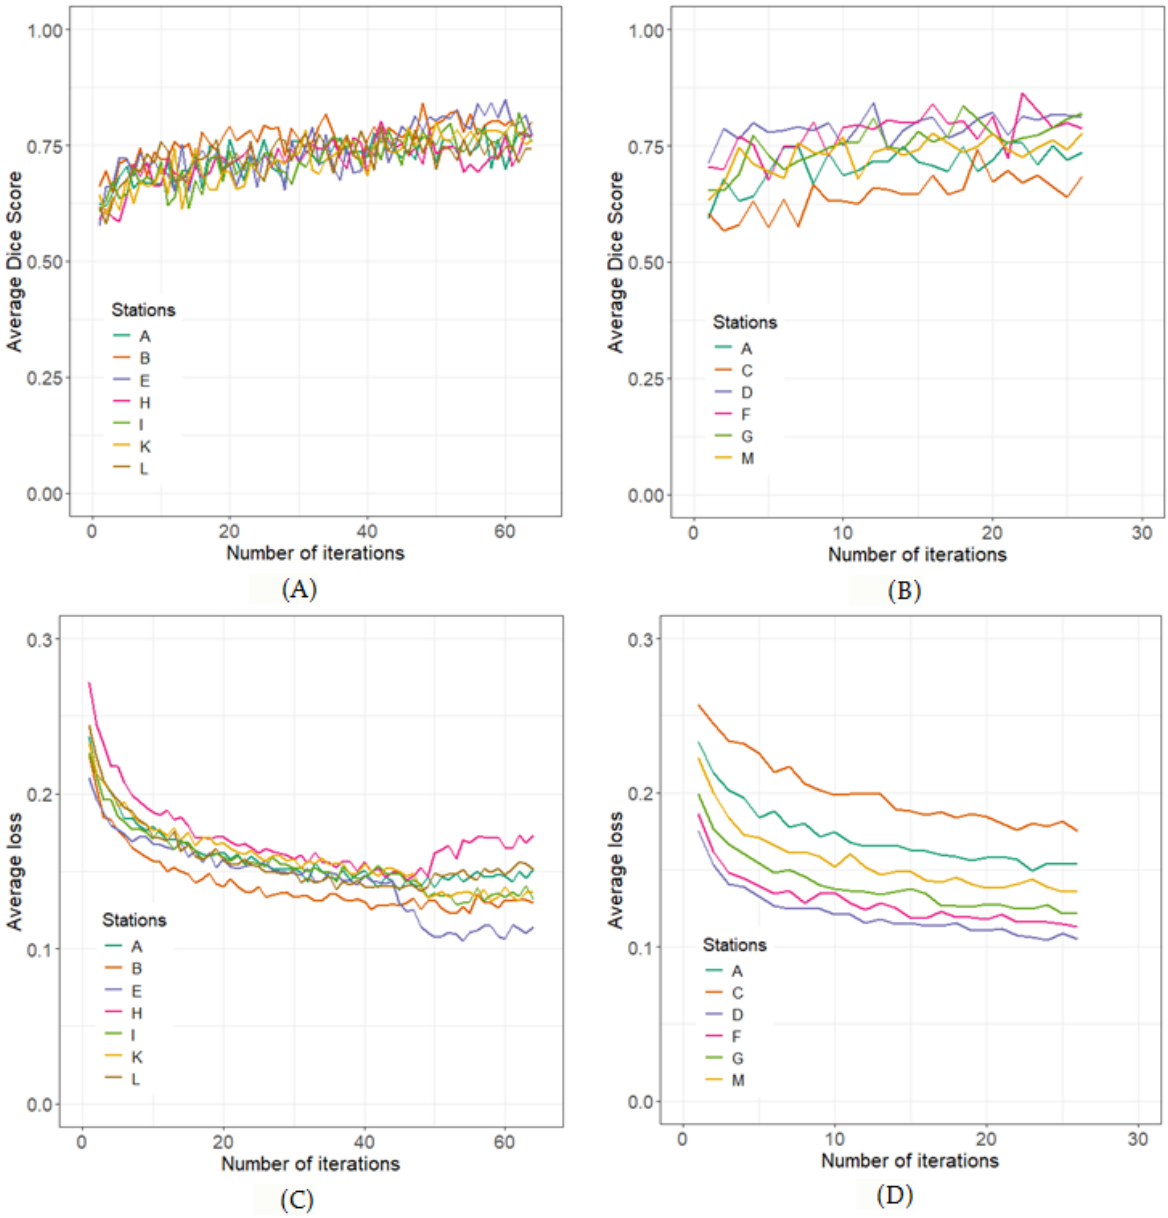
The second phase, that is, the design and development phase, primarily focused on the creation, testing, and customization of the Vantage6 infrastructure for studies specifically focused on deep learning. To meet the security demands of these

XSL•FO
RenderX

investigations, this study involved the development of the SAS, which was not originally included in the Vantage6 architecture. The CNN algorithm was packaged as a Docker container and made compatible with the Vantage6 infrastructure, allowing it to be easily deployed and used within the Vantage6 ecosystem. Prior to the deployment of the algorithm, it underwent testing using multiple test configurations consisting of data stations that were populated with public datasets.

The primary objective of the third phase entailed the recruitment of partners who displayed both interest and suitability from various global locations. The project consortium members became part of the project by obtaining the necessary institutional review board approvals and signing an infrastructure user agreement. This agreement enabled them to install the required infrastructure locally and carry out algorithmic execution. The inclusion criteria for patient data, as well as the technology used for data anonymization and preprocessing, were provided to each center. The team collaborated with each partner center to successfully implement the local component of the infrastructure.

The concluding stage of the study involved the simultaneous establishment of connections between all partner centers and the existing infrastructure. The algorithm was subsequently initiated by the researcher and the completion of the predetermined set of federated iterations was awaited across all centers.



Proof of Concept

The architectural strategy described above was implemented among ARGOS consortium partners on real-world lung cancer CT scans. For an initial “run-up” of the system, we deployed the abovementioned PHT system across 12 institutions, located in 8 countries and 4 continents. A list of members participating in the ARGOS consortium can be found on the study protocol [26]. In total, 2078 patients’ data were accessible via the infrastructure for training (n=1606) and holdout validation (n=472). For this initial training experiment, the 12 centers were divided into 2 groups. The first, referred to as group A, comprised 7 collaborators, and we were able to reach a total of 64 iterations of model training each with 10,000 steps per iteration. Likewise, group B comprising 6 hospitals was able to train the deep learning model for 26 iterations. It was observed that no significant improvement of the model was observed for both groups after 26th iteration. The results from the proof-of-concept study are shown in Figure 6.

While the training time for the models was similar at each center, how quickly they could be uploaded and downloaded depended heavily on the quality of the internet connection. This meant the entire process was significantly slowed down by the center with the slowest internet.

XSL•FO
RenderX

Figure 6. Plots showing the results from training the convolutional neural network on two groups as follows: group 1 (A, B, E, H, I, K, L) and group 2 (A, C, D, F, G, M). (A) Average Dice score per iteration of the model trained on group 1. (B) Average Dice score per iteration of the model trained on group 2. (C) Average training loss per iteration of the model trained on group 1. (D) Average training loss per iteration of the model trained on group 2.

Discussion

This study demonstrated the feasibility of a privacy-preserving federated deep learning infrastructure and presented a proof-of-concept study for GTV segmentation in patients with lung cancer. Using the PHT framework, the infrastructure linked 12 hospitals across 8 nations, showcasing its scalability and global applicability. Notably, throughout the process, no patient data were shared outside the participating institutions, addressing significant data privacy concerns. The introduction of a SAS further ensured that model averaging occurred in a secure environment, mitigating potential data leakage issues in FL.

One of the most used methodologies in recent years has been the use of FL for promoting research on privacy-sensitive data. To orchestrate FL on nonstructured data in the horizontal partitioning context, it is essential to develop specialized software for edge computation and technical infrastructures for cloud aggregation. These infrastructures enable federated machine learning (FML) responsibilities to be carried out in a secure and regulated manner. However, only a limited number of these studies have documented the background governance strategies and the ethical, legal, and social implications framework for conducting such studies.

The study presented a novel approach for executing large-scale federated deep learning on medical imaging data, integrating geographically dispersed real-world patient data from cross-continental hospital sites. The deep learning algorithm was designed to automatically delineate the GTV from chest CT images of patients with lung cancer who underwent radiotherapy treatment. The underlying FL infrastructure architecture was designed to securely perform deep learning training and was tested for vulnerabilities from known security

XSL•FO
RenderX

threats. This paper predominantly discussed the FL infrastructure architecture and presented a firsthand experience of conducting such studies. The preliminary training of the deep learning algorithm serves as the feasibility demonstration of the methodology, and further refinement is required to achieve acceptable clinical-grade accuracy and generalizability.

The study used an open-source and freely accessible technological stack to demonstrate the feasibility and applicability of federated deep learning. Vantage6, a Python-based FL infrastructure, is used to train and coordinate deep learning execution. TensorFlow and Flask, both open-source Python libraries, are used for the development of the algorithm, subsequently encapsulated within Docker services for containerization purposes. The communication channels between the hospital, central server, and the aggregation node have been secured using Hypertext Transfer Protocol Secure and Secure Hash Algorithm encryption. The hospital sites' computer systems were based on the Ubuntu operating system and equipped with at least 1 GPU to enhance computational capabilities. The participating centers had the flexibility to choose any CUDA-compatible GPU devices and determine the number of GPUs to use, enabling resource-constrained centers to contribute. However, a limitation exists in terms of computational time due to the synchronous training process being dependent on the slowest participant.

The infrastructure has been tested against known security attacks and as defined by the Open Worldwide Application Security Project top-ten categories [55]. It has been found that the Vantage6 app is impeccable against insecure design, software and data integrity failures, security logging and monitoring failures, and server-side request forgery and sufficiently secured against broken access control, cryptographic failures, injection, security misconfigurations, vulnerable and outdated components, and finally identification and authentication failures. Since the infrastructure is dependent on other underlying technologies like Docker and Flask-API, the security measures in these technologies also affect the overall security of the infrastructure. Additionally, the infrastructure is hosted behind proxy firewalls, adding to its overall security against external threats.

In this study, we implemented a SAS positioned between the data nodes (eg, hospitals and clinics) and the central server. The SAS plays a crucial role in strengthening the privacy and confidentiality of the learning process. The SAS acts as an intermediary that temporarily stores the local model updates from the participating data nodes, ensuring complete isolation from the central server, researchers, and any external intruders. The key benefits of using a dedicated SAS over a random aggregation mechanism in FL are as follows:

- Privacy protection of individual user data and model updates:
  - The secure aggregation protocol ensures that the central server only learns the aggregated sum of all user updates, without being able to access or infer the individual user's private data or model updates.
  - By isolating the intermediate updates, the secure aggregation process prevents external attackers from performing model inversion attacks.
- Tolerance to user dropouts:
  - The SAS is designed to handle situations where some users fail to complete the execution. In the case of synchronous training, the server stores the latest successful model, enabling data nodes to pick up where they left off instead of restarting from scratch.
- Integrity of the aggregation process:
  - The secure aggregation protocol provides mechanisms to verify the integrity of the intermediate models by allowing only the known data nodes to send a model. This maintains the reliability and trustworthiness of the FL system.

FL offers 2 main approaches for model aggregation: sending gradients or weights [56,57]. In gradient sharing, data nodes update local models and transmit the gradients of their parameters for aggregation. Conversely, weight sharing involves sending the fully updated model weights directly to the server for aggregation. Sharing gradients have a higher risk of model inversion attacks. In the study presented here, the data nodes sent model weights instead of model gradients, thus preventing the "gradient leakage" problem. However, weight sharing is not failproof either [58], and the SAS plays a crucial role again in preventing users—internal or external—from accessing the weights from the aggregator machine.

The deployment of the FL infrastructure and training of the deep learning algorithm presented unique challenges that needed to be catered to. Some of them are listed below:

- Heterogeneity across hospitals: Initially, it was not possible to confirm the technology environment at each site. This required significant work to overcome the obstacles connected with each center while deploying a functional infrastructure, good communication, and efficient algorithms.
- Inconsistent IT policies: Standardizing the setup across institutions was hindered by varying IT governance and network regulations in different health care systems across different countries.
- Clinical expertise gap: The predominance of medical personnel over IT specialists at participating hospitals necessitated extensive documentation to ensure clinician comprehension of the FL process.
- Network bottlenecks: Network configurations at participating sites significantly impacted training duration, often leading to delays in model convergence.

The study presented in the paper has identified several areas that require further investigation and improvement. While the findings are valuable, the infrastructure, algorithm, and processes still need to be made more secure, private, trustworthy, robust, and seamless [59]. For example, incorporating homomorphic encryption of the learned models will enhance privacy and provide model obfuscation against inversion attacks. Finally, to further enhance confidence and trust in federated artificial intelligence, it is crucial to conduct additional studies involving a larger number of participating centers and a thorough clinical evaluation of the models.

Acknowledgments

We would like to express our sincere appreciation and gratitude to Integraal Kankercentrum Nederland (IKNL), the Netherlands, for their invaluable contribution in providing us with the necessary infrastructure support. We express our gratitude to Medical Data Works, the Netherlands, for their role as the infrastructure service provider in hosting the central and secure aggregation server. We also express our gratitude to Varsha Gouthamchand and Sander Puts for their contribution to the successful execution of the experiments. In conclusion, we express our gratitude to the various data-providing organizations for their substantial support and collaboration throughout all stages of the project. AC, LV, RF, and LW acknowledge financial support from the Dutch Research Council (NWO) (TRAIN project, dossier 629.002.212) and the Hanarth Foundation.

Conflicts of Interest

Dr AD and JvS are both cofounders, shareholders, and directors of Medical Data Works B.V.

Abstract

Background: Chat-based counseling services are popular for the low-threshold provision of mental health support to youth. In addition, they are particularly suitable for the utilization of natural language processing (NLP) for improved provision of care.

Objective: Consequently, this paper evaluates the feasibility of such a use case, namely, the NLP-based automated evaluation of satisfaction with the chat interaction. This preregistered approach could be used for evaluation and quality control procedures, as it is particularly relevant for those services.

Methods: The consultations of 2609 young chatters (around 140,000 messages) and corresponding feedback were used to train and evaluate classifiers to predict whether a chat was perceived as helpful or not. On the one hand, we trained a word vectorizer in combination with an extreme gradient boosting (XGBoost) classifier, applying cross-validation and extensive hyperparameter tuning. On the other hand, we trained several transformer-based models, comparing model types, preprocessing, and over- and undersampling techniques. For both model types, we selected the best-performing approach on the training set for a final performance evaluation on the 522 users in the final test set.

Results: The fine-tuned XGBoost classifier achieved an area under the receiver operating characteristic score of 0.69 (P<.001), as well as a Matthews correlation coefficient of 0.25 on the previously unseen test set. The selected Longformer-based model did not outperform this baseline, scoring 0.68 (P=.69). A Shapley additive explanations explainability approach suggested that help seekers rating a consultation as helpful commonly expressed their satisfaction already within the conversation. In contrast, the rejection of offered exercises predicted perceived unhelpfulness.

Conclusions: Chat conversations include relevant information regarding the perceived quality of an interaction that can be used by NLP-based prediction approaches. However, to determine if the moderate predictive performance translates into meaningful service improvements requires randomized trials. Further, our results highlight the relevance of contrasting pretrained models with simpler baselines to avoid the implementation of unnecessarily complex models.

Introduction

Most mental health disorders develop early in life [1,2], causing a massive burden on an individual [3], as well as societal, level [4]. This makes early intervention in youth highly relevant [5]. In sharp contrast to the need, accessing help has been described as challenging for young people [5-7]. Therefore, low-threshold services are needed to tackle the burden of mental illness [8].

One such form of intervention gaining popularity is chat-based counseling hotlines [9-11]. Smartphones and chat interactions play a crucial role in youth life [12,13]. The ability to access help within their native digital life reduces numerous health care barriers, making the services a common first access point of help for youth [14]. Indeed, heavy utilization and adoption of those services have been reported globally [14-16]. In addition, the first evidence supports the acceptability [14] and effectiveness [17] of 24/7 chat services.

Considering the increasingly established relevance of those hotlines, the implementation of technological innovation could be highly impactful for the timely and efficient provision of care to youth. Repeatedly, artificial intelligence (AI) has been framed as a key potential for improvements in mental health care [18,19], as well as within digital settings [20]. As AI depends on the availability of large and high-dimensional datasets, chat services seem a quite promising candidate for that. This has indeed been used for diverse natural language processing (NLP) approaches, the subbranch of AI dealing with language. For example, an NLP-based triaging system has been reported to be able to reduce waiting times for those in crisis at a chat hotline [21]. Data-driven decisions regarding further treatment paths have also been investigated by looking into the prediction of recurrent chatting [22] or premature departure from conversations [23]. As suicide risk is a common case at chat hotline services [24], other work focused on early detection and intervention in those situations. Here, several model structures and algorithmic approaches have been suggested [25,26].

This study intends to contribute to the development of NLP approaches within youth chat counseling hotlines. Specifically, the promising but underinvestigated use case of automated evaluation of service quality will be explored. A recent study linked asynchronous chat counseling interactions with reported outcomes and satisfaction of the chatters, using a large dataset of more than 150,000 clients and reporting promising effect sizes of multiple *R*'s of around 0.45 [27]. Another past approach investigated the prediction of chat quality on a label of 675 transcripts of chat counseling sessions [28]. However, while we were not able to find a similar-minded approach within 24/7 hotline services, automated quality evaluation seems particularly relevant for those. Early experiences with help seeking have been linked with future help-seeking behavior in the past [29]. As often being the first contact with any kind of institutionalized help for youth [14], the satisfaction with this interaction is therefore arguably highly relevant for further help-seeking behavior. The reliable identification of those with negative experiences would allow a timely intervention by following up or referrals to other services. Second, the low threshold nature of counseling hotlines makes evaluation more difficult, as it is hard to collect follow-up responses from young help seekers. For example, the aforementioned study of chat hotline effectiveness reported a response rate of 22% among the users [17]. There is also the risk of a bias toward those more satisfied being more likely to respond, which is seen as a common methodical problem in evaluation sciences [30,31]. The ability to estimate the satisfaction with the service out of the conversation data for those who did not respond to any follow-up surveys could therefore significantly improve the evaluation and monitoring of the service quality.

In light of the relevance of the automated evaluation of chat interactions at chat hotlines, as well as the interventions raising relevance for youth mental health care, this project uses a naturalistic sample of 2609 young chatters that were counseled by the German 24/7 hotline service krisenchat. Feedback regarding the perceived helpfulness of the chat is used to train classifiers on the anonymized consultation texts. Performance is evaluated on a previously unseen test set addressing the feasibility of the approach, hypothesizing that we can significantly predict the feedback response by the chatter. Additionally, we assume that applying a pretrained transformer-based model as the state-of-the-art NLP will allow us to outperform a simpler non–transformer-based approach.

Methods

Preregistration

This study was preregistered at Open Science Framework [32]. The preregistration was updated once, as we adapted the used statistical test for the algorithm comparison (see the *Final Evaluation* section under *Methods*) and corrected the questionnaire item used for the outcome variable. We used the checklist for reporting machine learning studies by Klement and El Emam [33], which can be found in Multimedia Appendix 1. Due to legal restrictions regarding the highly vulnerable sample of this study, we are unable to share the dataset. However, the code used for training the algorithm and predicting the helpfulness can be found on GitHub [34], as a starting point for future work.

Ethical Considerations

The data collected and used for this study were part of a larger research project that was ethically approved by the University of Leipzig (372/21-ek). Additionally, we submitted the proposed secondary data analysis to the ethics committee of the Humboldt-Universität zu Berlin. They confirmed that this analysis does not require additional approval. Before the use of this study, the data were subject to a multistep anonymization procedure. Specifically, personally identifying information was marked by counselors and deleted by the organization. Additionally, there also was an automatized method in place to delete names and locations that might have been missed by the counselors. Finally, a k-anonymity principle was applied, deleting all words that were not part of at least 5 different chats.

Setting and Intervention

The anonymized data used for this study were provided by krisenchat, a German 24/7 chat counseling service for people

XSL•FO
RenderX

aged up to 25 years. At krisenchat, those contacting the service through WhatsApp are provided with chat counseling, either by volunteer or employed psychologists, psychotherapists, or social workers. A central aspect of the consultations is the provision of exercises and resources, for example, by sharing YouTube videos, blog posts, or providing them within the chat. However, counselors are also trained in providing emotional support as needed, as well as providing information about mental health care structures in Germany, such as access to psychotherapy or the youth office.

