In addition, the classifier models exhibited resource efficiency. While finetuning LLMs is a resource-intensive process, we found that adjusting the logistic regression model can be executed in seconds. This efficiency has major implications for rapid model development and deployment.

Enhancing classifier performance necessitates the consideration of several key factors that the working group identified. These factors include providing additional context, predefining known key terminology for specific sections, and exploring methods to reduce false negatives. In future iterations, our approach will expand the scope of classifiers beyond section identification to assess the usefulness of the identified content for inclusion in an SRD. This transition marks a shift from mere classification to a more profound evaluation of content, offering applications in content retrieval tailored to individual user needs.

Data Abstraction and Filtering Output

Our exploration of paraphrasing performance in LLMs has been highly informative. Quantitative assessment of paraphrased content requires robust tools like semantic similarity and BLEU scores. By leveraging these tools, we gain a deeper understanding of the effectiveness of paraphrasing, ensuring that content retains its intended meaning while being substantially different from the original in terms of phrasing or wording.

The observed variability in LLM-generated paraphrases highlights the difficulty of consistently fine-tuning an LLM for paraphrasing. The diverse approaches to paraphrasing are highlighted by the distinct preferences of human reviewers. Developing a universal model for all preferences is an ambitious endeavor. The working group proposed an alternative approach to this challenge: using simple models that offer users multiple paraphrase options. We can enhance the content ranking and establish core data by providing choices and using smaller datasets, as user selections can potentially be used to train classifiers to identify the kind of content that the user prefers.

The working group also recommends the following next steps with LLMs to further this exercise: (1) fine-tuning an LLM for medical text, (2) better prompt engineering, and (3) LLMs with better citation training. Incorporating these considerations into our discussion of paraphrasing performance and prospects, we navigate the evolving landscape of AI-driven content generation in the pharmaceutical industry. These insights not only promise enhanced content but also embody a user-centric approach that empowers industry professionals to access tailored, high-quality content.

Need for Human Control in AI-Assisted Scientific Writing

A recent study used ChatGPT to obtain medical information and treatment options for shoulder impingement syndrome [14]. While ChatGPT's answers were useful for patients, it sometimes provided inaccurate information (prevalence reported with no evidence supporting the number) and biased information (risk factors reported that are not established). Goodman et al [15] conducted a cross-sectional study corroborating these limitations of LLMs. Most responses were accurate and comprehensive, indicating the potential use of LLMs. Occasionally, incorrect answers were provided, and the chatbot provided inaccurate citations when asked for the source of information. Other studies have demonstrated similar drawbacks (misinterpretation of medical terms, hallucination, missed information, factually incorrect statements, and fabricated references) in the use of LLMs in scientific writing and simplified radiology reports [13,15,16]. Accuracy, lack of bias, and traceability to the original publication are crucial in medical information. Thus, using LLMs without considerable human intervention for medical information responses or SRDs is a highly risky proposition. While AI can help humans create a "first draft" of the final SRD, it is imperative for the human writer to retain control over the tool's input, data extraction for the SRD, and the ultimate inclusion of paraphrased content in the SRD. Our approach includes various "checkpoints" during AI-assisted SRD creation, allowing human writers to intervene and enhance the content's credibility.

The use of LLMs for scientific writing also presents concerns regarding plagiarism and the use of nonacademic language [13,17]. In addition, LLMs are unable to determine the credibility of their information sources, for example, a blog post versus a PubMed-indexed paper [15]. Our model can overcome numerous limitations by integrating machine learning and LLM systems.

Limitations

Despite the working group's diligent effort to maintain scientific rigor in this study, several limitations warrant consideration. The classical machine learning classifiers may have biased models due to training on a constrained dataset and limited reviewer assessments. Instead of relying on experts to label more examples, it may be more efficient to extract labeled examples from existing datasets (eg, adverse events sections from full-text papers in PubMed Central). The use of LLMs like GPT presented known challenges for paraphrasing medical text, such as generative AI issues of "hallucination," lack of transparency, bias, and privacy concerns [18].

The dynamic generative AI landscape implies that the findings of paraphrase exercises only reflect a snapshot in time. OpenAI introduced GPT-4 Turbo, a 2023 model trained on a larger dataset, while we were drafting this manuscript [13]. Nori et al [19] demonstrated that prompt engineering with GPT-4 outperformed fine-tuned medical models for question answering. The framework described in this paper is similar to the emerging pattern of retrieval augmented generation [20] in leveraging LLMs. The focus of retrieval augmented generation is to provide the LLM with accurate, up-to-date information [20]. The same business drivers from the medical information space prompted this evolution, driven by a need for accuracy and content lineage tracking. The fact that several others have reached a similar conclusion on integrating LLMs into highly regulated industries such as drug manufacturing is a strong validation.

RenderX

Conclusions

This study sought to identify the challenges inherent in the development of SRDs and to establish a framework for integrating LLM and machine learning into the SRD creation process. Our tool leverages LLMs and machine learning to enhance AI applications in the pharmaceutical realm. Integrating these two technologies not only saves resources but also addresses major challenges associated with LLMs. Our models can clearly identify sections, paraphrase effectively, and assess content usefulness. These initial findings suggest that machine learning classifiers can predict, to some extent, the sentences authors will choose for summarization and paraphrases they will find useful. Even a modest ability to rank results could improve the suggestions' quality beyond random. However, the current tool does not have the capacity to generate an SRD for the pharmaceutical sector using zero-shot classification. Nevertheless, it underscores the essential role of traditional machine learning in enhancing future AI models, moving us closer to efficient content handling in the industry. This model has the potential to be a valuable tool in the medical information domain of the pharmaceutical industry, augmenting the efficiency of human document creators, thereby optimizing workflows and improving the quality of services. Further research is required for the optimization, refinement, and validation of these models, using larger training sets and multiple reviewers, before full-scale implementation in the industry.

Acknowledgments

This research was sponsored by phactMI and Microsoft. No generative artificial intelligence was used in the development of this manuscript. The authors would also like to acknowledge Mario E Inchiosa's contribution to the study.

Data Availability

All data generated or analyzed during this study are included in this published article and its supplementary information files.

Authors' Contributions

All authors contributed to the conceptualization, formal analysis, investigation, methodology, resources, and writing-review and editing. In addition, JL and RH were responsible for data curation; JJ for funding acquisition; JL for project administration; RH for software; EH-D for supervision; SG, AC, RH, and SB for validation; RH and EH-D for visualization; and JL, EH-D, SB, and RH for writing-original draft.

Conflicts of Interest

JL was a fellow at phactMI 2022-2024. AC is an employee of Pfizer (and owns stock) and is on the Board of Directors for phactMI. SB is an employee of Eli Lilly and Company. RH is an employee of Win-Vector Labs and, at the time of the research, was employed by Microsoft. None declared by other authors.

Abstract

Background: The application of machine learning methods to data generated by ubiquitous devices like smartphones presents an opportunity to enhance the quality of health care and diagnostics. Smartphones are ideal for gathering data easily, providing quick feedback on diagnoses, and proposing interventions for health improvement.

Objective: We reviewed the existing literature to gather studies that have used machine learning models with smartphone-derived data for the prediction and diagnosis of health anomalies. We divided the studies into those that used machine learning models by conducting experiments to retrieve data and predict diseases, and those that used machine learning models on publicly available databases. The details of databases, experiments, and machine learning models are intended to help researchers working in the fields of machine learning and artificial intelligence in the health care domain. Researchers can use the information to design their experiments or determine the databases they could analyze.

Methods: A comprehensive search of the PubMed and IEEE Xplore databases was conducted, and an in-house keyword screening method was used to filter the articles based on the content of their titles and abstracts. Subsequently, studies related to the 3 areas of voice, skin, and eye were selected and analyzed based on how data for machine learning models were extracted (ie, the use of publicly available databases or through experiments). The machine learning methods used in each study were also noted.

Results: A total of 49 studies were identified as being relevant to the topic of interest, and among these studies, there were 31 different databases and 24 different machine learning methods.