Sample

Data were accessed and shared by the organization on January 17, 2024. On this date, there were feedback questionnaires available for 4560 chatters. Those questionnaires were sent out as part of a larger research project on the service [14]. A total of 264 participants were either younger than 13 years or older than 25 years of age and therefore excluded. While the upper age limit resulted from the scope of the service, the lower age limit resulted from data privacy considerations. An additional 1631 of the chatters were in contact with the service in the last 4 months. A help seeker's inactivity for at least 4 months is an organizational requirement for assuming the consultation purpose has ended and the chat is deleted by anonymization. Accordingly, active chats were also excluded, leading to 2664 concluded conversations and the related feedback questionnaire, with feedback provided between July 22, 2022, and September 17, 2023. For those cases, all messages exchanged between help seekers and counselors within 72 hours before the response to the feedback questionnaire were included. We then excluded cases where conversations consisted of fewer than 10 messages. This led to additional exclusions and resulted in a final sample of 2609 chatters. Their consultations consisted of 141,404 messages, 82,335 by the help seekers and 59,052 by the counselors. Therefore, on average, there were 54 messages exchanged in the three days before the feedback response, 23 messages by the counselor and 31 messages by the help seeker.

Outcome Variable

The feedback questionnaire answered by the chatters included several questions regarding the chat interaction (see Multimedia Appendix 2 for the full questionnaire). For this study, we decided on the use of a single item asking for the helpfulness of the chat ("Did the chat help you?" in German: "Hat dir der Chat geholfen?"), as being the most direct assessment available of chat quality and success, as perceived by the young clients. While the item had four possible answers ("Yes," "Rather Yes," "Rather No," and "No"), we decided to dichotomize it into "Yes" or "No." Reasons for that were improved actionability (as most clinical decision-making is binary by nature, such as providing additional help—yes or no), as well as considering the high-class imbalance. Overall, 89% (n=2332) of the chatters rated the chat as helpful. Specifically, 61 chatters responded with "No," 216 chatters responded with "Rather No," 1138 chatters responded with "Rather Yes," and 1194 chatters responded with "Yes."

Algorithm Training

All decisions regarding algorithmic specifications were made on the 80% of the available data used as a training set. Specifically, we separated the newest 20% of the consultations (522 chats who submitted their feedback after May 27, 2023) as a test set, a commonly used approach to mimic the evaluation of a previously implemented model (eg, [35]).

For our non–transformer-based approach, we preprocessed the data by lowering all words, deleting stop words, and using a lemmanizer [36]. Afterward, a term frequency-inverse document frequency (TF-IDF) vectorizer was used for feature extraction. This vectorizer counts the occurrences of words and weights them based on their frequency across the whole sample. This algorithm was trained using a 5-times repeated 5-fold stratified cross-validation principle. Hyperparameters were tuned using Bayesian optimization maximizing the receiver operating characteristic (ROC) area under the curve (AUC) score for 250 iterations. While there has been some discussion about the applicability of this metric facing class imbalance (eg, [37]), we saw its appropriateness backed up by systematic comparisons [38] and analysis [39] on the issue. All hyperparameters optimized during this procedure are summarized in Table 1. Those also included, as suggested by a reviewer, the range of ngrams used by the vectorizer. Therefore, bigrams and trigrams of words of the messages were also usable as predictors. The used over- or undersampling method was also selected during this procedure, comparing oversampling, undersampling, and Synthetic Minority Oversampling Technique [40]. As a classifier, we applied and tuned an extreme gradient boosting (XGBoost) [41] classifier, as well as a logistic regression. The training pipeline can be found on GitHub.

Table 1. Overview of shortlisted transformer-based models.

Model	Input length, n	Source
uklfr/gottbert-base	512	[42]
distilbert/distilbert-base-german-cased	512	[43]
LennartKeller/longformer-gottbert-base-8192-aw512	8192	[44]

We used hugging face for all transformer-based approaches [42]. We shortlisted GottBERT [43], as well as a German DistilBERT model [44], as language-specific models to be evaluated. However, we assumed that a significant share of our data would exceed those models' input length. Therefore, we also intended to evaluate a Longformer model [45]. This model can process much longer input sequences at reasonable computational costs by applying a sparse attention mechanism (see Table 1 for the shortlisted models including links). We also intended to explore over- and undersampling, as well as class weights to tackle the class imbalance. To represent the chat structure appropriately to the algorithm, we introduced two new

XSL•FO
RenderX

special tokens to the models, named "[USER]" and "[CNSLR]." Those were added at the beginning of each message, presenting the conversation structure in a processable format to the models. For hyperparameter tuning, a grid search across the learning rate (2×10^{-5}, 3×10^{-5}, and 5×10^{-5}) and the batch size (1, 2, and 4) was performed for the preselected most promising model. The training and tuning were done at a stratified train-validation split (70:30 of the data used for algorithm training), as the repeated cross-validation principle applied for the TF-IDF approach was infeasible due to computational costs. Therefore, a train-validation-test split (56:24:20) was used as an evaluation principle, with the same data being kept aside as final test data for the nontransformer approach. All transformer-based models were trained on an NVIDIA GeForce RTX 3090 graphics processing unit with 24 GB video random access memory.

Final Evaluation

The 522 newest conversations with feedback were used as a test set. The distribution of the outcome did not differ significantly between the training and test data (t_{520}=–1.1; *P*=.30). We decided to predict the outcome with the best performing TF-IDF approach and the most promising transformer approach, as identified on the train set as described above. We then applied a permutation test [46] to evaluate the significance of both algorithms. Finally, we contrasted the achieved AUCs of the two approaches, applying a DeLong test [47], which has been suggested for this scenario [48]. We decided for this procedure above the 5×2 McNemar test [49] originally proposed in our preregistration. This reconsideration was mainly made due to the inability of the McNemar test to statistically compare AUC scores. The comparison of accuracies seemed disadvantageous to us, as focusing on the performance for one specific threshold. In contrast, considering the different proposed use cases, we were more interested in a threshold-independent comparison of classifier performance. As a threshold-dependent metric, we reported the Matthews correlation coefficient (MCC), which is particularly helpful in cases of imbalanced classes [50]. We followed the suggestion in the literature to use a default threshold of 0.5 [51] for the calculation of a confusion matrix and the corresponding MCC score.

Explainability

We used Shapley additive explanation (SHAP) values [52] as an explainability framework. This game-theory–based approach is applicable for transformer models [53] and XGBoost classifier [54].

Results

Algorithm Training

For the TF-IDF-based approach, the best set of hyperparameters selected through the tuning approach led to a mean ROC AUC score of 0.70 (SD 0.02) across repeated cross-validation for the XGBoost classifier. For this, a minimum occurrence of the word stems for 20 different chatters and for five different counselors was selected as a hyperparameter for the vectorizers. Random oversampling was selected for handling class imbalance. Counselors word stems were only selected when occurring in 30% or less of the conversations, while chatters word stems were allowed in up to 90% of the conversations. In addition, trigrams and bigrams were included, as well as predictors (see Table 2 for all hyperparameters). This was slightly above the performance of logistic regression, scoring 0.66 for the best set of hyperparameters.

RenderX

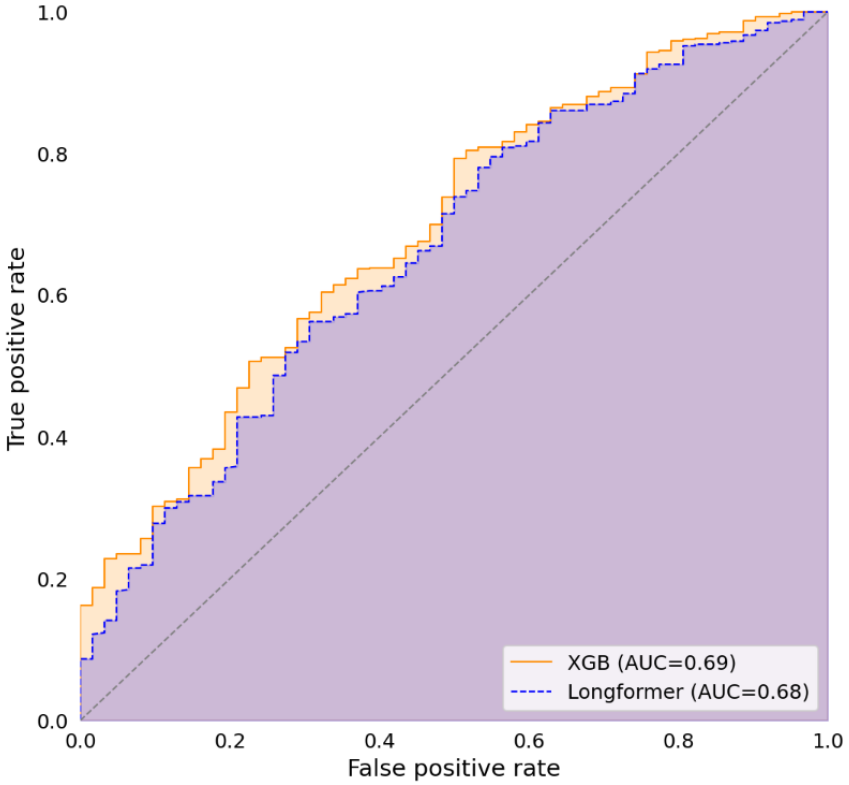
Table 2. Overview of tuned hyperparameters (definitions adapted from [22]).

Hyperparameters	Description	Value range	Selected parameter
max_df_chatter	Terms that appear in more chatter documents than the threshold value are ignored. The value represents the proportion of documents	0.2, 0.3, 0.4, 0.5, 0.6, 0.7, 0.8, 0.9, 1.0	0.9
min_df_chatter	Terms that appear in fewer chatter documents than the threshold value are ignored	1, 2, 5, 10, 25, 50, 75, 100, 150, 200	20
max_df_couns	Analogous to max_df_chatterfor counselor messages	0.2, 0.3, 0.4, 0.5, 0.6, 0.7, 0.8, 0.9, 1.0	0.3
min_df_couns	Analogous to min_df_chatter for counselor messages	1, 2, 5, 10, 25, 50, 75, 100, 150, 200	5
Sampling method	Method for handling imbalance	ROS[a], RUS[b], SMOTE[c]	RandomOverSampler
colsample_bytree	Subsample ratio of columns for growing trees	0.2, 0.4, 0.6, 0.7, 0.8, 0.9, 1.0	1.0
eta	Learning rate	0.005, 0.01, 0.05, 0.1, 0.2	0.1
gamma	Minimum loss reduction to make a further split on a leaf node	0, 0.25, 0.5, 1, 1.5, 2, 5, 10	1.5
max_depth	Maximum depth of a tree	2, 4, 6, 8, 10, 12, 14, 16	16
min_child_weight	Minimum sum of instance weight (Hessian) needed in a child	1, 5, 10, 20	10
subsample	Subsample ratio of the training instances prior to growing trees	0.2, 0.4, 0.6, 0.7, 0.8, 0.9, 1.0	0.9
use_idf	Whether to term frequencies should be reweighted by the inverse document frequencies	True, false	True
ngram_range	Length of word sequences used as predictors	(1,1), (1, 2), (1,3)	(1,3)

[a]ROS: random over sampler.

[b]RUS: random under sampler.

[c]SMOTE: Synthetic Minority Oversampling Technique.



For the transformer-based approach, we reached a ROC AUC of 0.58 for the DistilBERT and 0.59 for the GottBERT models, using class weights (9:1) and five epochs. Comparable performances were reached when random oversampling was used instead of the class weights. We expected the performance to be limited by strong truncation. Therefore, we explored the average length of the input sequence with DistilBERT as tokenizer. Data points in the train set contained on average 1889 (SD 873) tokens, showing that those models could just use a share of the available data on the chat conversations. However, with the longest conversation holding 8507 tokens, the Longformer model structure seemed capable of capturing nearly all information contained in our data. Indeed, using the Longformer model in combination with class weights (9:1), three epochs, a learning rate of 3e-5, and a batch size of one resulted in a significantly higher ROC AUC of 0.69. Neither other methods for handling class imbalance nor different epoch sizes lead to a further improved performance.

Final Evaluation

While the performance between the transformer and non–transformer-based approach was similar during training (0.69 vs 0.70), this comparison is limited by the differences in the used validation principle. However, the large previously unseen test set allowed us the comparison of the two best-of-class models in a final evaluation. Here, we reached an ROC AUC of 0.68 for the Longformer model and an ROC AUC of 0.69 for the TF-IDF–based approach, both significantly outperforming randomness in a permutation test (P<.001 for both). However, as expected, considering the similar performance, there was no significant difference between the two approaches (P=.69). The ROC curves are plotted in Figure 1, showing how threshold and model performance interacted.

RenderX

Figure 1. ROC AUC curves comparing the two algorithms. AUC: area under the curve; ROC: receiver operating characteristic; XGB: extreme gradient boosting.

Consequently, we used the TF-IDF approach as the simpler algorithm for further insights, as well as the explainability approach. The average precision score here was 0.93 (SD 0.02) on the test set. The MCC score for the default threshold of 0.5 was 0.25 on the test set. The confusion matrix on this threshold can be found in Figure 2. Here, a positive predictive value of 0.90 and a negative predictive value (NPP) of 0.50 were achieved, with "positive" being coded as helpful. The sensitivity was 0.98 and the specificity was 0.18.

RenderX

Explainability

We applied SHAP values on the vectorizer-based approach. The most predictive word identified here was “no” by the chatters, being associated with a higher chance of an unhelpful perceived chat. Two other predictors of unhelpfulness were the word “bad” (original: “schlimm”) by the counselor, as well as “nevertheless” (original: “trotzdem”) by the chatter, and “further on” (original: “weiterhin”) by the counselor. In addition, some bigrams were among the most predictive variables. For example, “shift end” (German: “Schicht endet”), indicating that a counselor had to end a conversation due to their shift being over, was associated with negative feedback. For an improved understanding of the context those words were used, we looked into chats using those and giving negative feedback afterward. While “no” was used in diverse settings, there was a notable number of cases where chatters denied the counselor’s offering of further help such as an exercise. “Bad” was used on several occasions where chatters reported highly traumatic experiences they had. Finally, “further on” was a phrase repeatedly used by counselors to announce the end of their shift and offer further support from a colleague afterward. There were also several words being predictive of perceived helpfulness. Several of those implied that a chatter expressed satisfaction with the interaction at the end of a chat. For example, the word stem “thanks” (original: “dank”) was predictive of higher perceived helpfulness, as was “great” (original: “toll”). We also investigated those conversations that were predicted with the highest likelihood of being labeled as unhelpful afterward. Again, there were several cases included where chatters rejected suggested exercises by the counselor. In addition, in several conversations with a high risk of unhelpfulness, it was reported that mental health care is already received, such as regularly seeing a psychiatrist or being hospitalized in a clinic. As one of the core functions of chat hotlines is the redirection into care, it might be harder to make a satisfying offer to those. The 20 most predictive words as identified by the tree-based SHAP approach can be found in Figure 3.

Figure 3. The 20 most predictive word stems as identified by the SHAP approach for the TF-IDF algorithm. SHAP: Shapley additive explanations; TF-IDF: term frequency-inverse document frequency.

Discussion

Primary Findings

This project investigated the use of NLP techniques for an automated evaluation of the perceived helpfulness of chat-based counseling. We were able to reach a ROC AUC of 0.67 on the previously unseen test set for a transformer, as well as for a non–transformer-based approach. Our explainability part revealed several linguistic markers of perceived unhelpful chat consultations such as the written expression of thankfulness, or the extensive use of the word "no" for rejecting the different offers made by counselors.

The reached performance was moderate, though significant and in line with past work from the identical settings [22]. However, the feasibility of an AI use case always depends on the performance considering the proposed use case. The given study implied two potential uses of predicted helpfulness of the chats.

The first use case was the real-time identification of unsuccessful consultations, as perceived by the chatter. Due to the very harmful impact of such experiences, those predictions could be used for a tailored follow-up, for example, with details of different treatment options for those affected. In our example, we would have identified 30 of the 62 unhelpful rated conversations with the approach, though 79% of all identified cases would have been false negatives (with negative referring to perceived unhelpfulness).

An alternative approach would have been a much stricter threshold, letting us mark significantly less chats but with higher NPP. For example, on a threshold of 0.3, our NPP would have doubled. However, the consequences of wrongly identifying chatters as unsatisfied might be less relevant than missing those being unsatisfied in light of the possible negative consequences of further help seeking. Overall, whether one of those approaches could be valuable would depend on whether the benefits for those correctly identified are larger than the costs of providing the intervention based on the prediction. Finally, this is an empirical question that we cannot answer here sufficiently. This highlights the large need for randomized controlled trials for prediction studies, moving from feasibility to actually showing clinical benefits [55].

A second use case of the proposed algorithm lies less on the individual and more on a population-based level. As evaluation within naturalistic and low-threshold settings is commonly difficult, the developed algorithm could be applied to those who did not respond to feedback questionnaires. This application would allow a better-informed estimation of satisfaction with the service where just a minority provides active feedback. A reliable estimate of this core metric of the service would propose a huge value for organizational purposes. Without any alternative of estimating the satisfaction of those not providing feedback being available, the proposed algorithm already provides an improvement over the status quo as clearly performing above the chance level. However, particularly for systematic comparison of, for example, monthly satisfaction, the question arises whether the performance is sufficient for reliable inference. Here, simulation studies might help to better understand the relation between performance and the reliability of algorithm-based evaluation.

Secondary Findings

Interestingly, there was no further gain in predictive capability by using the computational heavy and pretrained Longformer model. The failure of more complex NLP models to outperform simpler ones is not unique to the given setting and has been reported before [56-58]. However, based on the literature, we started the work on this paper with an opposing hypothesis. For example, a popular study [59] compared Bidirectional Encoder Representations from Transformer–based approaches with TF-IDF–based algorithms and reported a clearly better performance for the former. An in-depth look into the used methods provides several possible explanations for the diverging results. First, the cited study used a larger sample of 50,000 distinct cases, while using the much smaller Bidirectional Encoder Representations from Transformer base model. Therefore, the dataset size might have been insufficient to finetune such a sophisticated model. Second, the use case is different, while algorithmic performance is highly case specific. The cited study focuses on sentiment analysis. Arguably, the extraction from word vectors into higher-dimensional spaces like sentiment as done by transformer models is particularly relevant here. While our explainability approach revealed some sentiment-related predictors like words of thankfulness, overly sentiment seemed less central than it is for movie reviews as in the aforementioned study. Finally, it remains unclear how much the advantage of simpler models is used in comparative studies. For example, in our approach, we were able to perform extensive hyperparameter tuning using sophisticated cross-validation principles. The relevance of this to produce generalizable results, and therefore, realistic performance estimates is well established [60,61]. Such approaches are hard to reproduce at feasible computational costs for transformer-based models for a lot of ML practitioners in their day-to-day work. However, waiving those techniques also for the baseline is arguably biasing the comparison against them, as their better capability to be trained with extended cross-validation principles is a real benefit that might translate into predictive performance. Particularly, small predictive performance differences as reported regularly (eg, [25]) might disappear with decent hyperparameter tuning and cross-validation.

In conclusion, while the actual outperformance seems dependent on setting and data, the results of this study, as well as the aforementioned studies, highlight the relevance of benchmarking complex models with simpler ones. Otherwise, overly complex models might be implemented without benefits. There are numerous studies that apply interesting and promising algorithmic approaches but do not compare them with a simpler baseline at all (eg, [62-64]). However, we also argue that a fair comparison includes the utilization of hyperparameter tuning and cross-validation for computationally lighter models.

Limitations

There were limitations to the approach in this paper. First, while we predicted the helpfulness of a chat as perceived by chatters, this perception does not equal to actually being clinically beneficial. For example, in the aforementioned study by Imel

XSL•FO
RenderX

et al [27], the association between message content and satisfaction was much stronger than the association between content and symptom reduction. Therefore, future work could benefit from associating chat messages with clinically validated questionnaires as output. However, arguably changes in symptoms are difficult to measure in hotline settings, where a majority of chatters just contact the service once. Second, we were only able to train the algorithms on the data of those who responded to the feedback questionnaire. This might have introduced a bias, in case of systematic differences between those providing feedback and those who do not. Third, we focused on the application of the Longformer model in the transformer-based approach of this paper. Future work might also benefit from exploring task-specific adaptions of the used algorithms in detail. In addition, different methods of handling long text inputs such as BELT [65] might enable a better performance. Notably, there were no mental health–specific smaller models available in German. Those exist for other languages and use cases [66]. Such models, for example, pretrained on youth mental health data in German, could provide further performance gains as well. Finally, while we used a test set for a final one-time evaluation, this test set still came from the same chat counseling service. However, the relevance of truly external test sets has been highlighted repeatedly as being relevant for more valid claims regarding the generalizability of a chosen approach (eg, [67]).

Conclusions

In summary, there is a predictive signal regarding the perceived service quality in the chat messages at a 24/7 chat hotline for youth. This opens interesting use cases in the quality control and evaluation efforts at those hotlines. Future work such as the randomized evaluation of interventions based on the predicted helpfulness is needed for moving toward real-world implementation.