Conclusions: The results provide a better understanding of how smartphone data are collected for predicting different diseases and what kinds of machine learning methods are used on these data. Similarly, publicly available databases having smartphone-based data that can be used for the diagnosis of various diseases have been presented. Our screening method could be used or improved in future studies, and our findings could be used as a reference to conduct similar studies, experiments, or statistical analyses.

literature review; machine learning; smartphone; health diagnosis

Introduction

The use of machine learning for medical diagnosis is steadily growing. This can be attributed primarily to the availability of numerous health data as well as improvements in the classification and recognition systems used in disease diagnosis. The health care industry produces an abundance of health-related data [1], which can be used to create machine learning models.

XSL•FO
RenderX

These models can be used for diagnosing and predicting a variety of diseases, including breast cancer, heart diseases, and diabetes [2,3]. The prediction of these diseases is dependent on many factors according to the focus on different features (biomarkers) [4]. The application of machine learning methods helps classify and diagnose diseases in an easier way [1], and these diagnoses can help medical experts in the early detection of fatal diseases and therefore increase the quality of health care and the survival rate of patients significantly [1,2,4,5].

Machine learning methods and their applications are not limited to particular types of data and thus have been used in a variety of areas, such as detecting spontaneous abortion [6], identifying complex patterns in brain data [7], and improving diagnostic accuracy and identifying faults in axial pumps [8]. To diagnose and predict different diseases, machine learning methods have also been applied to data obtained from experiments by using publicly available datasets, such as the UCI machine learning library [2], National Health and Nutrition Examination Survey (NHANES) [3,6], traumatic brain injury (TBI) [4], and SUITA datasets [9]. Similarly, numerous smartphone-based health care apps have been developed to help both health care officials and the general population with regard to their health-related concerns. The apps developed can be broadly divided into 3 specific user groups: health care professionals, medical/nursing students, and patients [10]. The purpose of such apps covers a wide range of areas, such as disease diagnosis, drug reference, medical education, clinical communication, and fall detection. However, all iOS- or Android-based apps developed for health care purposes have not been discussed in the literature [10].

A literature review is a systematic way of collecting studies relevant to a research topic, assessing the methodologies and results of the studies, and making recommendations for improvements if necessary [11]. In the health care domain, the implementation of literature reviews has been considered important for conducting further research and developing guidelines for clinical practice [12]. Literature studies, such as umbrella reviews, have been conducted to study the management of the information of patients, such as those with cancer, and how their records are handled [13]. Similarly, literature-based studies have investigated the evidence of leadership in nursing [14]. Uddin et al [15] found a total of 48 literature studies that dealt with disease prediction using various supervised machine learning algorithms and attributed the rise in the use of machine learning for health prediction to the wide adoption of computer-based technologies in the health sector and to the availability of large health-related databases.

The ubiquity of smartphones makes them a convenient tool to gather various health-related data, particularly as smartphones are equipped with various sensors that are able to track and gather different health-related information [16]. However, there is a lack of research on studies involving the adoption of smartphones for disease prediction using machine learning methods and identifying the types of experiments conducted, databases utilized, and machine learning methods used. With that in mind, in this paper, we aim to conduct a scoping review by assessing research papers from repositories, such as PubMed and IEEE Xplore, which have used machine learning methods with smartphone-derived data to predict diseases related to the eyes, skin, and voice, and from databases available for public use. We aim to answer the following important research questions:

1. What are the databases available for eye-, skin-, and voice-related diseases?
2. What are the machine learning models used in such studies?
3. How the data are collected using smartphones?

The rest of the paper is organized as follows: we explain how we gathered, screened, and analyzed the literature in the methods section; present the results of our study in the results section; and finally discuss the results and clarify how the results correspond to our research questions in the discussion section.

Methods

Overview

We describe in detail the procedures undertaken for conducting the scoping review, with inspiration taken from the guidelines provided by Mak and Thomas [17]. After deciding on the topic of research, we identified the steps to be taken for the literature review as follows:

1. Search criteria
2. Literature assembly
3. Study selection
4. Research questions
5. Inclusion and exclusion criteria
6. Full-text paper assessment

Search Criteria

Numerous studies have conducted literature reviews to assess the use of machine learning for disease prediction. We formulated the following search string using a combination of different words related to topics, such as smartphone, smartwatch, machine learning, health, and medicine, to search different electronic databases: *((ML OR machine learning) AND (health* OR medic* OR disease) AND (smartphone OR smart phone OR smartwatch OR smart watch OR smart devices))*.

Before finalizing the search string, we experimented with many combinations, including different variations of specific keywords and symbols, such as "*," to cover a wider area and maximize the results.

Literature Assembly

We applied the search string to different databases and narrowed the databases to PubMed [18] and IEEE Xplore [19]. The search results from other databases produced a very high number of results that included unnecessary papers from disciplines unrelated to our topic of interest. When we applied the same search string, ACM Digital Library had about 24,000 results, ProQuest had about 125,000 results, and Google Scholar had more than 1 million results. Furthermore, in Science Direct, our search string did not produce any results owing to the use of Boolean connectors. We concluded that the search of PubMed and IEEE Xplore was enough to obtain papers related to research in technology, engineering, and biomedical sciences.

The results from each of the databases were then exported to an external file. To convert the results from the 2 databases into

XSL•FO
RenderX

a single file, including the titles and abstracts, we used Mendeley [20] and Zotero [21]. The file, which contained a total of 2390 papers, was then screened in the Jupyter Notebook environment using Python (version 3.7.17) [22].

Study Selection

For refining the collected papers, we used a title screening method [23] to filter out papers that might not be of direct relation to our research topic. We created a list of keywords that match the research topic, screened the titles of all papers, and filtered out all papers that did not contain any of the following keywords: machine, artificial, smartphone, disease, mobile, health, healthcare, wearable, model, features, and training.

The identified papers at this point covered a wide variety of diseases and health areas. Using the keyword identification method, we tried to find the distribution of different diseases in the papers based on the 5 senses [24]. We first determined the frequency of keywords related to the 5 senses in the titles of the collected papers by using the following keywords: eye, eyesight, vision, audio, voice, vocal, nasal, nose, hearing, ear, touch, feel, face, skin and dermatology.

The result for the frequency of the keywords in the titles can be seen in Table 1. We then merged the keywords with their respective senses and assembled the papers into the following 6 categories: ear, eye, nose, touch, skin, and audio. We determined the total distribution of the papers, as shown in Table 2. We replicated the procedure to determine the frequency of health categories (Table 3) and their distribution (Table 4) in the abstracts of the collected papers.

Table 1. Health categories in titles.

Health care area	Number of matches
Eye	12
Eyesight	0
Vision	13
Audio	15
Voice	16
Vocal	5
Nasal	0
Nose	2
Hearing	5
Ear	2
Touch	6
Feel	0
Face	13

Ear	6.1
Eye	26.4
Touch	3.9
Skin	32.8

Research Questions

Based on the results from Tables 1-4, we identified the following 3 categories with the highest distribution of papers: eye, skin, and voice, and formulated the following research questions:

1. What are the databases available for eye, skin, and voice analysis?
2. What are the machine learning models used for eye, skin, and voice analysis?
3. How are the data collected from smartphones?

The keyword screening method [23] was applied to the titles of 2390 papers, which resulted in the successful screening of 2352 papers. In the next step, we screened the abstracts of the papers to distinguish papers related to each of the 3 topics (eye, skin, and voice) by using relevant keywords.