Abstract

Background: Electronic health records (EHRs) and routine documentation practices play a vital role in patients' daily care, providing a holistic record of health, diagnoses, and treatment. However, complex and verbose EHR narratives can overwhelm health care providers, increasing the risk of diagnostic inaccuracies. While large language models (LLMs) have showcased their potential in diverse language tasks, their application in health care must prioritize the minimization of diagnostic errors and the prevention of patient harm. Integrating knowledge graphs (KGs) into LLMs offers a promising approach because structured knowledge from KGs could enhance LLMs' diagnostic reasoning by providing contextually relevant medical information.

Objective: This study introduces DR.KNOWS (Diagnostic Reasoning Knowledge Graph System), a model that integrates Unified Medical Language System–based KGs with LLMs to improve diagnostic predictions from EHR data by retrieving contextually relevant paths aligned with patient-specific information.

Methods: DR.KNOWS combines a stack graph isomorphism network for node embedding with an attention-based path ranker to identify and rank knowledge paths relevant to a patient's clinical context. We evaluated DR.KNOWS on 2 real-world EHR datasets from different geographic locations, comparing its performance to baseline models, including QuickUMLS and standard LLMs (Text-to-Text Transfer Transformer and ChatGPT). To assess diagnostic reasoning quality, we designed and implemented a human evaluation framework grounded in clinical safety metrics.

Results: DR.KNOWS demonstrated notable improvements over baseline models, showing higher accuracy in extracting diagnostic concepts and enhanced diagnostic prediction metrics. Prompt-based fine-tuning of Text-to-Text Transfer Transformer with DR.KNOWS knowledge paths achieved the highest ROUGE-L (Recall-Oriented Understudy for Gisting Evaluation–Longest Common Subsequence) and concept unique identifier F_1-scores, highlighting the benefits of KG integration. Human evaluators found the diagnostic rationales of DR.KNOWS to be aligned strongly with correct clinical reasoning, indicating improved abstraction and reasoning. Recognized limitations include potential biases within the KG data, which we addressed by emphasizing case-specific path selection and proposing future bias-mitigation strategies.

Conclusions: DR.KNOWS offers a robust approach for enhancing diagnostic accuracy and reasoning by integrating structured KG knowledge into LLM-based clinical workflows. Although further work is required to address KG biases and extend generalizability, DR.KNOWS represents progress toward trustworthy artificial intelligence–driven clinical decision support, with a human evaluation framework focused on diagnostic safety and alignment with clinical standards.

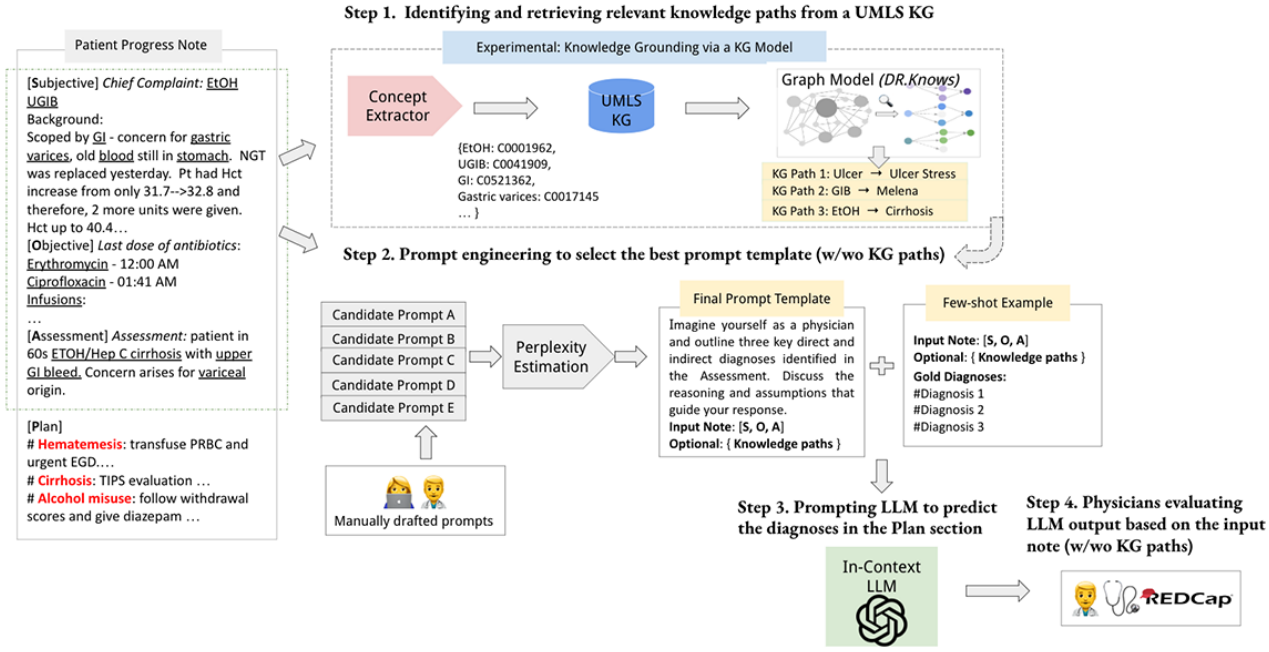
Introduction

Background

The ubiquitous use of electronic health records (EHRs) and the standard documentation practice of daily care notes are integral to the continuity of patient care because these records provide a comprehensive account of the patient's health trajectory, inclusive of condition status, diagnoses, and treatment plans [1]. Nevertheless, the growing complexity and verbosity of EHR clinical narratives, which are often filled with redundant information, can overwhelm health care providers and increase the risk of diagnostic errors [2-5]. Physicians often skip sections of lengthy and repetitive notes and rely on decisional shortcuts (ie, decisional heuristics) that can contribute to diagnostic errors [6].



Current efforts at automating diagnosis generation from daily progress notes leverage large language models (LLMs). Gao et al [7] introduced a summarization task that takes progress notes as input and generates a summary of active diagnoses. The authors annotated a set of progress notes from the publicly available EHR dataset Medical Information Mart for Intensive Care III (MIMIC-III) [8]. The BioNLP 2023 shared task, known as ProbSum, built upon this work by providing additional annotated notes and attracting multiple efforts focused on developing solutions [9-11]. Demonstrating a growing interest in applying LLMs to serve as solutions, these prior studies use language models such as Text-to-Text Transfer Transformer (T5) [12], developed by Google Research; and Open AI's Generative Pretrained Transformer (GPT) [13]. Unlike the conventional language tasks where LLMs have shown promising abilities, automated diagnosis generation is a critical task that requires high accuracy and reliability to ensure patient safety and improve health care outcomes. Concerns regarding the potential misleading and hallucinated information that could result in life-threatening events prevent LLMs from being used for diagnostic prediction [14].

The Unified Medical Language System (UMLS) [15], a comprehensive resource developed by the National Library of Medicine in the United States, has been extensively used in natural language processing (NLP) research. The UMLS serves as a medical knowledge repository, facilitating the integration, retrieval, and sharing of biomedical information. It offers concept vocabulary and semantic relationships, enabling the construction of medical knowledge graphs (KGs). Prior studies have leveraged UMLS KGs for tasks such as information extraction [16-19] and question answering [17]. Mining relevant knowledge for diagnosis is particularly challenging for 2 reasons: the highly specific factors related to the patient's complaints, histories, and symptoms documented in the EHR; and the vast search space within a KG containing 4.5 million concepts and 15 million relations for diagnosis determination.

In this study, we explore the use of KGs as external resources to enhance LLMs for diagnosis generation. Our work is motivated not only by the potential in the NLP field of augmenting LLMs with KGs [20] but also by the theoretical exploration in medical education and psychology research, shedding light on the diagnostic decision-making process used by clinicians. Forming a diagnostic decision requires the examination of patient data, retrieving encapsulated medical knowledge, and the formulation and testing of the diagnostic hypothesis, which is also known as clinical diagnostic reasoning [21,22]. We propose a novel graph model, DR.KNOWS (Diagnostic Reasoning Knowledge Graph System), designed to retrieve the top N case-specific knowledge paths related to disease pathology and feed them into foundational LLMs to improve the accuracy of diagnostic predictions (as shown in Figure 1). Two distinct foundational models are the subject of this study: T5, known for being fine-tunable; and a sandboxed version of ChatGPT, a powerful LLM where we explore zero-shot prompting.

XSL•FO
RenderX

Figure 1. Study overview: we focused on generating diagnoses (text given in red in the "Plan" section) using the SOAP (subjective, objective, assessment, and plan) format progress note with the aid of large language models (LLMs). The input consists of "Subjective," "Objective," and "Assessment" sections (the dotted line box below the heading "Patient Progress Note"), and the diagnoses in the "Plan" section are the ground truth. We introduced an innovative knowledge graph (KG) model, namely DR.KNOWS (Diagnostic Reasoning Knowledge Graph System), that identifies and extracts the most relevant knowledge trajectories from the Unified Medical Language System (UMLS) KG. The nodes of the UMLS KG represent concept unique identifiers (CUIs), and the edges denote the semantic relations among the CUIs. We experimented with prompting ChatGPT for diagnosis generation, with and without the knowledge paths predicted by DR.KNOWS. Furthermore, we investigated how this knowledge grounding influences the diagnostic output of LLMs using human evaluation. The underlined text shows the UMLS concepts identified through a concept extractor. EtOH: ethanol; GI: gastrointestinal; REDCap: Research Electronic Data Capture; T5: Text-to-Text Transfer Transformer; UGIB: upper gastrointestinal bleeding.

Objectives

Our work and contribution are structured into two primary components: (1) designing and evaluating DR.KNOWS, a graph-based model that selects the top N probable diagnoses with explainable paths; and (2) demonstrating the usefulness of DR.KNOWS as an additional module to augment pretrained language models in generating relevant diagnoses. Along with the technical contributions, we propose the first human evaluation framework for LLM-generated diagnoses that adapts a survey instrument designed to evaluate diagnostic safety. Our research poses a new exciting problem that has not been addressed in the realm of NLP for diagnosis generation, that is, harnessing the power of KGs for the controllability and explainability of foundational models. By examining the effects of KG path–based prompts on foundational models on a real-world hospital dataset, we strive to contribute to an explainable artificial intelligence (AI) diagnostic pathway.

Several studies have focused on the application of clinical note summarization to discharge summaries [23], hospital course narratives [24], real-time patient visit summaries [25], and problem and diagnosis lists [7,26,27]. Our work follows the line of research on problem and diagnosis summarization. The integration of KGs with LLMs has been gaining traction as an emerging trend due to the potential enhancement of factual knowledge [20], especially on domain-specific question-answering tasks [28-30]. Our work stands out by integrating KGs into LLMs for diagnosis prediction, using a novel graph model for path-based prompts.

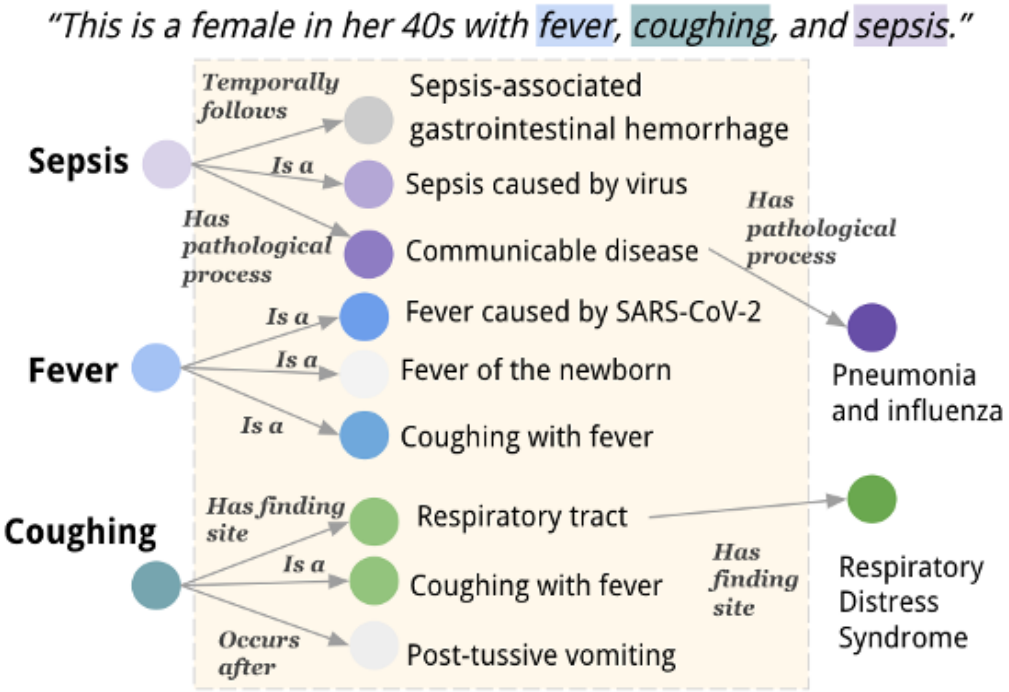
Methods

Problem Formulation

Daily Progress Notes for Diagnosis Prediction

Daily progress notes are formatted using the SOAP (subjective, objective, assessment, and plan) format [30]. The subjective section of a SOAP daily progress note comprises the patient's self-reported symptoms, concerns, and medical history. The objective section consists of structural data collected by health care providers during observation or examination, such as vital signs (eg, blood pressure and heart rate), laboratory results, or physical examination findings. The assessment section summarizes the patient's overall condition, with a focus on the most active problems and diagnoses for that day. Finally, the plan section contains multiple subsections, each outlining a diagnosis or problem and its treatment plan. Our task is to predict the list of problems and diagnoses that are part of the plan section. Our research used the ProbSum dataset, an annotated resource created for the BioNLP 2023 shared task with gold standard diagnoses derived from progress notes [27].

Using UMLS KGs to Find Potential Diagnoses, Given Medical Narratives



The UMLS concepts vocabulary comprises >180 sources. For our study, we focused on the Systematized Nomenclature of Medicine–Clinical Terms (SNOMED CT). The UMLS vocabulary is a comprehensive, multilingual health terminology and the US national standard for EHRs and health information exchange. Each UMLS medical concept is assigned a SNOMED

XSL•FO
RenderX

CT concept unique identifier (CUI) from the clinical terminology system. We used semantic types, networks, and semantic relations from UMLS knowledge sources to categorize concepts based on shared attributes, enabling efficient exploration and supporting semantic understanding and knowledge discovery across various medical vocabularies.

Given a medical KG where the nodes represent concepts and the edges denote semantic relations along with an input text describing a patient's problems, we could perform multihop reasoning across the KG and infer the final diagnoses. Figure 2 demonstrates how UMLS semantic relations and concepts can be used to identify potential diagnoses from the evidence provided in a daily care note. The example patient presents with medical conditions of fever, cough and sepsis, which are the concepts recognized by medical concept extractors (Clinical Text Analysis and Knowledge Extraction System [31] and QuickUMLS [32]) and the starting concepts for multihop reasoning. Initially, we extracted the direct neighbors for these concepts. Relevant concepts that aligned with the patient's descriptions were preferred. For precise diagnoses, we chose the top N most relevant nodes at each hop.

Figure 2. Problem formulation: inferring possible diagnoses within 2 hops from a Unified Medical Language System (UMLS) knowledge graph given a patient's medical description. The UMLS medical concepts are highlighted in the colored boxes ("female," "sepsis," etc). Each concept has its own subgraph, where concepts are the vertices, and semantic relations are the edges (owing to space constraints, we have omitted the subgraph for "female" in this graph presentation). On the first hop, we could identify the most relevant neighboring concepts to the input description. The darker the color of the vertices, the more relevant they are to the input description. A second hop could be further performed based on the most relevant nodes, leading to the final diagnoses "Pneumonia and influenza" and "Respiratory distress syndrome." Of note, we use the preferred text of concept unique identifiers for presentation purposes. The actual UMLS knowledge graph is built on concept unique identifiers rather than preferred text.

The UMLS's vast repository consists of 270 semantic relations, but not all are crucial for diagnostic reasoning. Adding the nonrelevant relations into a KG introduced substantially complexities in both computation and retrieval processes. A board-certified physician (MA) refined these to identify the 107 most relevant relations for diagnostics, which were then used to build the UMLS KG. This selection, including relations such as "causative agent of" and excluding ones such as "inverse isa," is vital to maintaining computational efficiency and retrieval accuracy within the KG.

Data Overview

We used 2 sets of progress notes from different clinical settings in this study: MIMIC-III and in-house EHR datasets. MIMIC-III is one of the largest publicly available databases containing deidentified health data from patients admitted to intensive care units. It was developed by the Massachusetts Institute of Technology and Beth Israel Deaconess Medical Center. MIMIC-III includes data from >38,000 patients admitted to intensive care units at the Beth Israel Deaconess Medical Center between 2001 and 2012. The second set, namely the in-house EHR data, was a subset of EHRs that included adult patients (aged 18 years) admitted to the University of Wisconsin health system between 2008 and 2021. In contrast to the MIMIC-III subset, the in-house set covered progress notes from all hospital settings, including the emergency department, general medicine wards, and subspecialty wards. While the 2 datasets originated from separate hospitals and departmental settings and might reflect distinct note-taking practices, both followed the SOAP documentation format for progress notes.

Gao et al [7,9] introduced a subset of 1005 progress notes from MIMIC-III with active diagnoses annotated from the "plan" sections, namely, the ProbSum dataset. Therefore, we applied this dataset for training and evaluation for both graph model intrinsic evaluation and diagnosis summarization. The in-house dataset did not contain human annotation. Even so, by parsing

XSL•FO
RenderX

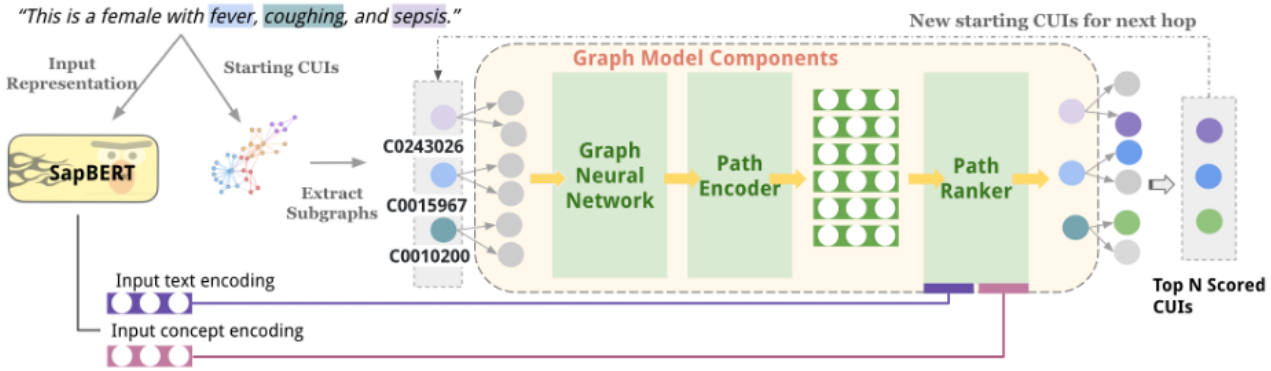
the text with a medical concept extractor that was based on UMLS SNOMED CT vocabulary, we were able to pull out concepts that belonged to the semantic type of "T047 Disease and Syndromes." We deployed this set of concepts as the ground truth data to train and evaluate the graph model. The final in-house dataset contained 4815 progress notes. We present the descriptive statistics in Table 1. When contrasted with MIMIC-III, the in-house dataset exhibited a greater number of CUIs in its input, leading to an extended CUI output. In addition, MIMIC-III encompassed a wider range of abstractive concepts compared to the in-house progress notes.

Table 1. Average number of concept unique identifiers (CUIs) in the input and output across the 2 electronic health record datasets: Medical Information Mart for Intensive Care III (MIMIC-III) and in-house. Abstractive concepts are those not found in the input but present in the gold standard diagnoses.

Datasets	Departments	Input CUIs (n), mean (SD)	Output CUIs (n), mean (SD)	Abstractive CUIs (%)
MIMIC-III	ICU[a]	15.95	3.51	48.92
In-house	All	41.43	5.81	<1

[a]ICU: intensive care unit.

Graph Model Development



Overview

This section introduces the architecture design for DR.KNOWS. The DR.KNOWS model is designed to enhance automated diagnostic reasoning by integrating structured clinical knowledge from the UMLS into patient-specific diagnostic predictions. By leveraging a graph-based approach, DR.KNOWS retrieves and ranks relevant knowledge paths from the UMLS, ensuring that only clinically pertinent information is considered. Using a graph neural network, DR.KNOWS incorporates topological information from the UMLS KG into concept representations to better determine each node's relevance to the patient's specific conditions.