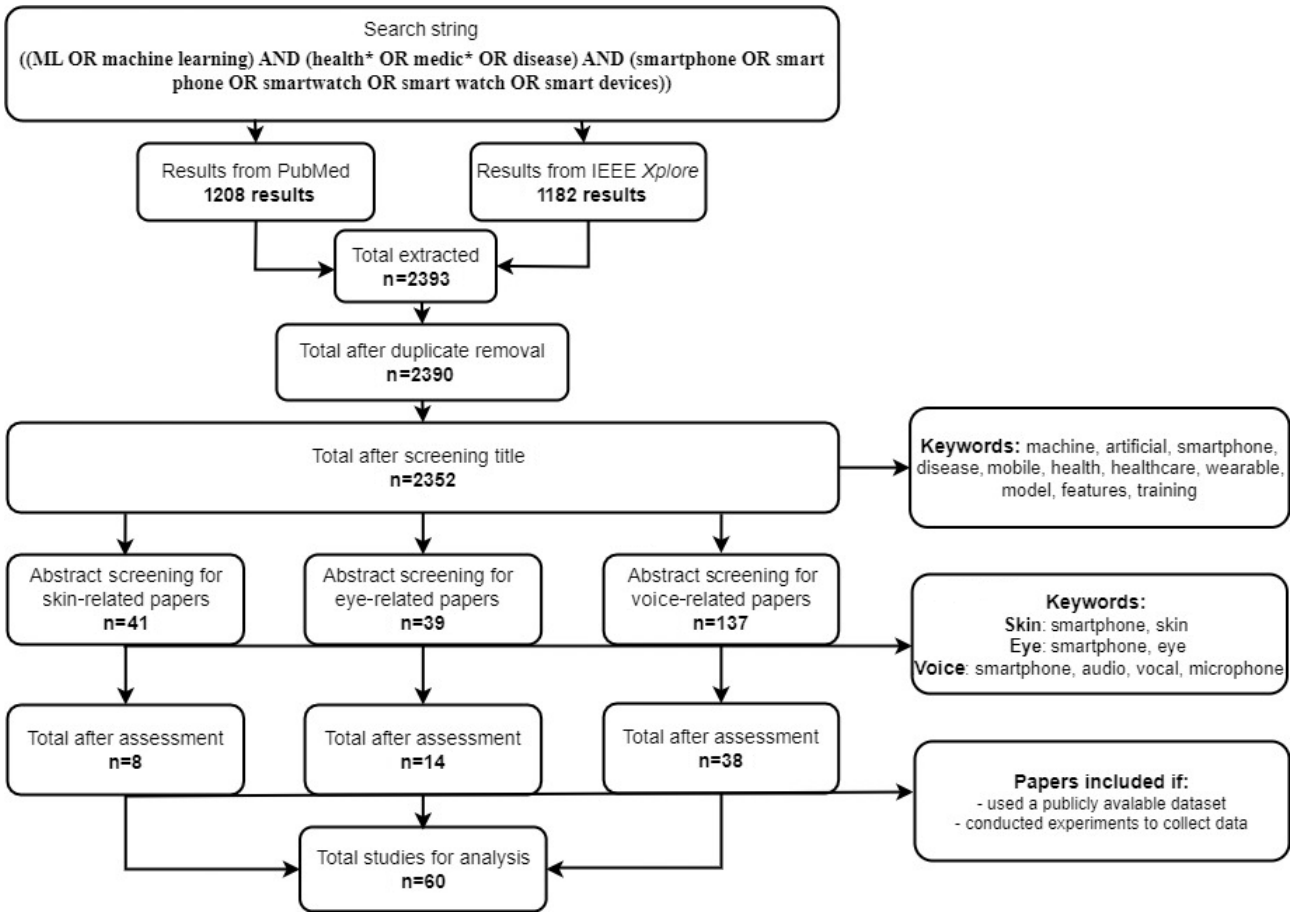
Inclusion and Exclusion Criteria

The primary inclusion criterion was that the study should perform an experiment or use a database involving data obtained by using smartphones. Some studies conduct experiments themselves to gather data from participants, while others use publicly available datasets. We divided the studies based on this distinction (experiments and databases). This information can help researchers determine if they want to conduct similar experiments or simply use publicly available databases.

Since the search terms specified the use of both smartphones and machine learning methods, it reduced the probability of obtaining literature results related to topics other than disease prediction among humans. The other criteria for the articles were that they should be in the English language and should be available for full-text viewing. Studies that involved data collection with external devices other than smartphones and those that used only smartwatches and not smartphones were excluded. Furthermore, studies that were literature reviews were not included in the final analysis.

Full-Text Assessment

The inclusion and exclusion criteria were applied to 217 papers available after title and abstract screening. After assessment of these papers, there were 8, 14, and 38 studies related to the skin, eyes, and voice, respectively. We performed full-text analysis of these papers to extract the desired information.



XSL•FO
RenderX

Results

Overview

We explain the analysis of papers that were extracted and report about the databases used, experiments conducted, and machine learning methods used. The steps and results of our review process can be seen in Figure 1.