Architecture Overview

As shown in Figure 3, all identified UMLS concepts with an assigned CUI from the input patient text were used to retrieve 1-hop subgraphs from the constructed large UMLS KG. Each node in this graph represents a CUI; therefore, we use "node" and "concept (CUI)" interchangeably throughout. These 1-hop subgraphs are encoded by a stack graph isomorphism network (SGIN) [33], which generates node embeddings that capture both neighboring concept information and pretrained concept embeddings. We chose the SGIN for node embedding because it matches the expressive power of the Weisfeiler-Lehman graph isomorphism test, maximizing the graph neural network's ability to capture meaningful representations. The resulting node embeddings serve as the basis for path embeddings, which the path encoder further processes.

Figure 3. DR.KNOWS (Diagnostic Reasoning Knowledge Graph System) model architecture. The input concepts ("female," "fever," etc) are represented by concept unique identifiers (CUIs) represented as a combination of letters and numbers (eg, "C0243026" and "C0015967"). SapBERT: Self-alignment Pretrained Bidirectional Encoder Representations from Transformers.

The path encoder module then evaluates these 1-hop paths by examining their semantic and logical alignment with the input text and concept representations, assigning a relevance score to each path. The top N scores across these paths, aggregated across each node's neighboring paths, guide the selection of nodes for the next hop. If no suitable diagnosis node is found, the path exploration terminates by assigning a self-loop to the current node.

While the dominant technique for retrieval-augmented generation systems relies heavily on vector representations and cosine similarity for retrieving and ranking candidate text, our work goes beyond this by adding 2 extra layers of design. First, we leverage the expressive power of the graph structure to enhance the retrieval process. Second, we select paths not simply based on their embeddings but through an attention network that encodes the path-concept relationships, ensuring a more accurate and contextually relevant selection process. In the following paragraphs, we present details regarding each component in the architecture of DR.KNOWS.

Contextualized Node Representation

We define the deterministic UMLS KG $G = VE$ based on SNOMED CT CUIs and semantic relations, where V is a set of CUIs, and E is a set of semantic relations. Given an input text x containing a set of source CUIs $V_{src} \subseteq V$ and their 1-hop relations $E_{src} \subseteq E$, we can construct relation paths for each

XSL•FO
RenderX

source node $v_{src} \subseteq V_{src}$ as $P = \{p_1, p_2,...p_j\}$ such that $p_j = \{v_1, e_1, v_2,...e_{j-1}, v_j\}$, $j \subseteq J$, where J is the maximum length that a source node v_{src} could reach and is nondeterministic. Relations e are encoded as one-hot embeddings. We concatenate all concept names for v_i with special tokens such as [SEP] (for "separator"), such that l_i = [name 1 [SEP] name 2 [SEP]...] and encode l_i using Self-alignment Pretrained Bidirectional Encoder Representations from Transformers (SapBERT) [34] to obtain h_i as concept representation. This allows the CUI representation to serve as the contextualized representation of its corresponding concept names. We chose SapBERT for its contrastive learning-based training, which discriminates similar concepts and their synonyms. It is evaluated on entity linking tasks and has shown state-of-the-art performance. The h_i is further updated through topological representation using the SGIN to become node representation:

$N(v_i)$ represents the set of neighboring nodes of node v_i,  is the representation of node v_i at layer k, $^{(k)}$ is a learnable parameter at layer k, and $MLP^{(k)}$ is a multilayer perceptron at layer k. GIN iteratively aggregates neighborhood information using graph convolution followed by nonlinearity, modeling interactions among nodes within the set . Furthermore, the stacking mechanism is introduced to combine multiple GIN layers. The final node representation v_i at layer K (last layer) is computed by stacking the GIN layers, where [...;...] denotes matrix concatenation.

We empirically observed that some types of CUIs are less likely to lead to useful paths for diseases, for example, the concept "recent" (CUI: C0332185) is a temporal concept, and the neighbors associated with it are less useful to predict diagnoses. We designed a weighting scheme based on term frequency–inverse document frequency to assign higher weights to more relevant CUIs and semantic types:

W_{CUI} are then multiplied by the corresponding h_i to assign weighted representations to the concept representation.

Path Reasoning and Ranking

For each node representation h_i, we use its n-hop  of the set neighborhood for  for h_i and the associated relation edge  to generate the corresponding path embeddings, with t being the index of the node and its associated neighborhood and relations:

$hi, if\ n=1$

$pi = \{$

, otherwise

where "FFN" is the feedforward network, and n is the number of hops in the subgraph G_{src}. The path embedding p_i is the node embedding itself for the first hop and is recursively aggregated with new nodes and edges as the path extends to the next hop.

To determine each path's relevance to the patient's specific symptoms, we used 2 attention mechanisms—multihead attention (MultiAttn) and trilinear attention (TriAttn)—to compute scores S for each path. Both mechanisms use the patient's input text representation h_x and input list of CUIs h_v, encoded by SapBERT, to capture explicit and intricate relationships in the input data. MultiAttn was used to explicitly capture relationships between the input text, the list of concepts, and the current path, while TriAttn was used to automatically learn these complex relationships through the inner products of the 3 matrices. As demonstrated in Figure 2, for each hop the path tries to achieve based on the input patient description, the candidate concept can add relevant information, provide no new information and remain neutral, or contradict the information already present in the context.

Using MultiAttn, we define the context relevancy matrix H_i and the concept relevancy matrix Z_i as follows:

$Hi = [hx; pi; hx - pi; hx \odot pi]$

$Zi = [hv; pi; hv - pi; hv \odot pi]$

$\alpha i = MultiAttn(Hi \odot Zi),$

$SMulti = \varphi(Relu(\sigma(\alpha i)))$

These relevancy matrices are inspired by a prior work on natural language inference [35], representing logical relations such as neutrality, contradiction, and entailment via matrix concatenation, difference, and product, respectively. Alternatively, TriAttn learns the intricate relations by 3 attention maps:

$\alpha i = (hx, hv, pi) = \Sigma abc\ (hx)a\ (hv)b\ (pi)c\ Wabc$

$STri = \varphi(Relu(\sigma(\alpha i)))$

h_x, h_v, and p_i have the same dimensionality D, and φ is an MLP player. Finally, we aggregate the MultiAttn or TriAttn scores on all candidate nodes and select the top N nodes (concepts) V_N for the next iteration based on the aggregate attention scores:

$V_N = argmax_N(\beta)$

By comparing attention scores across candidate paths, the path ranker selects the top N nodes most relevant to each patient's symptoms, maximizing contextual relevance.

Loss Function

Our loss function consists of 2 parts: a CUI prediction loss L_{pred} and a contrastive learning loss L_{CL}:

$L = L_{pred} + L_{CL}$

XSL•FO
RenderX

For CUI prediction loss, we use binary cross entropy loss to calculate whether the predicted node V_N is in the gold standard label Y:

Where M is the number of sets of gold labels. For contrastive learning loss L_{CL}, we encourage the model to learn meaningful and discriminative representations through comparison with positive and negative samples:

where A_i is the anchor embedding, defined as $h_x \odot h_v$, representing the input text and concept representation. Σ_i indicates a summation over a set of indices i, typically representing different training samples or pairs. Inspired by the study by Hu et al [29], we construct *cos* (A_i, f_i) and *cos* (A_i, f_{i-}) to calculate cosine similarity between A_i and positive feature f_{i+} or negative feature f_{i-}, respectively. A positive feature represents the paths correctly leading to the ground truth concept, while a negative feature embodies the paths that, although starting from the source, culminate in an incorrect concept. This equation measures the loss when the similarity between an anchor and its positive feature is not significantly greater than the similarity between the same anchor and a negative feature, considering a margin for desired separation.

We designed a training algorithm to iteratively select and rank the most relevant paths to extend. This algorithm helped to reduce the computational requirement because it does not rank all n-hop paths within 1 pass. This algorithm is presented in Multimedia Appendix 1.

Selection of Foundational Models and Experiment Setup

Our study centers around the following question: To what extent does the incorporation of DR.KNOWS as a knowledge path–based prompt provider influence the performance of language models in diagnosis summarization?

We present results derived from 2 distinct foundational models, varying significantly in their parameter scales, namely T5-Large, which comprises 770 million parameters [12]; and GPT-3.5-Turbo, which features 154 billion parameters [13]. Specifically, we were granted access to a restricted version of the GPT-3.5-Turbo model, which served as the underlying framework for the highly capable language model, ChatGPT.

These 2 models represent the prevailing direction in the evolution of language models: smaller models such as T5 that offer easier control and larger models such as GPT that generate text with substantial scale and power. Our investigation focused on evaluating the performance of T5 in fine-tuning scenarios and GPT models in zero-shot settings. Our primary objective was not solely to demonstrate cutting-edge results but also to critically examine the potential influence of incorporating predicted paths, generated by graph models, as auxiliary knowledge contributors.

We selected 3 distinct T5-Large variants for fine-tuning using the ProbSum summarization dataset. The chosen T5 models encompass the vanilla T5 [12], a foundational model that has been extensively used in varied NLP tasks; Flan-T5 [36], which has been fine-tuned using an instructional approach; and Clinical-T5 [37], which has been specifically trained on the MIMIC dataset.

Given that our work encompasses a public EHR dataset (MIMIC-III) and a private EHR dataset with protected health information (in-house), we conducted training using 3 distinct computing environments. Specifically, most of the experiments on MIMIC-III were conducted on Google's cloud computing platform, using 1 to 2 NVIDIA A100 40 GB graphics processing units (GPUs) and a conventional server equipped with 1 RTX 3090 Ti 24 GB GPU. The in-house EHR dataset is stored on a workstation located within a hospital research laboratory. The workstation operates within a Health Insurance Portability and Accountability Act–compliant network, ensuring the confidentiality, integrity, and availability of electronic protected health information, and it is equipped with a single NVIDIA V100 32 GB GPU. To use ChatGPT, we used an in-house ChatGPT-3.5-Turbo version hosted on our local cloud infrastructure. No data were sent to Microsoft or OpenAI. This setup ensured that no data were transmitted to OpenAI or external websites, and we were in strict compliance with the MIMIC data use agreement.

While GPT can handle 4096 tokens, T5 is limited to 512 tokens. To ensure a fair comparison, we focused on the subjective and assessment sections of progress notes as input. These sections provide physicians' evaluations of patients' conditions and fall within T5's 512-token limit. This differs from the objective sections, which mainly contain numerical values. Detailed information on data preprocessing, T5 model fine-tuning, and GPT zero-shot setting is presented in Multimedia Appendix 1.

Prompting Foundational Models to Integrate Graph Knowledge

To incorporate graph model–predicted paths into a prompt, we applied a prompt engineering strategy using domain-independent prompt patterns, as delineated in the study by White et al [38]. Our prompt was constructed with 3 primary components: the output customization that specifies the persona; the output format and template; and the context-control patterns, which are directly linked to the input note and the output of DR.KNOWS. In our test set, for the few input EHRs where no paths could be found (<20 instances), we directly fed the input into the LLMs (T5 and ChatGPT) to generate diagnoses.

Given that our core objective was to assess the extent to which the prompt can bolster the model's performance, it became imperative to test an array of prompts. Gonen et al [39] presented a technique, BETTERPROMPT, which relied on "selecting prompts by estimating language model likelihood." Essentially, we initiated the process with a set of manual task-specific prompts, subsequently expanding the prompt set via automatic paraphrasing facilitated by ChatGPT and backtranslation. We then ranked these prompts by their perplexity score (averaged over a representative sample of task inputs), ultimately selecting those prompts that exhibited the

XSL•FO
RenderX

lowest perplexity. Guided by this framework, we manually crafted 5 sets of prompts to integrate the path input, which are visually represented in Table S1 in Multimedia Appendix 1. Specifically, the first 3 prompts were designed by a non–medical domain expert (computer scientist), whereas the final 2 sets of prompts were developed by a medical domain expert (a critical care physician and a medical informaticist). We designated the last 2 prompts (with the medical persona) as "subject matter prompts" and the first 3 prompts as "non–subject matter prompts."

The chosen final prompt came from a template with minimal perplexity, incorporating predicted knowledge paths from the DR.KNOWS model as part of the input. We explored 2 path representation methods: "structural," which uses "→" to link source concepts, edges (relation names), and target concepts; and "clause," which converts paths into clause-style text by directly joining the source and target concepts with their relations. Preliminary experiments showed superior performance with the "structural" representation, leading to its exclusive use in our reported results. The final prompt selected for the foundational models is a paraphrased prompt from the subject matter expert–crafted prompt: "Imagine you are a medical professional equipped with a knowledge graph, and generate the top three direct and indirect diagnoses from the input note. <Input note>…These are knowledge paths: <path 1>; <path 2>…Separate the diagnoses using semicolons, and explain your reasoning starting with <Reasoning>." For the setup where the input did not contain paths, we simply used the prompt with the medical persona and task description as follows: "Imagine you are a medical professional, and generate the top three direct and indirect diagnoses from the input note. <Input note>..." The manually crafted prompts, their paraphrased versions, and their perplexity scores are presented in Table S1 in Multimedia Appendix 1.

Evaluation Metrics

Automated Evaluation Metrics for Quantitative Analysis

We conducted 2 evaluations for the DR.KNOWS models: the first was an intrinsic evaluation to determine how many gold standard concepts the graph model can retrieve. The second evaluation examined whether the retrieved knowledge paths could enhance the LLM's diagnosis prediction task. Regarding the first evaluation, our primary objective was to evaluate the effectiveness of DR.KNOWS in predicting diagnoses using CUIs. We used a concept extractor to analyze text within the plan section, specifically extracting CUIs classified under the semantic type T047 DISEASE AND SYNDROMES. We only included CUIs that were guaranteed to connect with at least 1 path, having a maximum length of 2 hops between the target and input CUIs. These chosen CUIs constituted the "gold standard" CUI set, used for both training and assessing the model's performance. As DR.KNOWS predicts the top N CUIs, we measured the Recall@N and Precision@N as follows:

The *F*-score, the harmonic mean between recall and precision, will also be reported.

To evaluate foundational model performance on EHR diagnosis prediction, we applied the aforementioned evaluation metric as well as Recall-Oriented Understudy for Gisting Evaluation (ROUGE) [40]. Specifically, ROUGE is a widely used set of metrics designed for evaluating the quality of machine-generated text by comparing it to reference texts. We used the ROUGE–Longest Common Subsequence (ROUGE-L) variant, which is based on the longest common substring; and the ROUGE-2 variant, which focuses on bigram matching. Both ROUGE metrics were used in the ProbSum shared task.

For reporting results from automated metrics, we provided the mean scores across all samples in the test set, along with 95% CIs on 1000 bootstrapped samples.

Human Evaluation for Qualitative Analysis

Existing evaluation frameworks for AI, such as those used in radiology report generation, do not address diagnosis prediction with LLMs, leaving a significant gap. To address this, our prior work introduced a new human evaluation framework based on the Safer DX Instrument [41], aiming to provide a structured approach for assessing LLMs in diagnosis tasks. In this study, we used this framework to assess the impact of knowledge paths on LLM diagnostic predictions, specifically through a qualitative analysis of the "reasoning" output by LLMs, aiming to gauge the depth and accuracy of the models' diagnostic reasoning processes.

Specifically, we evaluated the model-generated "reasoning" section on the following aspects: (1) *reading comprehension*, (2) *rationale*, (3) *recall of knowledge*, (4) *omission of diagnostic reasoning*, and (5) *abstraction* and *effective abstraction*. *Reading comprehension* was intended to capture whether a model understood the information in a progress note. *Rationale* was intended to capture the inclusion of incorrect reasoning steps. *Recall of knowledge* was intended to capture the hallucination of incorrect facts as well as the inclusion of irrelevant facts in the output. *Omission* of a diagnosis served the same purpose as noted previously by capturing instances when the model failed to support conclusions or provide evidence for a diagnostic choice. *Abstraction* and *effective abstraction* were intended to evaluate the amount of *abstraction* present in each part of the output. This was to ascertain how the knowledge paths influenced the type of output produced and whether the model was able to use abstraction. *Omission* as well as *abstraction* and *effective abstraction* were formatted as *yes* or *no* questions. *Reading comprehension*, *rationale*, and *recall of knowledge* were assessed on a Likert scale ranging from 1 to 5, with 1 indicating strong agreement with poor quality and 5 indicating strong disagreement (representing high quality).

We recruited 2 medical professionals to evaluate LLM outputs using human evaluation guidelines developed by us. Full details of the guidelines, evaluation training, and interannotator agreement are reported in a separate publication (currently under review). The evaluation framework used the REDCap (Research Electronic Data Capture; Vanderbilt University) web application to present the evaluators with input notes, gold standard

XSL•FO
RenderX

diagnoses, and model-predicted diagnoses. The evaluators, treated as separate arms in a longitudinal framework, assessed models with KG paths and those without across 2 defined events. Detailed step-by-step guidelines were provided for completing the evaluations in REDCap.

Two senior board-certified clinical informatics physicians served as advisors, pilot testers, and trainers for the 2 medical professionals who completed the human evaluations. The 2 physicians used 5 samples cases to iteratively refine the guidelines provided to the evaluators; these sample evaluations also served as examples for the evaluators to reference during training. The evaluation guidelines consisted of clear descriptions of the meaning of evaluative scores for each aspect of the human evaluation framework as well as a completed example workflow.

Results

Intrinsic Evaluation of DR.KNOWS on Predicting Diagnostic Concepts

We compared DR.KNOWS with QuickUMLS, which is a concept extractor baseline that identifies medical concepts from raw text. We took input text, parsed it with QuickUMLS, and outputted a list of concepts. Table 2 presents results from the 2 EHR datasets, MIMIC and in-house. The selection of different top N values was determined by the disparity in text length between the 2 datasets. DR.KNOWS demonstrated superior precision and *F*-scores compared to QuickUMLS across both datasets compared to the baseline, with precision scores of 19.10 (95% CI 17.82-20.37) versus 13.59 (95% CI 12.32-14.88) on the MIMIC dataset and 22.88 (95% CI 20.92-24.85) versus 12.38 (95% CI 11.09-13.66) on the in-house dataset. In addition, its *F*-scores of 25.20 (95% CI 23.93-26.48) on the MIMIC dataset and 25.70 (95% CI 24.06-27.37) on the in-house dataset exceeded the comparison scores of 21.13 (95% CI 19.85-22.41) and 20.09 (95% CI 18.81-21.37), respectively, underscoring the effectiveness of DR.KNOWS in accurately predicting diagnostic CUIs. The TriAttn variant of DR.KNOWS consistently outperformed the MultiAttn variant on both datasets, with *F*-scores of 25.20 (95% CI 23.93-26.48) versus 23.10 (95% CI 21.83-24.39) on the MIMIC dataset and 25.70 (95% CI 24.06-27.37) versus 17.69 (95% CI 16.40-18.96) on the in-house dataset. The concept extractor baseline achieved the highest recall scores—56.91 on the MIMIC dataset and 90.11 on the in-house dataset—because it identified all input concepts that overlapped with the reference CUIs, in particular on the in-house dataset, which was largely an extractive dataset. Training the DR.KNOWS model took an average of 2 of 3 (SD 1.22) hours per epoch on 5000 samples, using 8000 MB of GPU memory.

Table 2. Performance comparison between concept extraction and 2 variants of DR.KNOWS on target concept unique identifier prediction using the Medical Information Mart for Intensive Care (MIMIC-III) and in-house datasets.

Model	MIMIC-III				In-house			
	Top N knowledge paths	Recall score (95% CI)	Precision score (95% CI)	*F*-score (95% CI)	Top N knowledge paths	Recall score (95% CI)	Precision score (95% CI)	*F*-score (95% CI)
Concept extractor	—[a]	56.91 (55.62-58.18)	13.59 (12.32-14.88)	21.13 (19.85-22.41)	—	*90.11*[b] (88.84-91.37)	12.38 (11.09-13.66)	20.09 (18.81-21.37)
MultiAttn[c]	4	26.91 (25.64-28.19	*22.79* (21.51-24.06)	23.10 (21.83-24.39)	6	24.68 (23.35-25.91)	15.82 (14.55-17.10)	17.69 (16.40-18.96)
MultiAttn	6	29.14 (27.85-30.41)	16.73 (15.46-18.00)	19.94 (18.66-21.22)	8	28.69 (27.43-29.98)	15.82 (14.55-17.11)	17.33 (16.06-18.60)
TriAttn[d]	4	29.85 (26.23-33.45)	17.61 (16.33-18.89)	20.93 (19.67-22.21)	6	34.00 (31.04-36.97)	*22.88* (20.92-24.85)	23.39 (21.71-25.06)
TriAttn	6	37.06 (35.80-38.33)	19.10 (17.82-20.37)	*25.20* (23.93-26.48)	8	44.58 (41.38-47.78)	22.43 (20.62-24.23)	*25.70* (24.06-27.37)

[d]TriAttn: trilinear attention.

Assessing the Impact of DR.KNOWS on Diagnosis Prediction

The best systems for each foundational model on the ProbSum test set are presented in Table 3, including those with predicted paths provided by DR.KNOWS and those without. Overall, the prompt-based fine-tuning of T5 surpassed ChatGPT's prompt-based zero-shot approach on all metrics, and ChatGPT's prompt-based few-shot approach showed comparable performance to T5. Notably, models that incorporated paths, particularly for the CUI *F*-score, showed significant improvements. The vanilla T5 model with a path prompt excelled, achieving the highest ROUGE-L score (30.72, 95% CI 30.40-32.44) and CUI *F*-score (27.78, 95% CI 27.09-29.80). This ROUGE-L score could have ranked third on the ProbSum leaderboard [27], which is noteworthy considering that the top 2 systems used ensemble methods [10,11].

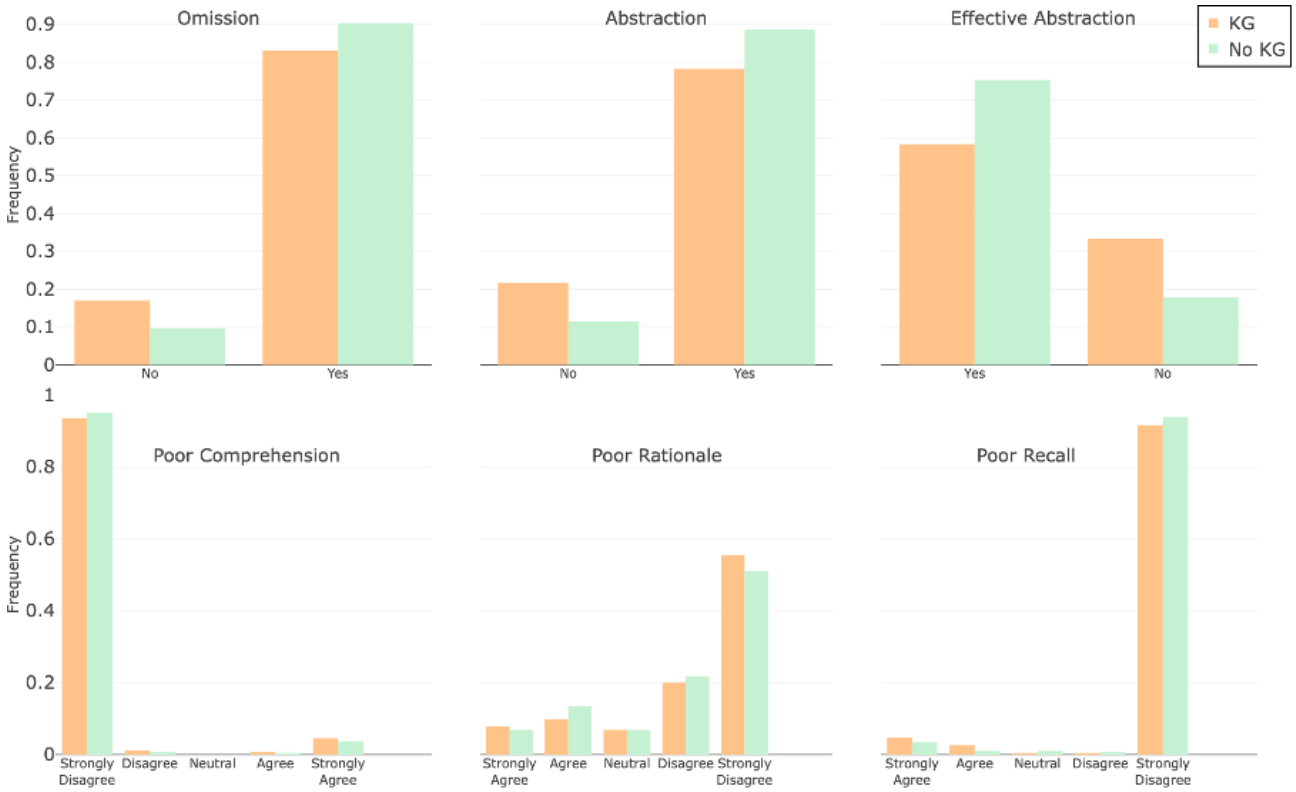
[a]Prompt styles with DR.KNOWS path prompting.

[b]Best performance values are italicized.

[c]95% CIs with a distinct CI for the DR.KNOWS-prompted path compared to no-path scenarios.

The comparison between ChatGPT with DR.KNOWS and ChatGPT without in the predicted paths scenario provided additional insights. In the few-shot setting, the incorporation of paths led to marked improvements; for instance, in the 3-shot setting, the with-path scenario outperformed the no-path scenario on all metrics, with ROUGE-L score of 24.32 (95% CI 22.44-24.25) compared to ChatGPT 3-shot no-path ROUGE-L score of 21.84 (95% CI 19.44-22.09) and CUI *F*-score of 25.30 (95% CI 24.52-26.06) versus 21.02 (95% CI 20.26-21.79). In the 5-shot setting, ChatGPT with paths achieved a ROUGE-L score of 25.43 (95% CI 25.53-25.35) compared to 21.23 (95% CI 19.58-21.72) for ChatGPT without paths and CUI *F*-score of 26.02 (95% CI 25.25-26.78) versus 20.96 (95% CI 20.19-21.73).

Human Evaluation Results



After the annotation procedure, the 2 medical professionals completed a supervised set of evaluations and were considered validated once they achieved a κ coefficient of 0.7 with the physician trainers and each other.

Although the T5 and ChatGPT models displayed similar performance on automated metrics, their outputs diverged significantly. The T5 models, lacking instruction tuning, failed to respond adequately to prompts requesting the generation of a <Reasoning> section. Consequently, our human evaluation focused exclusively on the outputs produced by ChatGPT. We conducted human evaluation of the top-performing ChatGPT output (5-shot approach), comparing scenarios with the DR.KNOWS knowledge paths with KG and without KG. The final evaluation set consisted of 92 input notes and 2 sets of ChatGPT-predicted text.

The results are reported in Figure 4. First, there was no significant increase in *omission of diagnoses*, with 16% (15/92) observed with KG as opposed to 10% (9/92) without KG (*P*=.16). Regarding *rationale* (correct reasoning), ChatGPT with KG exhibited stronger agreement with the human evaluators (51/92, 55%) than ChatGPT without KG (46/92, 50%; *P*<.001). In the *abstraction* category (assessing the presence of abstraction in the model output), there was a notable drop from 88% (81/92; without KG) to 78% (71/92; with KG) in the affirmative responses (*P*=.03), indicating that less abstraction was required when KG paths were included. Differences were also noted in *effective abstraction* in favor of the KG paths (*P*=.002).

XSL•FO
RenderX

Figure 4. Human evaluation of ChatGPT outputs comparing scenarios with ("KG" [knowledge graph]) the DR.KNOWS (Diagnostic Reasoning Knowledge Graph System) knowledge paths and without ("No KG").

Error Analysis

We discovered 2 primary types of errors in the DR.KNOWS outputs that could result in missed opportunities for improving knowledge grounding. Figure 5 presents an example where ChatGPT did not find the provided knowledge paths useful. In this case, the majority of the provided knowledge paths were highly extractive ("leukocytosis," "reticular dysgenesis," and "paraplegia" are the target concepts to which the knowledge paths led, and all are associated with a "self-loop" relationship). On the abstraction paths, the retrieved target concepts "abdomen hernia scrotal" and "chronic neutrophilia" were not relevant to the input patient condition.

Figure 5. An example of an error in the knowledge paths retrieved by DR.KNOWS (Diagnostic Reasoning Knowledge Graph System). DR.KNOWS retrieved 2 paths leading to irrelevant and misleading diagnoses (marked in red). The counterclockwise gapped circular arrow symbol represents a self-loop.

Input progress note:
<Assessment> 73 yo M w/ mmp, C4-5 paraplegia, TF dependence, on broad spectrum abx for recent pna transferred from OSH w/ resp distress, leukocytosis, and HOTN <Subjective> Chief Complaint: resp distress and hypotension I saw and examined the patient, and was physically present with the ICU Resident for key portions of the services provided. I agree with his / her note above, including assessment and plan. HPI: 73 yo M w/mmp including C4-5 paraplegia, TF dependence, on broad spectrum abx for recent pna transferred from OSH w/ resp distress, leukocytosis, and HOTN. 24 Hour Events: PICC LINE - START 04:24 PM ARTERIAL LINE - START 07:00 PM HOTN responded to IVF, never required pressor support MS ANTIBX coverage broadened--> vanco/ CT chest ordered Leukocytosis normalizing History obtained from Medical records
Allergies: Methyldopa hives; Shellfish pt. with remote.

Dr.Knows retrieved top-6 knowledge paths:

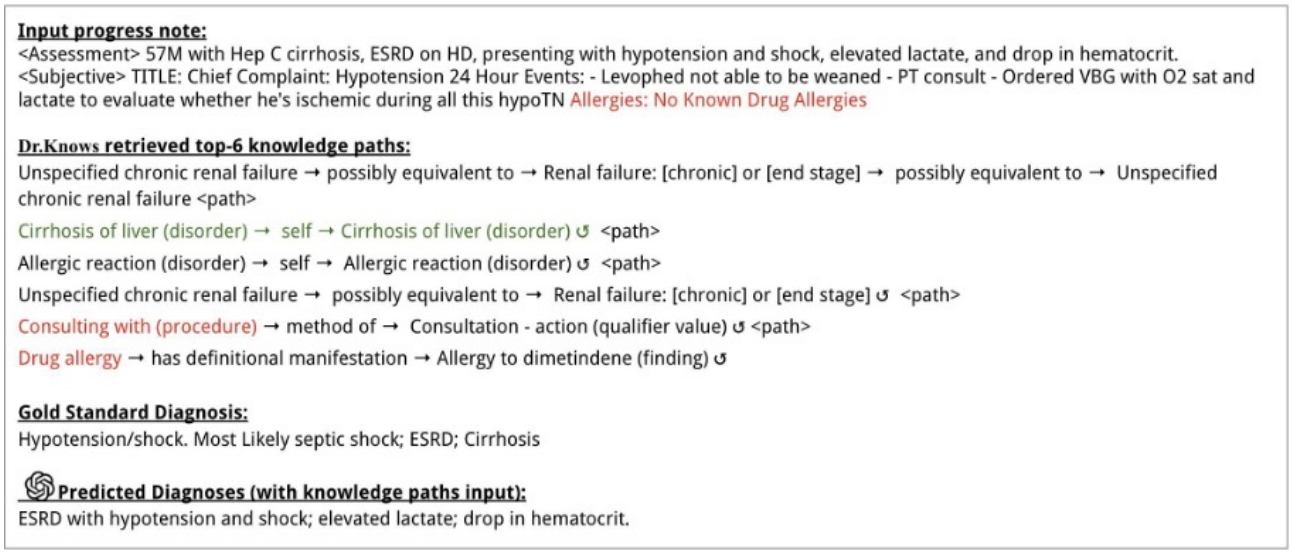
Leukocytosis → self → Leukocytosis ↺ <path>

reticular dysgenesis → self → reticular dysgenesis ↺ <path>

Leukocytosis → definitional manifestation of → Leukocytosis ↺ <path>

Paraplegia → self → Paraplegia ↺ <path>

Thoracic → has finding site → abdomen hernia scrotal ↺ <path>



Leukocytosis → definitional manifestation of → Leukocytosis → has definitional manifestation → Chronic neutrophilia

Another error observed occurred when DR.KNOWS selected the source CUIs that were less likely to generate pertinent paths for clinical diagnoses, resulting in ineffective knowledge paths. Figure 6 shows a retrieved path from "consulting with (procedure)" to "consultation-action (qualifier value)." Although some procedure-related concepts such as endoscopy or blood testing were valuable for clinical diagnosis, this specific path of consulting did not contribute meaningfully to the input case. Similarly, another erroneous pathway began with "drug allergy" and led to "allergy to dimetindene (finding)," which is contradictory, given that the input note explicitly states "no known drug allergies." While the consulting path's issue was its lack of utility, the "drug allergy" path could introduce the

XSL•FO
RenderX

risk of hallucination (misleading or fabricated content) within ChatGPT.

Figure 6. An example illustrating ChatGPT's performance with the knowledge paths extracted by DR.KNOWS (Diagnostic Reasoning Knowledge Graph System). Two paths had source concept unique identifiers ("Consulting with [procedure]" and "Drug allergy") that were less likely to generate pertinent paths for clinical diagnoses. Of note, the path of "Drug allergy" led to a path contradicting the "No Known Drug Allergies" description in the input. The path of "cirrhosis of liver" represents a correct diagnosis, but ChatGPT failed to include it. The counterclockwise gapped circular arrow symbol represents a self-loop. ESRD: end-stage renal disease.

In addition to the errors in the DR.KNOWS outputs, there were instances where ChatGPT failed to leverage the accurate knowledge paths presented. Figure 6 includes a knowledge path regarding "cirrhosis of liver," which was the correct diagnosis. However, ChatGPT response did not include this diagnosis.

Discussion

Principal Findings

DR.KNOWS showed significant advantages over the QuickUMLS concept extractor baseline in extracting correct concepts for diagnoses. On the ProbSum dataset, where the goal was to generate a list of diagnoses given the progress notes, prompt-based fine-tuning of T5 outperformed ChatGPT's zero-shot approach and showed comparable results to its few-shot approaches, with the inclusion of predicted paths by DR.KNOWS significantly enhancing performance across all metrics. The vanilla T5 with path prompts notably achieved top ROUGE-L and CUI *F*-scores, demonstrating the effectiveness of incorporating paths into the model. Human evaluation of ChatGPT's reasoning section showed strong agreement with human evaluators in terms of correct *rationale* and enhanced *effective abstraction*, indicating nuanced improvement in reasoning and abstraction quality with KG integration.

While DR.KNOWS leverages KG paths to enhance diagnosis prediction, it is important to acknowledge the potential biases and limitations inherent in KG data. KGs such as UMLS are comprehensive, but they may reflect biases based on the clinical domains and patient populations from which they were constructed, which could impact the relevance or appropriateness of the retrieved paths. To mitigate this, DR.KNOWS focuses on case-specific path selection, aiming to retrieve only the paths most directly relevant to the patient context. Nonetheless, future iterations could benefit from evaluating path relevance using additional contextual information, such as demographic details, to better align with patient-specific needs and reduce bias.

Error analysis showed that DR.KNOWS occasionally struggled with identifying knowledge paths unrelated to the patient representation; in addition, the analysis emphasized the importance of selecting accurate starting medical concepts. Currently, DR.KNOWS relies solely on semantic-based ranking on the candidate paths, that is, the cosine similarity between candidate path embeddings and input text, with the embedding quality being crucial for ranking performance. Improving the representation and embedding methods, as well as exploring probabilistic modeling techniques [42,43], could enhance path relevance. Furthermore, incorporating a graph reasoning mechanism that enables symbolic chain-of-thought reasoning might compensate for the weaknesses of contextualized embeddings and cosine-similarity metrics [44], presenting a valuable future direction. This integration could improve the diagnostic potential of DR.KNOWS, allowing for more nuanced and bias-aware reasoning.

The error analysis also presented instances where ChatGPT neglected to incorporate certain beneficial knowledge paths. It is important to acknowledge that ChatGPT operates as a black box application programming interface model, with its internal weights and training processes being inaccessible. To enhance the efficacy of the graph-based retrieve-and-augment framework, it would be advantageous to explore the potential of graph prompting and instruction tuning on open-source language models. These methods could refine the model's ability to use relevant information effectively. Other relevant research also uses advanced prompting techniques, such as self-retrieval–augmented generation [45] and step-back prompting [46]. The Google Research team recently presented a study investigating multiple ways of encoding graphs into

XSL•FO
RenderX

LLM inputs [47], which might inform a future direction for this work beyond the typical structural or clause-based path prompting.

In conclusion, LLMs such as ChatGPT hold promise for generating diagnoses for clinical decision support; however, methods such as graph prompting are needed to guide the model down the correct reasoning paths to avoid hallucinations and provide comprehensive diagnoses. While we show some progress in a graph prompting approach with DR.KNOWS, more work is needed to improve methods that leverage the UMLS knowledge source for grounding to achieve more accurate outputs. Nonetheless, DR.KNOWS represents a step toward trustworthy AI in medicine, providing knowledge grounding to LLMs and potentially reducing factual errors in diagnostic outputs [48]. Furthermore, our proposed human evaluation framework, derived from diagnostic safety evaluations used in clinical settings, enables the assessment of LLMs from the perspective of diagnostic safety. It carries strong face validity and reliability to evaluate a model's strengths and weaknesses as a diagnostic decision support system. This ensures that the models not only perform well on technical metrics but also align with clinical standards of safety and reliability.

Limitations

Our work on leveraging KGs for LLM diagnosis generation has shown promising results; however, there are notable limitations that must be acknowledged. First, while the UMLS concept extractors (Clinical Text Analysis and Knowledge Extraction System and QuickUMLS) are powerful tools, they are not without flaws. One significant limitation is their inability to accurately identify all relevant concepts, particularly indirect or nuanced medical concepts. These indirect concepts can be crucial for accurate diagnosis generation; yet, the current concept extractors may fail to recognize them, leading to incomplete or less accurate knowledge representation.

Second, our path selection methodology relies heavily on cosine similarity, a common approach within the retrieval-augmented generation framework. Despite its prevalence, this method has inherent limitations due to its heavy reliance on the quality of embedding representations. If the embeddings do not adequately capture the semantic nuances of medical concepts, the similarity measure may lead to the retrieval of less relevant or noisy knowledge paths. This can ultimately impact the quality and reliability of the diagnostic suggestions generated by the LLM.

These limitations highlight the need for the continued refinement of both the concept extraction and path selection processes. Future work should explore more sophisticated techniques to enhance concept identification and improve the robustness of embedding representations, thereby reducing the reliance on cosine similarity and increasing the overall accuracy and utility of the KG-based approach.

Abstract

Background: Cerebrovascular diseases are the second most common cause of death worldwide and one of the major causes of disability burden. Advancements in artificial intelligence have the potential to revolutionize health care delivery, particularly in critical decision-making scenarios such as ischemic stroke management.

Objective: This study aims to evaluate the effectiveness of GPT-4 in providing clinical support for emergency department neurologists by comparing its recommendations with expert opinions and real-world outcomes in acute ischemic stroke management.

Methods: A cohort of 100 patients with acute stroke symptoms was retrospectively reviewed. Data used for decision-making included patients' history, clinical evaluation, imaging study results, and other relevant details. Each case was independently presented to GPT-4, which provided scaled recommendations (1-7) regarding the appropriateness of treatment, the use of tissue plasminogen activator, and the need for endovascular thrombectomy. Additionally, GPT-4 estimated the 90-day mortality probability for each patient and elucidated its reasoning for each recommendation. The recommendations were then compared with a stroke specialist's opinion and actual treatment decisions.

Results: In our cohort of 100 patients, treatment recommendations by GPT-4 showed strong agreement with expert opinion (area under the curve [AUC] 0.85, 95% CI 0.77-0.93) and real-world treatment decisions (AUC 0.80, 95% CI 0.69-0.91). GPT-4 showed near-perfect agreement with real-world decisions in recommending endovascular thrombectomy (AUC 0.94, 95% CI 0.89-0.98) and strong agreement for tissue plasminogen activator treatment (AUC 0.77, 95% CI 0.68-0.86). Notably, in some cases, GPT-4 recommended more aggressive treatment than human experts, with 11 instances where GPT-4 suggested tissue plasminogen activator use against expert opinion. For mortality prediction, GPT-4 accurately identified 10 (77%) out of 13 deaths within its top 25 high-risk predictions (AUC 0.89, 95% CI 0.8077-0.9739; hazard ratio 6.98, 95% CI 2.88-16.9; P<.001), outperforming supervised machine learning models such as PRACTICE (AUC 0.70; log-rank P=.02) and PREMISE (AUC 0.77; P=.07).

Conclusions: This study demonstrates the potential of GPT-4 as a viable clinical decision-support tool in the management of acute stroke. Its ability to provide explainable recommendations without requiring structured data input aligns well with the

XSL•FO
RenderX

routine workflows of treating physicians. However, the tendency toward more aggressive treatment recommendations highlights the importance of human oversight in clinical decision-making. Future studies should focus on prospective validations and exploring the safe integration of such artificial intelligence tools into clinical practice.

(JMIR AI 2025;4:e60391) doi:10.2196/60391

KEYWORDS

GPT-4; ischemic stroke; clinical decision support; artificial intelligence; neurology

Introduction

The advent of GPT-4 [1], launched by OpenAI in March 2023, marked a significant milestone in the evolution of artificial intelligence (AI) and its applications in various domains, including health care. GPT-4, a model under the umbrella of GPT, exemplifies the advancement in large language model (LLM) technology [2,3]. The foundational architecture of this technology involves training on extensive datasets, enabling the model to function as a "few-shot learner." This capability allows GPT-4 to adapt to new domains and continuously refine its performance through ongoing learning [2,4-6].