Figure 1. Flow diagram for identifying relevant literature.

Research on Voice

Owing to the recent global pandemic, research on the analysis of speech for either cough or COVID-19 has grown [25]. Apart from that, the analysis of audio has a wide range of applications from the prediction of emotional stress [26] and the detection of diseases, such as Parkinson disease [27], to the detection of tourist emotions for spot recommendation [28].

Studies Conducted Using Databases

A cough-based COVID-19 detection model was created using more than 25,000 cough recordings from the CoughVid dataset [25]. The dataset was created through recordings via a web interface that could be accessed by a personal computer or a smartphone, and the prediction was made using a stack ensemble classifier consisting of machine learning methods, such as decision tree (DT), random forest (RF), k-nearest neighbor (KNN), and extreme gradient boosting (XGBoost).

Since datasets containing the voices of COVID-19–affected patients were not in abundance, datasets with recordings of cough sounds along with sneezing, speech, and nonvocal audio were used to pretrain the classifier [29]. Brooklyn and Wallacedene datasets used for the training were created using an external microphone, while datasets, such as TASK, were created using an external microphone along with a smartphone. It is very likely that smartphones were used to create datasets, such as the Google audio dataset and Freesound, which consist of audio from more than 1.8 million YouTube videos. Similarly, the Librispeech dataset consists of audio from 56 speakers who may or may not have used smartphones. For the classification and testing of the model, 3 datasets, namely Coswara, ComparE, and Sarcos, were used by applying machine learning methods, such as convolutional neural network (CNN), long short-term memory (LSTM), and RestNet50. All 3 datasets were created with the recordings of the cough of participants. ComparE and Coswara consist of additional speech sounds, with the Coswara dataset also including breathing sounds. The data acquisition method was web-based, and thus, smartphones could have been used for recording such audio data.

The Coswara dataset, with recordings of over 1600 participants, was created by collecting breathing, coughing, and voice sounds, using the microphones of smartphones via an interactive website application. With a combination of hand-crafted features and deep-activated features learned through model training, a deep learning framework was proposed and studied by using the recordings of 240 participants from the Coswara dataset (120 participants were identified as positive for COVID-19) [30].

XSL•FO
RenderX

The dataset created in the mPower study [31], which was conducted for the detection of Parkinson disease using audio data, has been used in various other studies [27,28]. The dataset was divided into training and test sets, and 2 classifiers, namely support vector machine (SVM) and RF, were applied to compare 6 cross-validation techniques [32]. Similarly, a desktop application, PD Predict, that records audio and makes predictions was created using the mPower dataset [33]. Two machine learning classifiers were used: gradient boosting classifier (GBC) pipeline with Lasso (gbcpl) and GBC pipeline with ElasticNet (gbcpen).

Moreover, using a dataset containing 18,210 recordings from the mPower study [31], a Parkinson disease prediction model was created through 4 classifiers: SVM, KNN, RF, and XGBoost [32]. Another Parkinson disease prediction model was created with 2 databases: PC-GITA and Vishwanathan [34] by using SVM. For creating the PC-GITA dataset, a smartphone was used to record 100 Columbian-Spanish speakers, among whom 50% had Parkinson disease. Similarly, 46 participants, among whom 24 were diagnosed with Parkinson disease, were used to create the Vishwanathan dataset, which consists of recordings of utterances of the alphabets “a,” “u,” and “m.”

Five machine learning models, namely logistic regression (LR), RF, XGBoost, CatBoost, and Multilayer, were used to predict the emotional state of participants [35]. The dataset Extrasensory was used for training the model. The dataset was created using data from smartphones and smartwatches. Contextual data, such as location, phone state, accelerometer data, and light and temperature data, and emotional state information (disclosure of emotion at different intervals using a smartphone app) were collected.

Studies Conducted Through Experiments

A total of 1513 subjects above 50 years of age, including healthy subjects and subjects who were diagnosed with Parkinson disease, used a smartphone app to complete daily surveys and 4 activities intended to test the presence or effect of Parkinson disease [31]. The activities included tapping (tap 2 buttons alternatively), walking (walk in a straight line for 20 steps and back in the same route), voice (10-second utterance of the “aaah” sound), and memory (recall the order of illumination of flowers shown in the app). The data related to the accelerometer, gyroscope, touchscreen, and microphone were then collected to test the results of these activities. LR, RF, deep neural network (DNN), and CNN were used separately and as multi-layer classifiers for model creation and verification.