In the realm of clinical medicine, the potential applications of LLMs like GPT-4 are particularly intriguing. These models offer promise as supportive tools for health care professionals, aiding in the efficient summarization of patient data, assisting in decision-making processes, and potentially improving the accuracy and speed of medical interventions [7,8]. Recent research has underscored the capabilities of GPT-4 in complex medical tasks [9]. Notably, the model has demonstrated proficiency in examinations akin to the United States Medical Licensing Examination, achieving scores that meet or nearly meet the passing thresholds [10]. Additionally, in assessments modeled after neurology board exam questions, GPT-4 has shown a high accuracy rate, improving with repeated attempts [9,11,12].

The management of acute ischemic stroke (AIS) presents a critical and time-sensitive challenge in clinical settings. The approach to diagnosing and treating AIS requires a synthesis of information including patient symptoms, physical and neurological examinations, medical history, and imaging results. Despite the availability of established guidelines by the American Heart Association/American Stroke Association for stroke management [13-16], the pivotal role of the treating physician's judgment remains. Variability in clinical presentations and the urgent need for decision-making underscore the potential value of AI-assisted tools in this context. Moreover, predicting early mortality in AIS is essential for guiding treatment decisions, optimizing resource allocation in health care settings, facilitating effective communication with patients and their families, supporting research and clinical trials, and contributing to quality improvement initiatives. In accordance, several traditional machine learning models have been trained for this task in recent years [17-20].

Here, we leveraged patient data from the emergency department (ED) of a large referral hospital, focusing on individuals presenting with stroke symptoms, to evaluate the effectiveness of GPT-4 in delivering accurate clinical decisions for the treatment of AIS. We also assessed its proficiency in predicting 90-day mortality outcomes. The aim of this study was to quantify the extent to which an advanced language model like GPT-4 can augment the clinical decision-making process in AIS management. Specifically, we hypothesized that GPT-4 could provide accurate treatment recommendations and mortality predictions comparable to those of human experts, potentially contributing to improved patient outcomes in one of the most critical areas of emergency medicine.

Methods

Cohort Selection

This retrospective study comprised 100 consecutive cases from the ED of Rambam Healthcare Campus. All patients treated between January 2022 and April 2023 received a confirmed diagnosis of AIS. The inclusion criteria encompassed patients aged older than 18 years, a National Institutes of Health Stroke Scale (NIHSS) [21] score of 5 or higher (with the exception of patient 93 who received tissue plasminogen activator [tPA] offsite), and less than 5 hours from symptom onset to undergoing a noncontrast computed tomography (CT) of the brain. All included patients underwent noncontrast brain CT, CT angiography, and CT perfusion while in the ED. This cohort was specifically chosen for its alignment with American Heart Association guidelines for acute stroke management [13], making each patient a potential candidate for both tPA and endovascular thrombectomy (EVT) treatment. A total of 17 patients not meeting these criteria were categorized as "complex" cases, in which the clinical scenario warranted extra consideration of off-guideline treatment options, and there was a need to assess the individual patient's unique characteristics, medical history, and condition. For every patient, comprehensive medical records from their ED arrival, including imaging results, were collected and translated from Hebrew to English. Exclusion criteria were patients with incomplete clinical data or where stroke was not the final diagnosis.

Clinical data for each patient included demographics, medical history, chief complaints, symptom onset time, physical and neurological examinations, NIHSS score, imaging results (including Alberta Stroke Program Early CT Score [22] when available), treatment received, and mortality data. An experienced stroke specialist, blinded to the outcomes, reviewed the cases and made treatment decisions among no treatment, tPA, EVT, or a combination of tPA and EVT. All data were deidentified, removing identifiers, names, and dates.

Analysis Pipeline

The analysis used the OpenAI application programming interface "create chat completion" method with the model

XSL•FO
RenderX

gpt-4-1106-preview. Default parameters were set (temperature=1; top_p=1; n=1), and submissions were made using the R (R Foundation for Statistical Computing) wrapper library *openai*. Full prompt and example are available in Multimedia Appendix 1.

To assess the reliability of GPT-4 responses, each case underwent 5 submissions, as well as an additional submission without the accompanying clinical presentation narrative. For every treatment decision, GPT-4 provided a narrative explanation. In 95% (475/500) of cases, GPT-4 returned responses in the requested structure, which were automatically scraped with R. Unstructured responses were manually entered. For estimations provided as a range, the average was used. If GPT-4 provided a number with a greater symbol (eg, >50), the number was recorded with an additional 5. In 0.8% (4/500) of cases, GPT-4 did not return numeric responses for treatment decisions, and in 8.6% (43/500) of responses, it did not provide a 90-day mortality estimate.

Statistical Analysis

GPT-4's responses were scaled from 1 to 7 for treatment decisions and from 0 to 100 for 90-day mortality estimations. Averages were calculated across the 5 repeats. All statistical analyses were conducted using R (version 4.3.2), using base R functions, *predictive receiver operating characteristic (ROC)* 1.18.5, and *survival* 3.5.7. ROC curves were smoothed. Agreement between treatment decisions was measured using a linear weighted Cohen κ coefficient, using the *psych* 2.3.12 library.

Ethical Considerations

This study was approved by the Rambam Medical Center Helsinki Committee (0156-24-D) as a retrospective analysis. The requirement for informed consent was waived due to the retrospective nature of the study and the use of deidentified data. All patient information was anonymized prior to analysis, with all identifiers, names, and dates removed to ensure privacy and confidentiality. No compensation was provided to participants as this was a retrospective study using existing clinical data. The study did not involve any images that could potentially identify individual participants. This research was conducted in accordance with the principles of the Declaration of Helsinki and adhered to all relevant institutional and national research ethics guidelines.

Results

Patient Demographics and Clinical Data

We generated a cohort from 100 consecutive cases of patients presenting with acute stroke symptoms at the ED of Rambam Healthcare Campus. All cases underwent full clinical and radiological evaluation in the emergency setting for acute stroke and were fully evaluated by a neurologist (Table 1 and Figure 1A). Revascularization treatment was administered to 78 of the patients: 36 were treated with tPA, 30 with EVT, and 12 received both. Within this cohort, 13 patients died within 90 days and 21 in total. Overall, 17 cases were classified as "complex" when not fitting exact treatment guidelines [13]. The data for each case encompassed demographics, NIHSS [21] scores, the timing of arrival to brain CT, onset of symptoms, and details from textual brain imaging results and risk factors that were available as medical history at the time of admission to the ED (Table S1 in Multimedia Appendix 2).

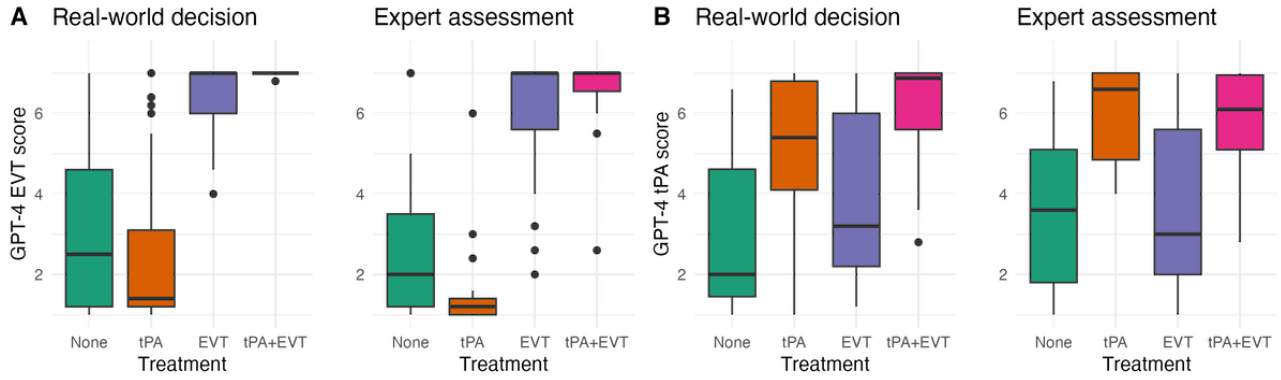
Figure 1. Study design and GPT-4 performance evaluation. (A) Illustration of the study design involving 100 consecutive patients with stroke who underwent a comprehensive stroke workup, including perfusion, angiography, and noncontrast brain CT upon arrival at the emergency department. Clinical information, demographics, comorbidities, and CT perfusion results were recorded. The textual reports from these investigations were entered into the GPT-4 API, which was instructed to provide scores indicating whether to treat the patient, whether to administer tPA, whether to pursue EVT, and an estimate of 90-day mortality. (B) Box plots presenting average scores of GPT-4 assessments for decision to treat (y-axis). The comparison is made against real-world decisions and expert assessments of each case (true: to treat the patient and false: to not treat). (C) ROC curves and AUC scores of GPT-4 average scores for decision to treat, compared to real-world decisions and expert assessments. API: application programming interface; AUC: area under the curve; CT: computed tomography; EVT: endovascular thrombectomy; ROC: receiver operating characteristic; tPA: tissue plasminogen activator.

A stroke specialist, blinded to the outcomes, retrospectively reviewed each case. In 82 of the cases, the expert's decisions aligned with the actual treatments administered. Of note, the expert recommended not treating 11 patients who received treatment and suggested treatment for 7 who did not receive any. Concerning specific treatments, full agreement was observed in 61 cases, although the expert more frequently recommended combining tPA and EVT than what was observed in practice (Cohen κ=0.51, signifying moderate agreement).

GPT-4 Clinical Decisions

Independently, each case was assessed with GPT-4, generating a treatment recommendation scale from 1=intervention not recommended to 7=highly recommended (Figure 1A; Table S2 in Multimedia Appendix 2). To account for the variability in GPT-4 responses, each case was assessed 5 times. Cohen κ for treatment scores across runs ranged from 0.56 to 0.73. As expected, the predefined "complex" cases demonstrated significantly greater variance between runs (*P*=.02).

Comparing GPT-4's treatment scale to both the expert's decision and the actual treatment revealed that the average scores from GPT-4 for patients who were treated were, on average, 1.9 points higher than those not treated (*P*<.001), and there was a 2.1-point difference in comparison to the expert decision (*P*<.001; Figure 1B). The average scores provided an area under the ROC curve (AUC-ROC) of 0.80 (95% CI 0.69-0.91) compared to the real-world decision, and 0.85 (95% CI 0.77-0.93) compared to the expert decision (Figure 1C). These average scores for AUCs were higher than those of each independent run (Multimedia Appendix 3). Additionally, removing the clinical presentation narrative from GPT-4's analysis resulted in a drop in AUC to 0.70 with the real-world decision and 0.72 with the expert decision (Multimedia Appendix 3), highlighting the importance of unstructured narrative data in treatment decision-making.



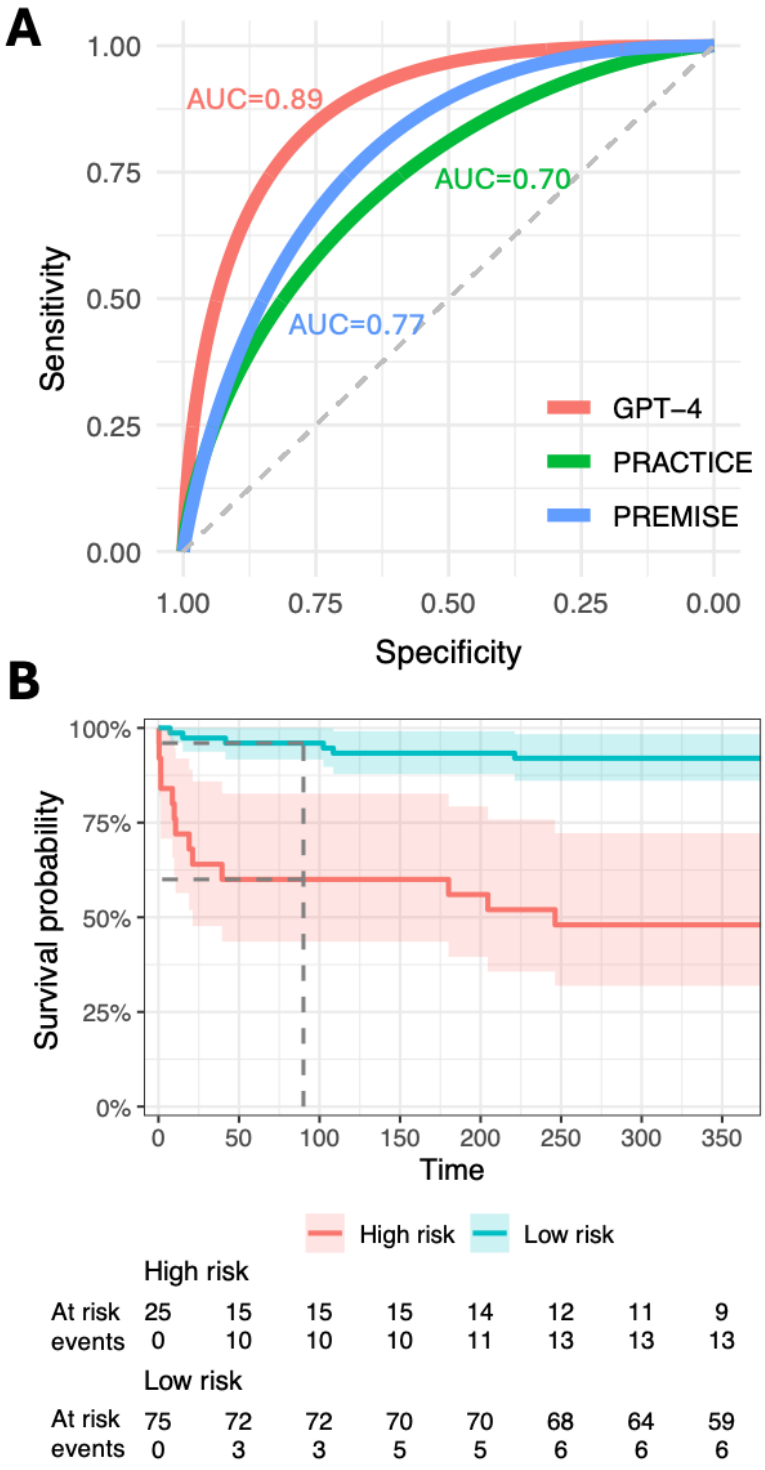
XSL•FO
RenderX

Similarly, setting the temperature of GPT-4 to 0 resulted in AUCs of 0.70 and 0.72 with the real-world and expert decisions, respectively, suggesting the need to allow GPT-4 more creativity to obtain better decisions.

Using a score threshold of 4, we observed 22 disagreements between GPT-4 and the real-world treatment and 20 disagreements with the expert decision. Notably, a substantial proportion of these disagreements coincided with cases where the expert and real-world decisions diverged, with 18 (60%) out of 30 such cases showing this dual disagreement. Moreover, complex cases were more prone to discrepancies, as 7 disagreements with the real-world decision and 5 with the expert decision were noted among the 17 complex cases. The specialist examined the explanatory text produced by GPT-4 for all discrepancies between the model and their blinded assessments, evaluating whether they agreed that the explanatory text, as part of the original model output, was logical and could be deemed good practice. Of the 20 instances where disagreements occurred, in 3 cases, the expert, after having carefully considered GPT-4's detailed explanations, conceded that GPT-4's assessment was preferable to their original decision. In additional 2 cases, the expert acknowledged that GPT-4's suggested approach was indeed acceptable and aligned with viable treatment options. In instances where the expert disagreed with GPT-4's reasoning, the disagreements primarily revolved around 3 key issues. First, GPT-4 inaccurately associated abnormal angiographic findings with clinical presentations. An illustrative case is that of a patient with stenosis of the right-sided middle cerebral artery who was presented with right hemiparesis (case 94). Despite these 2 elements potentially being anatomically unrelated, GPT-4 linked them erroneously. The second notable issue pertained to ethical considerations, particularly in a case involving a patient with active laryngeal cancer and cognitive decline. According to guidelines, the patient was deemed eligible for treatment, but the expert's decision was to not proceed with treatment as life expectancy was short and he was palliative (case 14). Third, discrepancies arose in deviations from guidelines, particularly in cases of distal thrombectomies. For instance, in the case of a patient with M2 obstruction (considered distal thrombus) aged 96 years, GPT-4 recommended against treatment, which is the established guidelines; however, the expert call was to proceed with thrombectomy due to a high NIHSS score and good results in such cases in the past from personal experience (case 54).

In assessing GPT-4's ability to choose the best treatment option, it showed near-perfect agreement with real-world decisions in recommending EVT: GPT-4 suggested EVT for all patients (42/42, 100%) treated with EVT (average score>4). The expert suggested EVT for 55 patients, of which 50 were also recommended EVT by GPT-4, corresponding to an AUC of 0.94 (95% CI 0.89-0.98) with real-world decisions and 0.95 (95% CI: 0.90-0.99) with the expert (Figure 2A). For tPA treatment, GPT-4 recommended it for 38 (79%) of the 48 patients who received it, showing a closer agreement with the expert. Of the 41 patients recommended for tPA by the expert, GPT-4 agreed on 35 (85%), corresponding to an AUC of 0.77 (95% CI 0.68-0.86) with real-world decisions and 0.82 (95% CI 0.73-0.90) with the expert (Figure 2B).

Figure 2. GPT-4 treatment type scores. Box plots depict GPT-4 treatment type scores, with the y-axis representing probability score (1-7 scale). Each treatment category is color coded: green for no intervention, orange for tPA, purple for EVT, and pink for tPA and EVT. (A) GPT-4 scores for EVT, stratified by real-world decisions and expert assessments. (B) GPT-4 scores for tPA, stratified by real-world decisions and expert assessments. EVT: endovascular thrombectomy; tPA: tissue plasminogen activator.



Mortality Risk

We further evaluated the ability of GPT-4 to predict 90-day mortality. The model estimated an average mortality risk of 55.1% for patients who died within 90 days, compared to 31.5% for survivors (P<.001), yielding an AUC of 0.89 (95% CI 0.81-0.98; Figure 3A). To contextualize these results, we compared GPT-4's performance with that of 2 recent machine learning models specifically trained for 90-day mortality prediction. In our cohort, the PRACTICE model [18] achieved an AUC of 0.70, significantly worse than the GPT-4 predictions (log-rank P value=.02), while the PREMISE model [19] reached an AUC of 0.77 (P=.07; Figure 3A). These comparisons underscore GPT-4's remarkable accuracy in mortality risk assessment, outperforming specialized, trained predictive models.

XSL•FO
RenderX

Figure 3. GPT-4 mortality predictions. (A) ROC curve for 90-day mortality estimations by GPT-4 (red), PRACTICE (green), and PREMISE (blue). (B) Kaplan-Meier plot stratifying individuals into low- and high-risk categories for mortality based on GPT-4's 90-day mortality estimations. AUC: area under the curve; ROC: receiver operating characteristic.

For identifying high-risk patients, we set a threshold at the top 25% of the cohort, which corresponded to a predicted mortality risk cutoff of 41%. Within this high-risk group, 10 patients passed away within 90 days of admission, and an additional 3 within the subsequent year (Figure 3B). Conversely, among the remaining 75 patients categorized as lower risk, only 3 deaths occurred within the 90-day period, and 6 in total during the first year. The calculated hazard ratio was 6.98 (95% CI 2.88-16.9; P<.001), reinforcing the model's capability to stratify patients based on their mortality risk effectively.

Discussion

Here, we demonstrate the potential of GPT-4 as a clinical decision-support tool in AIS management. Our main findings

XSL•FO
RenderX

show that treatment recommendations by GPT-4 closely aligned with both expert opinions (AUC 0.85) and real-world decisions (AUC 0.80). Notably, GPT-4 exhibited high accuracy in predicting 90-day mortality (AUC 0.89), outperforming specialized machine learning models.

AIS is a leading cause of mortality and disability worldwide [23-25]. The urgency of stroke care is particularly critical in regions with limited access to specialized stroke units or qualified physicians [26,27]. GPT-4's ability to operate seamlessly within existing treatment routines, relying solely on routine chart information, makes it valuable for quick triage in underresourced settings [7]. This accessibility could democratize high-level medical consultation, extending expert-level decision-making to underresourced health care facilities.

In our study, GPT-4 demonstrated high accuracy in predicting 90-day mortality for patients with AIS undergoing endovascular treatment. The model used a diverse range of clinical and imaging variables, offering a more comprehensive approach compared to existing models like Houston intraarterial therapy, Houston intraarterial therapy 2, PREMISE, and PRACTICE [18,19,28,29]. Unlike traditional health care predictive models that rely on structured data, GPT-4 provided recommendations based on narrative text. Our analyses highlighted the significance of unstructured data, as evidenced by the drop in prediction accuracy when the narrative clinical presentation was excluded. This showcases GPT-4's capability to handle complex medical data in a way that aligns with the natural flow of clinical information.