An Android-based smartphone app was developed to record 5 activities (voice, finger tapping, gait, balance, and reaction time) in 129 participants, including subjects who were healthy and those who were diagnosed with Parkinson disease, in order to study the effects of the disease [26]. Disease severity score learning (DSSL), a rank-based machine learning algorithm scaled from 0 to 100 (higher numbers reflect increasing severity of the disease), was used to show the results. In another study, 2 vocal tasks of patients diagnosed with Parkinson disease were recorded in a soundproof booth: one in which the participants spoke the vowel “a” for 5 seconds, and another in which the participants spoke a sentence in their native Lithuanian language [36]. The recordings were conducted using both an external microphone and a smartphone, and the model was created using RF.

In another study, 237 participants diagnosed with Parkinson disease performed 7 smartphone-based tests, such as pronouncing “aaah” on the smartphone for as long as possible, pressing a button on the screen if it appears, pressing 2 alternate buttons on the screen, and holding the phone with their hand at rest or outstretched. Their balance and gait were also analyzed from the position of the smartphone [37]. The data obtained from the smartphone were used to train the machine learning algorithm using RF. The dataset was divided into training and test sets, and the prediction accuracy was tested using 10-fold cross-validation and leave-one-out cross-validation.

In addition to voice, facial features can be used for the detection of Parkinson disease [38]. Using both facial and audio data from 371 participants, among whom 186 were diagnosed with Parkinson disease, it was observed that early-stage detection of Parkinson disease is possible by combining both data. Participants were asked to read an article containing 500 words, and an iPhone was used to record both audio and video. DT, KNN, SVM, LR, naive Bayes, RF, LR, gradient boosting (GBoost), adaptive boosting (AdaBoost), and light gradient boosting (LGBoost) were compared to assess their performance in terms of accuracy, precision, recall, F_1-score, and area under the receiver operating characteristic curve for binary classification.

Analysis of voice samples can also help in the prediction of depression or anxiety. A study was conducted with 2 sets of participants: one set of participants who had a diagnosis of depression or anxiety and another set of participants who did not have such a diagnosis [39]. Using an app developed for the study called Ellipsis Health, 5-minute voice samples and responses to survey questions were collected from a total of 263 participants (all current patients of a health care clinic) over a period of 6 weeks. Using a model developed with LSTM, the study tested the feasibility of assessing the presence of clinical depression and anxiety by using data from the smartphone app. With a similar approach, another study collected answers to questions in several self-reported psychiatric scales and questionnaires via audio recordings from 124 participants using an Android app developed specifically for the study [40]. Six different algorithms (LR, RF, SVM, XGBoost, KNN, and DNN) were used to study the features generated from audio and to evaluate the results.

In another study, behavioral and physiological data were collected from 212 participants through wearable sensors (including a wristband and a biometric tracking garment) and various surveys to create a dataset of human behaviors. The dataset was then studied to predict the emotional state of the participants [41]. A phone, Unihertz Jelly Pro, was also provided to participants to capture their speech data. An app, TILES, was created to track activities as well as receive responses to surveys. Furthermore, data from other smartphone apps, such as the Fitbit app (to receive updates from the Fitbit wristband), OMsignal app (to record data from the OMsignal smart garment), and

XSL•FO
RenderX

RealizD app (to record screen-on time and phone pickups), were also used.

Using only speech data, an automatic depression detection model was developed using deep convolutional neural network (DCNN) [27]. A total of 318 participants (153 diagnosed with major depressive disorder) were asked to record their voices through a smartphone while reading a predefined text. RF, SVM, KNN, and linear discriminate analysis classifiers were used, with RF providing the best accuracy. A similar study was conducted with 163 participants (88 diagnosed with depression), in which speech data were collected using VoiceSense, a voice-collection app installed on each participant's phone, through vocal responses to 9 general questions [42]. A repeated random subsampling cross-validation method, with random split of the dataset into training and test subsamples and multiple iterative repeats of the process, was used to obtain a predictive equation. Behavioral states of infants can also be predicted by analyzing the audio of their cries. About 1000 cries gathered from 691 infants using the smartphone app ChatterBaby were analyzed and classified into 3 states: fussy, hungry, and pain, using RF [43]. The study also aimed to verify that colic cries may indicate pain and are more similar to pain cries compared with either fussy or hungry cries.