A crucial aspect of deploying AI models like GPT-4 in health care is the transparency and interpretability of their decision-making process. While GPT-4's natural language outputs can give the impression of explainability, these may not necessarily reflect a truly reliable reasoning process. Our analysis focused on the face value of GPT-4's rationales, which were deemed insightful by the expert reviewer. However, we acknowledge the potential for convincing but flawed explanations, a known limitation of LLMs. This highlights the importance of critical evaluation and cautious interpretation of such model outputs, particularly in high-stakes medical decision-making contexts. Ongoing research is needed to address the transparency and reliability of AI systems' reasoning processes before their broader integration into clinical practice.

Despite its promising results, our study has several limitations. We must acknowledge certain challenges in applying GPT-4, especially regarding its ability to assess ethical issues. The model may face difficulties in addressing the nuanced and complex ethical considerations intrinsic to medical decision-making. This limitation emphasizes the necessity for cautious and supplementary human oversight when deploying AI tools like GPT-4 in sensitive health care contexts. The occurrence of "hallucinations" or erroneous outputs is another concern, although we demonstrated that running multiple assessments can mitigate this risk. Future research should focus on refining these methods to further reduce inaccuracies.

Another consideration is the generalizability of these findings. While it is possible that the recommendations may partially reflect the clinician's intuition encoded in the clinical notes, our analyses suggest that the model's assessments go beyond mere interpretation. The discrepancies observed between the GPT-4 recommendations and both the real-world treatment decisions and the expert evaluations indicate that the model is capable of making independent assessments based on the provided data. Furthermore, the clinical presentation notes and imaging report interpretations (Table S1 in Multimedia Appendix 2) do not explicitly convey the clinician's treatment preferences or intuitions, suggesting that GPT-4 is not simply regurgitating the clinician's thought process. Another possible limitation is the study's exclusion criteria, particularly the retrospective exclusion of patients with incomplete clinical data or those who were ultimately diagnosed with conditions other than stroke. While these exclusions were necessary to ensure the study focused on accurately diagnosed AIS cases for which GPT-4 decision-support capabilities could be most relevant, we acknowledge that this approach may limit the generalizability of our findings to broader clinical settings. In real-world scenarios, clinicians are often faced with diagnostic uncertainty and incomplete information when making treatment decisions. Finally, our study was conducted in a single center with a specific patient population. Further studies across diverse settings and larger populations are necessary to validate the efficacy and applicability of GPT-4 in various clinical environments.

In conclusion, our study introduces a groundbreaking approach to clinical decision support in stroke management using GPT-4. This model has shown the potential to process narrative text, provide explainable recommendations, and enhance medical decision-making. As we continue to explore and refine this technology, it holds the promise of transforming patient care and improving outcomes in one of the most critical areas of medicine.

Data Availability

All data generated or analyzed during this study are included in Multimedia Appendix 2.

Authors' Contributions

SS and DA conceived and designed the study. SS and AM collected the clinical data and translated the narratives. SP and SS reviewed the cases and provided expert analysis. DA conducted the computational and statistical analyses with inputs from SS. SS and DA drafted the manuscript with contributions and critical revisions from AM, MK, SP, and MCS. All authors reviewed and approved the final manuscript.

Multimedia Appendix 3
GPT-4 Assessments Performance. Area under the curve (AUC) for GPT-4 decision to treatment scores of each of the individual submissions (1-5) and the average. Each individual submission is lower than the average. In addition, we submitted the cases without the clinical presentation narrative, which yielded lower AUC (no narrative). Similarly, lower AUC was observed when cases were submitted with temperature=0.

Abstract

Background: Pharmaceutical manufacturers address health care professionals' information needs through scientific response documents (SRDs), offering evidence-based answers to medication and disease state questions. Medical information departments, staffed by medical experts, develop SRDs that provide concise summaries consisting of relevant background information, search strategies, clinical data, and balanced references. With an escalating demand for SRDs and the increasing complexity of therapies, medical information departments are exploring advanced technologies and artificial intelligence (AI) tools like large language models (LLMs) to streamline content development. While AI and LLMs show promise in generating draft responses, a synergistic approach combining an LLM with traditional machine learning classifiers in a series of human-supervised and -curated steps could help address limitations, including hallucinations. This will ensure accuracy, context, traceability, and accountability in the development of the concise clinical data summaries of an SRD.

Objective: This study aims to quantify the challenges of SRD development and develop a framework exploring the feasibility and value addition of integrating AI capabilities in the process of creating concise summaries for an SRD.

Methods: To measure the challenges in SRD development, a survey was conducted by phactMI, a nonprofit consortium of medical information leaders in the pharmaceutical industry, assessing aspects of SRD creation among its member companies. The survey collected data on the time and tediousness of various activities related to SRD development. Another working group, consisting of medical information professionals and data scientists, used AI to aid SRD authoring, focusing on data extraction and abstraction. They used logistic regression on semantic embedding features to train classification models and transformer-based summarization pipelines to generate concise summaries.

Results: Of the 33 companies surveyed, 64% (21/33) opened the survey, and 76% (16/21) of those responded. On average, medical information departments generate 614 new documents and update 1352 documents each year. Respondents considered paraphrasing scientific articles to be the most tedious and time-intensive task. In the project's second phase, sentence classification models showed the ability to accurately distinguish target categories with receiver operating characteristic scores ranging from 0.67 to 0.85 (all $P<.001$), allowing for accurate data extraction. For data abstraction, the comparison of the bilingual evaluation understudy (BLEU) score and semantic similarity in the paraphrased texts yielded different results among reviewers, with each preferring different trade-offs between these metrics.

XSL•FO
RenderX

Conclusions: This study establishes a framework for integrating LLM and machine learning into SRD development, supported by a pharmaceutical company survey emphasizing the challenges of paraphrasing content. While machine learning models show potential for section identification and content usability assessment in data extraction and abstraction, further optimization and research are essential before full-scale industry implementation. The working group's insights guide an AI-driven content analysis; address limitations; and advance efficient, precise, and responsive frameworks to assist with pharmaceutical SRD development.

Introduction

Pharmaceutical manufacturers play a crucial role in meeting health care professionals' information needs by providing them with scientific response documents (SRDs). These documents provide comprehensive and evidence-based answers to unsolicited questions concerning a medication or disease state [1]. The development and maintenance of SRDs are entrusted to the medical information department within these organizations. This department is composed of medical experts who possess in-depth knowledge of specific therapeutic areas and are responsible for various strategic activities, including the meticulous development of SRDs [2]. SRDs are tailored to address specific inquiries, presenting a concise summary, relevant background information, clinical data, and scientifically balanced references [1]. Considering the escalating demand for SRDs and the increasing complexity of therapies, the role of medical information departments has become more critical than ever. A 2018 survey of 27 pharmaceutical companies revealed that a medical information department creates an average of 716 new SRDs and maintains 2510 existing SRDs annually [2]. Fully developing a new SRD required an average of 31 hours for medical experts, while updating or revising existing SRDs involved an average of 21 hours [2]. Medical information experts use this time to answer the SRD query following a scientific method approach [3]. The strategic and resource-intensive nature of SRD development and the surge in health care professional inquiries emphasize the pressing need for timely and comprehensive information. To address these challenges, there is a growing interest across medical information departments in leveraging advanced technologies and artificial intelligence (AI) tools, such as large language models (LLMs) and traditional machine learning techniques, to enhance and streamline the SRD development process. There are several steps to develop an SRD, including reading articles, selecting article content, paraphrasing article content, creating a citation list, editorial changes, data integrity, and content review. Some of these steps may be more time-consuming than others.

To better understand the current advancements in AI, consider an analogy used in software development. Programming can be thought of as software 1.0, where a machine relies on explicit, step-by-step instructions from a programmer to perform designated tasks. Machine learning represents software 2.0, where developers present labeled examples of input and output data to the machine so that it can identify patterns that allow it to predict outcomes from inputs. This kind of supervised machine learning has enabled rapid progress in many areas of natural language processing, including applications in language translation, sentiment analysis, and information retrieval. More recently, LLMs, such as OpenAI's Generative Pre-trained Transformer (GPT), are complex machine learning models trained to predict subsequent words in natural language text based on the text so far. This allows the machine to generate statistically plausible output given a "prompt." Beyond simple prompt completion, such models can be trained to follow instructions in the prompt, such as "Summarize the following paragraph." Designing prompts that lead an LLM to produce a desired output is a novel and distinct paradigm in software development, which can be classified as "software 3.0" [4].

Language models convert language to numerical representation, and specialized models create semantic embedding by exporting a sentence as a vector of floating-point numbers [5]. By converting concepts into numeric vectors, embeddings enable computers to represent the connections between concepts. The relationship between two embeddings is determined by the vector distance, with smaller distances indicating higher relatedness and larger distances implying lower relatedness. Embeddings are easily consumed and compared by other machine learning models and algorithms for tasks like clustering text strings based on similarity or ranking search results by query relevance. Furthermore, embeddings exhibit semantic similarity—numerically similar embeddings correspond to similar meanings.

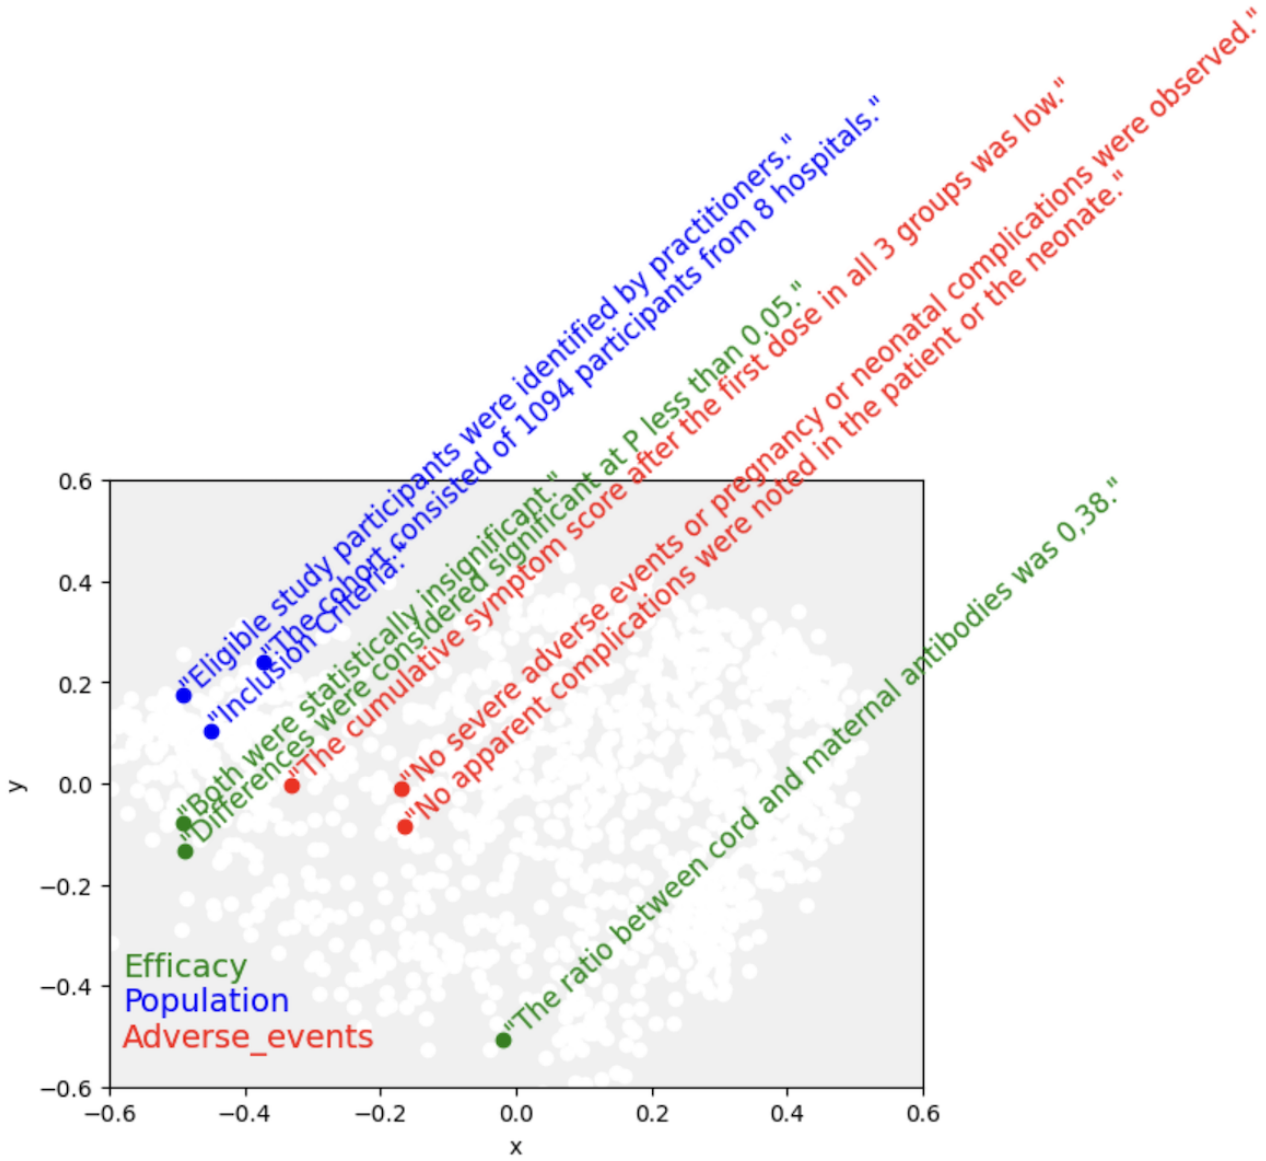

Figure 1 shows examples of semantic embeddings of sentences based on the dataset used in this study. The original 768-dimension embeddings were mapped down to 2 dimensions to visualize them, showing that sentences on similar topics are close together. Colors indicate the category to which the sentence belongs. Here, the 3 sentences in blue ("Population") are close semantically to one another, as are the 3 sentences in red ("Adverse_events"). One of the sentences in the "Efficacy" category is far from the other two, but on examining the sentences, it is considered an outlier talking about a ratio of antibodies, while the two that are close to one another both concern statistical significance.

LLMs apply traditional machine learning concepts and embeddings on a larger scale. Transformers process sequential

RenderX

data, such as natural language, all at once, enabling them to perform tasks like text summarization [6]. GPT is trained to predict the next word using preceding words, capturing linguistic patterns and semantic relationships in large text datasets. GPT often produces coherent and plausible responses. By providing labeled examples, GPT can be fine-tuned for specific tasks to enhance its capabilities. This fine-tuning process allows GPT to adapt its prelearned knowledge to effectively perform tasks such as text generation, question answering, and language translation [7].

Figure 1. High-dimensional data visualization of embeddings. The t-SNE (t-distributed stochastic neighbor embedding) algorithm was used to transform data into 2 dimensions. Different colors were chosen for different sections based on reviewer feedback (based on the test set used in the study).

AI tools have a well-established history in medicine, with potential applications like artificial neural networks aiding clinical prognosis and diagnosis through pattern recognition first identified in 2004 [8]. Furthermore, within academic and research writing, OpenAI's ChatGPT has been used to "extract" important information from academic papers (eg, author details, publication date, main findings, etc) and generate summaries of these lengthy papers [9]. However, the use of AI to create medical content, particularly SRDs, is still in its early stages. An April 2023 study showcased the potential of AI by using OpenAI's ChatGPT to generate draft responses to patient questions based on deidentified information [10]. This pioneering work highlights the need to explore AI's capabilities in medical content generation in depth.

Although ChatGPT demonstrates impressive language generation abilities, relying solely on it has limitations. ChatGPT, like any LLM, can hallucinate and produce content based on its prediction without logic or fact-checking abilities [11]. Furthermore, there exists a lack of transparency in the training sets used for LLMs like ChatGPT. This, coupled with the complexity of these models, may lead to false or biased information being unintentionally included in the generated content [12]. The accuracy of an SRD is crucial in its creation. Furthermore, traceability and accountability are essential considerations. The use of LLMs like ChatGPT often results in

XSL•FO
RenderX

the original authors and sources not being cited, leading to the misattribution of information [13].

This study has 2 aims. The first is to quantify the challenges of SRD creation by gathering the opinions of medical information professionals regarding the time consumption of the various steps of SRD development. To address these challenges and leverage the strengths of both human expertise and AI in the creation of SRDs, a synergistic approach that combines LLM with traditional machine learning classifiers is warranted. The second aim of this study is to develop a framework to explore the feasibility and value addition of integrating AI capabilities, including LLM and machine learning, into the SRD creation process.

Methods

Survey of phactMI Members

A working group from phactMI developed a cross-sectional survey to assess the time and tediousness of various aspects of SRD creation. phactMI, a nonprofit consortium of medical information leaders from the pharmaceutical industry, conducted the survey using the survey tool Alchemer. The initial contact for the web-based open survey link was emailed to one contact at each of the 33 member companies in March 2023 (see Multimedia Appendix 1 for email wording). Participation in the survey was voluntary, and no incentives were offered. The survey link was sent once, with one reminder sent during March 2023, and the survey closed on April 15, 2023. The working group pretested the survey using the Alchemer system before distribution. In the recruitment email, the purpose of the survey, length and duration, the lead investigator, and how all data were to be handled were disclosed. Proceeding to the first question was considered consent to participate.

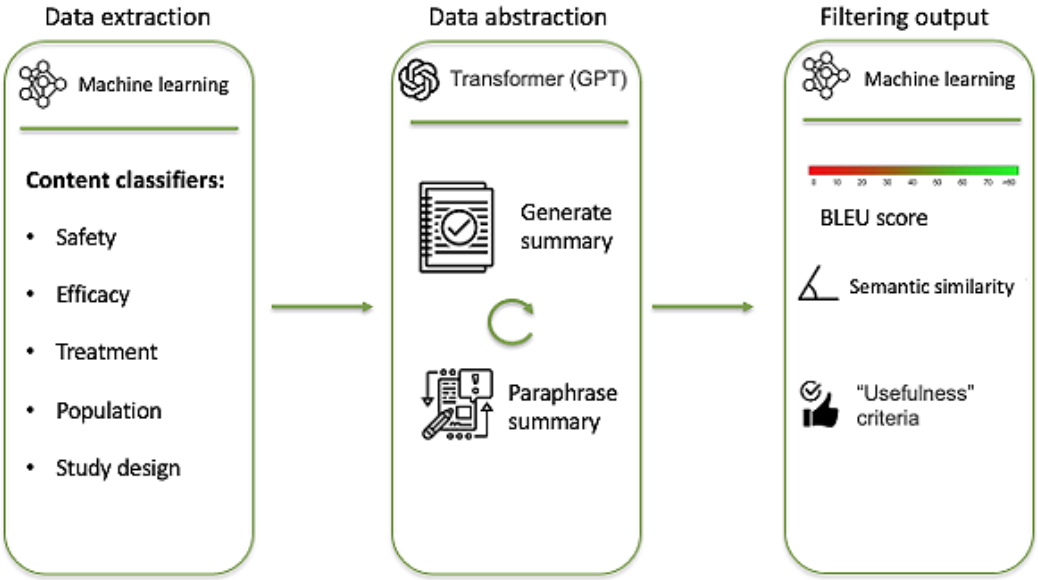
The creation of an SRD is a strategic endeavor comprised of several steps that may be more time-consuming and tedious than others. Specific data collected in the survey included the average time needed for creating an SRD, the average number of papers included in an SRD, etc. Survey respondents were given a list of activities, including paraphrasing article content, creating a citation list, making editorial changes, improving data integrity, selecting article content, reviewing content, and reading articles. Respondents were asked to rank given activities from 1 to 8 in terms of time consumption and tediousness (1 being the most time-consuming or tedious and 8 being the least time-consuming or tedious). The interpretations of time-consuming and tedious were left to the discretion of the survey respondents.

Not all steps had to be ranked by all respondents. A score for each step was created with a weighted calculation, with items ranked first being given a higher value or weight. Weighted values are based on the number of steps selected. The higher the score, the more time-consuming or tedious the steps were considered. The survey results were analyzed to identify those steps in the development of an SRD where the use of AI may offer maximum benefit.

The survey questions were not randomized, and there was no adaptive questioning. There was a total of 10 questions. All questions were displayed on the same page, so no back button or review step was necessary.

Only 1 response per company was allowed. Data were analyzed using descriptive statistics. The full survey questionnaire is provided in Multimedia Appendix 2. The Checklist for Reporting Results of Internet E-Surveys (CHERRIES) for this survey is provided in Multimedia Appendix 3.

Ethical Considerations



The survey was not approved by an institutional review board as it was not considered human subject data. All survey data were deidentified, saved, and reported in aggregate.

Authoring SRD

Another working group consisting of medical information professionals and data scientists was created. Their goal was to leverage AI to support the medical information department's creation of SRDs. Their aim was to develop a tool that could process scientific articles (input) and provide concise summaries (output). The group identified two key steps in the document authoring process: data extraction and data abstraction. Their problem was figuring out the process between the input and output (Figure 2). Data extraction is the selection of key sentences from publications that address all the data points authors would want to include in a response document, and data abstraction is the generation of a summary of extracted data, followed by paraphrasing to avoid plagiarism of original texts.

XSL•FO
RenderX

Figure 2. Proposed process design. BLEU: bilingual evaluation understudy; GPT: Generative Pre-trained Transformer.

Data Extraction and Machine Training

The working group selected scientific texts from the PubMed Central database focusing on clinical drug trials for data extraction. The narrative text from these articles, excluding text in tables, was extracted, cleaned, and placed into Prodigy, a data annotation tool. A total of 3 domain experts and medical information specialists labeled sentences from narrative text into 5 classifications: safety, efficacy, treatment, population, and study design. These classifications correspond to the main sections of a clinical trial used in the creation of an SRD. A fourth domain expert, a data editor, reviewed all the labels to ensure the labeling criteria were applied consistently. These labeled data were then fed into logistic regression classification models to train the models on identification. The training dataset is available in Multimedia Appendix 4.

Participating companies provided 3 SRDs to the working group. The team extracted clean, narrative text from the provided documents to feed into the models. The models categorized each sentence based on their previous training. Reviewers evaluated and assessed model classifications. Trained models' performance was evaluated with a receiver operating characteristic (ROC) curve plotting the true positive rate (TPR) and false positive rate (FPR). The area under the curve (AUC) provides an aggregate measure of performance across all possible thresholds, with a higher AUC indicating better performance of the model. A Wilcoxon-Mann-Whitney *U* test statistic was applied.

Data Abstraction

Summarizing the extracted data was the initial step in data abstraction. The working group used the Hugging Face transformers summarization pipeline leveraging the Facebook/BART-large-cnn model, a language model trained for summarization. The second step was to rewrite and synthesize the extracted text without plagiarizing the original reference by using the GPT-3 model (text-davinci-003). The model received the prompt "Paraphrase this without plagiarizing," followed by the summarized text. Multiple paraphrases were generated for each input.

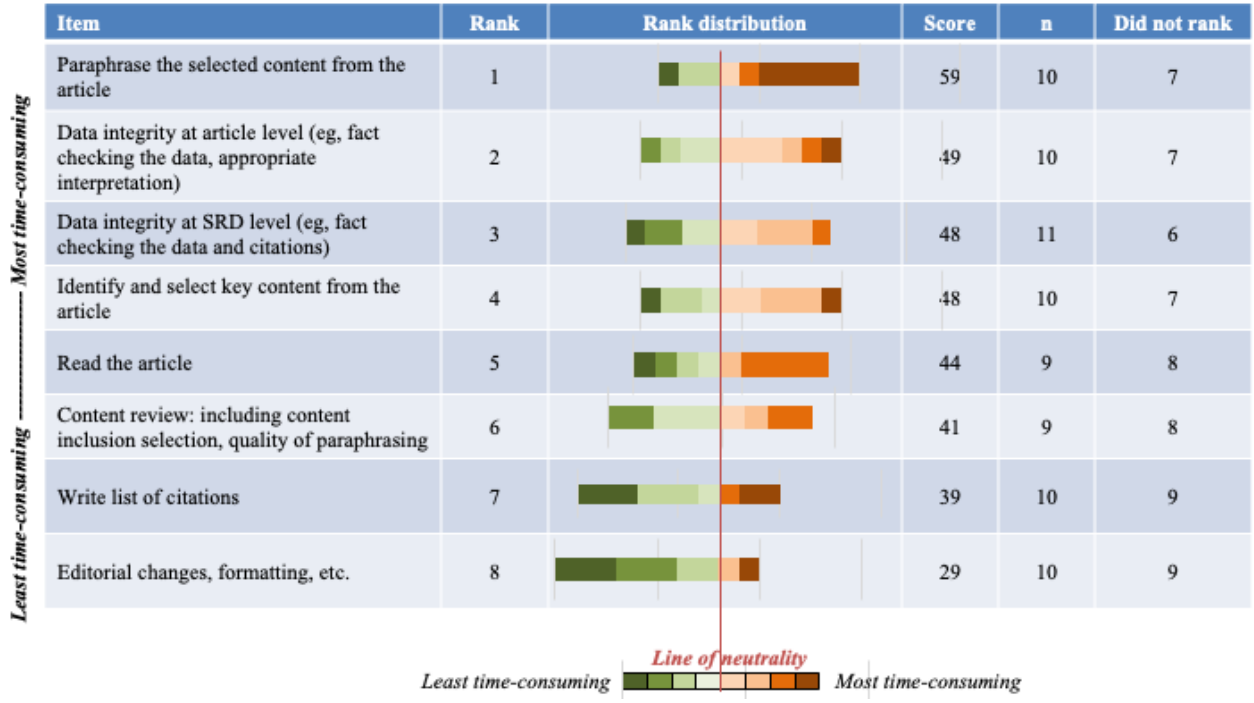
Filtering Output

A total of 2 criteria were used to sort and rank the paraphrased texts: semantic similarities and bilingual evaluation understudy (BLEU) scores. Semantic similarity, measured using cosine similarity between sentence transformer embeddings (distiluse-base-multilingual-cased-v2), assessed the likeness in meaning between the paraphrased sentences and the original text. The greater the semantic similarity between the two sentences, the better the quality of the paraphrasing. The second criterion was the BLEU score, which measured the similarity in word or phrase use between a generated text and the original text. It was calculated using *sacrebleu* with *effective_order* set to true. A low BLEU score reflects a higher quality of paraphrasing, as it indicates less similarity in words and phrases with the original text. Finding the right balance between semantic and textual similarities was crucial for the overall paraphrasing quality. Human reviewers then evaluated the paraphrased text and ranked the text by usefulness with rationales provided.

Throughout the study, the working group fostered collaboration between medical information professionals and data scientists to validate the results. Results from each step were edited by hand to make sure that the next step had clean inputs.

Results

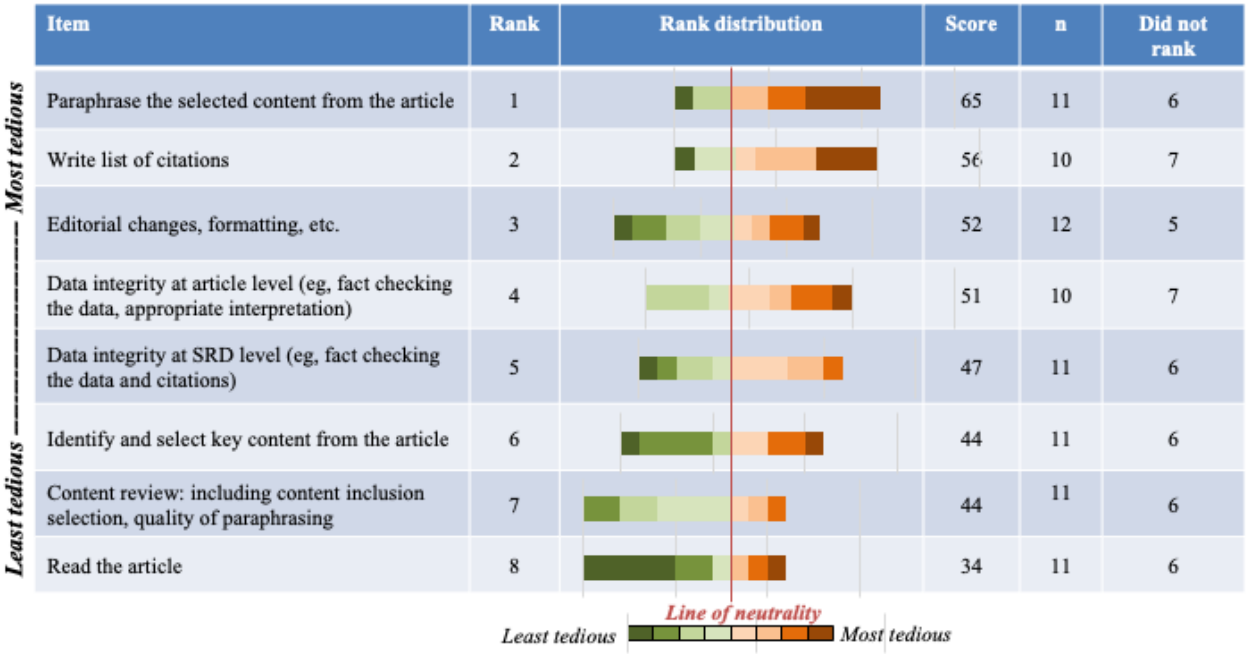
Survey of phactMI Members



A total of 21 of the 33 pharmaceutical member companies, based on IP address, opened the survey (view rate 64%). A total of 16 pharmaceutical member companies participated in the survey (participation rate 76%, 16/21), with a completion rate of 81% (13/16). No cookies were used to assign user identification. Duplicate entries were identified by either IP address or company name (if provided). The most complete or

XSL•FO
RenderX

most recent entry was kept for analysis. All data from unique entries were included in the analysis.



On average, a medical information department creates 614 (range: low to 2676) new SRDs and updates or revises 1352 (range: low to 6057) SRDs annually. Respondents indicate it takes, on average, 8.3 hours to create a new SRD and 3.8 hours to update an SRD. In addition, 87% (14/16) of respondents included content from at least 4 studies in SRDs summarizing clinical trial data. The survey results revealed that the top 3 most time-consuming steps in SRD development were paraphrasing study content, checking the data integrity of the paraphrased text versus the source publications, and checking the data integrity of the SRD (eg, checking that the text is cited to the correct publications; Figure 3). While paraphrasing article content was also the most tedious step, the other top steps differed, with writing citations and editorial changes rounding out the top 3 (Figure 4).

Figure 3. Ranking of steps deemed time-consuming by survey respondents. SRD: scientific response document.

Item	Rank	Rank distribution	Score	n	Did not rank
Paraphrase the selected content from the article	1		59	10	7
Data integrity at article level (eg, fact checking the data, appropriate interpretation)	2		49	10	7
Data integrity at SRD level (eg, fact checking the data and citations)	3		48	11	6
Identify and select key content from the article	4		48	10	7
Read the article	5		44	9	8
Content review: including content inclusion selection, quality of paraphrasing	6		41	9	8
Write list of citations	7		39	10	9
Editorial changes, formatting, etc.	8		29	10	9

Data Extraction

ROC curves are a fundamental way to evaluate classifier performance. AUC values can range from 0.5 to 1.0, with values closer to 1.0 indicating that the classifier's performance is better than random. Using 3187 sentence data points, ROC curves were generated to assess the classifier's performance (Figure 5). The model trained on treatment data had the highest AUC (0.85). Models trained on Prodigy data achieved AUC scores of 0.84, 0.74, 0.7, 0.67, and 0.74 for adverse events, population, efficacy, end points, and study design, respectively. The AUC scores for all classifier models exceeded 0.5 (random chance) with $P<.001$. Overall, the model was able to classify sentences appropriately and be better than a random chance (indicated by the dashed line).

Figure 5. Receiver operating characteristic (ROC) curve of machine learning models' performance. AUC: area under the curve.

Data Abstraction and Filtering Output

The clinical trial data were inputted into the LLM model to produce an AI-generated summary and an AI-generated paraphrase of the text. Table 1 provides 2 examples of the paraphrasing process, showing the input in the LLM model and output using the prompt "Paraphrase this without plagiarizing."

In Table 1, the colors correlate to the BLEU scores, with the reddest color being 100 and the bluest color being 0 (as shown by the scale on the right). The y-axis corresponds to the original sentences in the text (0, 1, 2, etc), and the x-axis corresponds to the paraphrased sentences (0, 1, and 2). Each original sentence is compared with each paraphrased sentence with a BLEU score. The lower the BLEU score, the fewer words and phrases there are in common between the original and the paraphrased sentences. Semantic similarity is the overall similarity between the two texts.

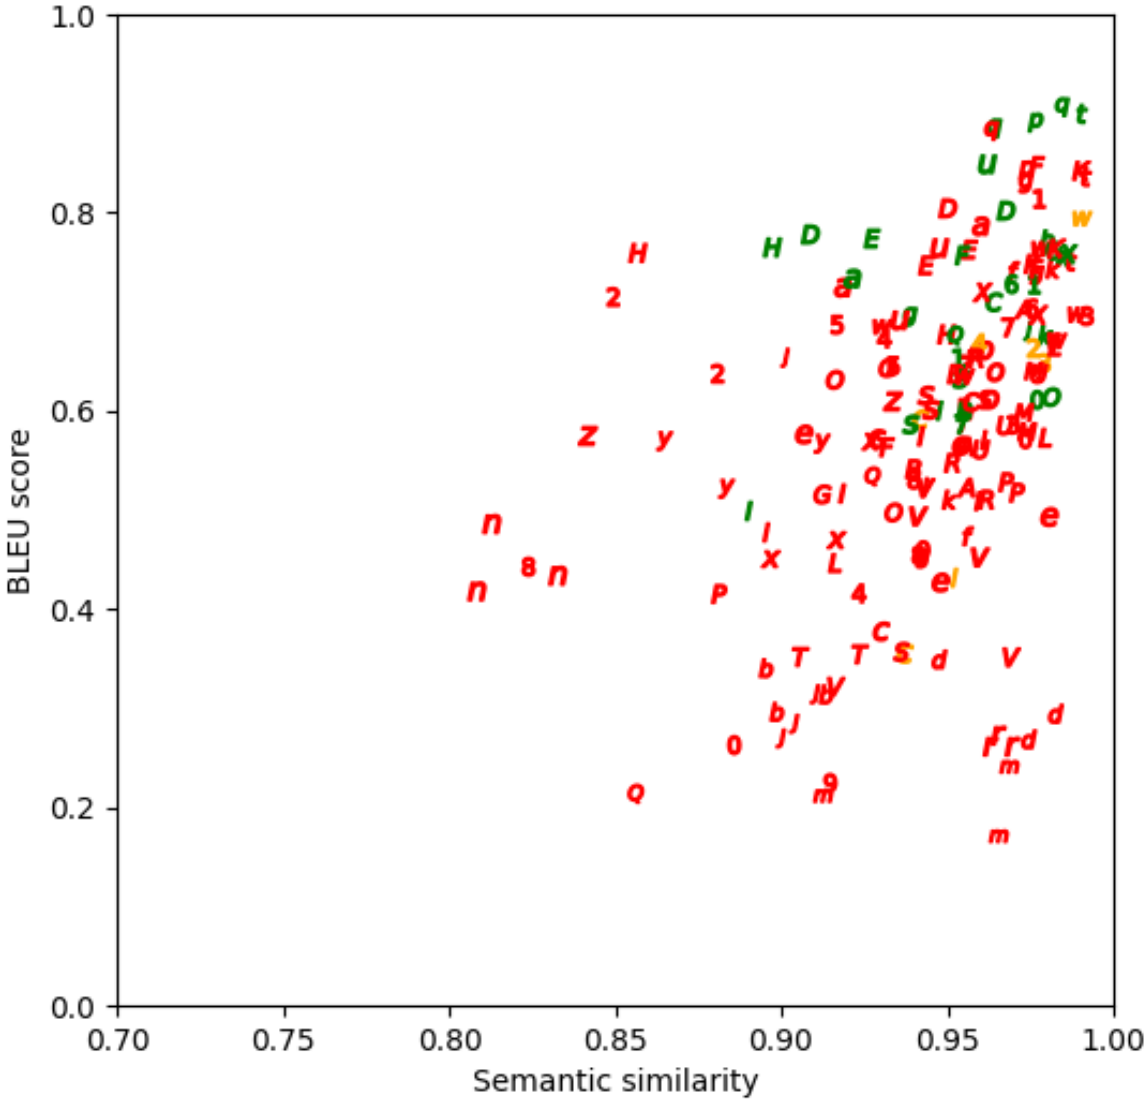
RenderX

Table 1. Artificial intelligence (AI)–generated summarized and paraphrased text examples.



Original text input	AI-generated summarized text:	AI-generated paraphrased text:
• In the sitagliptin group and glimepiride group, serious adverse experiences were reported for 16 and 11 patients, respectively. One serious adverse experience that was considered drug-related by the investigator was reported in the study: a 61-year-old female in the sitagliptin group experienced a serious drug-related adverse experience of thrombocytopenia (platelet count of 12 000/μL) resulting in discontinuation from the study. Apart from hypoglycemia, the only other adverse event with an incidence of at least 5% in either treatment group was nasopharyngitis (4.8 and 6.9% in the sitagliptin and glimepiride groups, respectively). Overall, clinical adverse experiences and drug-related adverse experiences were reported more frequently with glimepiride, primarily as a result of an increased incidence of hypoglycemia.	• In the sitagliptin group and glimepiride group, serious adverse experiences were reported for 16 and 11 patients, respectively. The only other adverse event with an incidence of at least 5% in either treatment group was nasopharyngitis (4.8 and 6.9%).	• In the sitagliptin group, 16 patients reported a serious adverse experience. • In the glimepiride group, 11 patients reported a serious adverse experience. • The only other adverse event with an incidence of at least 5% was nasopharyngitis.  Semantic similarity: 0.76 max BLEU[a]: 18.54
• Specific clinical adverse experiences of interest included hypoglycemia and prespecified selected gastrointestinal adverse experiences (abdominal pain, nausea, vomiting, and diarrhea). The incidences of serious clinical adverse experiences were similar between treatment groups. For serious adverse experiences that were considered by the investigator to be related to the study drug, there were three in the glipizide group (myocardial infarction, spontaneous abortion, and hydronephrosis) and one in the sitagliptin group (thrombocytopenia). The overall incidence of infection-related adverse experiences was similar in the two treatment groups. Of the adverse experiences with a higher incidence in the glipizide group, the 95% CI around the between-group difference in incidence excluded zero for cataracts, toothache, hypoglycemia, and hypoesthesia (Table 5). With the exception of hypoglycemia, these adverse experiences (occurring in either group) were generally rated as mild in intensity, not considered related to the study drug, and resolved while patients continued on the study drug. AE, adverse experience. Overall, clinical adverse experiences and drug-related adverse experiences were observed more often with glipizide, largely related to an increased incidence of hypoglycemia. The number of serious adverse experiences was similar in both treatment groups, and no specific pattern of serious adverse experiences was observed in either treatment group.	• The incidences of serious clinical adverse experiences were similar between treatment groups. Serious adverse experiences that were considered by the investigator to be related to the study drug were three in the glipizide group (myocardial infarction, spontaneous abortion, and hydronephrosis) and one in the sitagliptin group (thrombocytopenia). The overall incidence of infection-related adverse experiences was similar.	• There were similar incidences of serious clinical adverse experiences between treatment groups. • The serious adverse experiences that were considered by the investigator to be related to the study drug were three in the glipizide group (myocardial infarction, spontaneous abortion, and hydronephrosis) and one in the sitagliptin group (thrombocytopenia). • The overall incidence of infection-related adverse experiences was similar.  Semantic similarity: 0.86 max BLEU: 89.34

[a]BLEU: bilingual evaluation understudy.

Semantic similarity and BLEU scores calculated for the paraphrases show that in the two example scenarios in Table 1, one has a low BLEU score, and the other has a high BLEU score. The high BLEU score in example 2 contains more original text in the paraphrase compared to the low BLEU score in example 1. Figures 6-8 depict the graphed comparison of BLEU score and semantic similarity among three reviewers (users) to define usefulness. User 2 showed a preference for high semantic similarity, but there was no clear trend with the BLEU score. User 3 consistently favored paraphrases with both high semantic similarity and BLEU score. User 1 had no clear preference trend. Differences between what human reviewers found useful in paraphrases were noted.

Discussion

Principal Findings

In the survey section of this study, we found that in the strategic activity of creating SRDs, the major challenge was in paraphrasing articles. In the subsequent phase of this study, traditional machine learning classifiers and LLMs automated portions of the clinical trial summarization process of creating an SRD.

Our survey revealed a much shorter time (8.7 hours and 3.8 hours) to create or revise an SRD compared with the 2018 phactMI benchmarking survey (31 hours and 21 hours) [2]. The variations and limited external validity of the overall survey may be attributed to the nature of the survey, the number of responses, and survey types. Nevertheless, the survey's results continue to be valuable, as they offer nuanced insights from engaged participants and contribute to our understanding. Regardless of the amount of time, providing solutions to improve the efficiency of creating an SRD would be welcomed.

Data Extraction

Our study reveals the promise of machine learning models in classifying individual sections within scientific documents, particularly in the context of addressing inquiries within the pharmaceutical industry. The results from the ROC curves suggest that our classifier models outperform random guessing, demonstrating the highest AUC values for the treatment and adverse events classifiers. The transparency and interpretability of our classifier models were pivotal strengths. Unlike LLMs, which are known for their opaqueness in decision-making, our traditional machine learning models have successfully identified and resolved training logic deviation issues. Having clear

XSL•FO
RenderX

explanations in the output is invaluable for trust, accountability, and enhancing the models.