Along with emotional states, it is also possible to create models to predict complex psychiatric conditions, such as schizophrenia, by using data from smartphones. Numerous data were collected from 61 participants, including app usage, reception of calls and SMS text messages, smartphone acceleration data, screen on/off duration, location, speech and conversation, sleep, and ambient environment, and an ecological momentary assessment was performed every 2 to 3 days [44]. Multiple-output support vector regression (m-SVR) and multi-task learning (MTL) with leave-one-out cross-validation were used to train data for each patient and to predict the scores for all possible symptoms.

Audio data can also be used to predict health-related anomalies, such as fatigue level and blood pressure. Using 1772 voice recordings from 296 participants, a model was created to predict fatigue in people affected with COVID-19 [45]. Two types of audio data were collected: recording of participants reading a predefined text and another recording of them pronouncing the vowel "a" for as long as they could. The data were trained and tested using LR, KNN, SVM, and soft voting classifier algorithms. In another study, a stethoscope attached to a smartphone was used to collect heart sound signals from 32 healthy subjects, with the participants laying on a mattress and the stethoscope being placed on their chest [46]. SVM was used for training and testing the estimation model, and 10-fold cross-validation was used to test the accuracy of the model.

Other uses of audio analysis include the inspection of bowel sounds for tracking or predicting digestive diseases [47]. A total of 100 participants were asked to put the smartphone over the lower right and left areas of their abdomen to collect audio via a bowel sound recording app. CNN- and LSTM-based recognition models were developed. For cross-validation, multiple training-test splits were conducted, and 9-fold cross-validation was performed. Furthermore, it is also possible to determine the quality of sleep by analyzing the audio during sleep. Using an app that records audio with the built-in microphones of smartphones and a smart alarm, sleep events, such as snoring and coughing, were identified [48]. SleepDetCNN, a CNN-based model, was created to classify the sleep audio into 3 types: snoring, coughing, and others. Snoring was further studied in 16 patients with habitual snoring tendencies using a smartphone-based gaming app as a treatment for snoring [49]. A section of participants had 15 minutes of daily gameplay (3 voice-controlled games; 5 minutes each), and the majority of participants were provided with microphones to record their sleep for the entire night at least twice per week during the experiment period of 12 weeks. To train the classification models using SVM, 1000 sleep sounds were randomly selected and labeled as "snore" or "not snore" by 2 blinded members of the research team.

In addition to the prediction of diseases, data from smartphone microphones, combined with other data, such as accelerometer, gyroscope, light proximity, and Wi-Fi scan data, have been utilized for emotion prediction [39] as well as the recognition of day-to-day activities [50]. The ADL Recorder app, created for tracking and monitoring the activities of elderly people, recorded both behavioral and contextual data. Various kinds of machine learning classifiers, such as Bayesian network, hidden Markov model, Gaussian mixture model, RF, and KNN, were used throughout for analyzing data from different sensors, and J48 DT was used for the final recognition of activities.

Studies Conducted With Both Databases and Experiments

Due to recent global events, numerous experimental studies have been conducted for COVID-19 detection and prediction. Audio data from 497 participants, including those with and without COVID-19, were tested on a model created for analyzing respiratory behavior and compared with a clinical diagnosis [51]. The model, which used LR, was created to train data collected in a study of over 3000 patients diagnosed with asthma and other respiratory diseases. The participants used a smartphone app to send a continuous "aaah" sound spoken for a 6-second duration, along with responses to a questionnaire about any possible symptoms.

In another study, accelerometer and voice recorder data were collected from participants with and without Parkinson disease, and a detection model was created using naive Bayes, KNN, and SVM methods [52]. The same model was used to detect Parkinson disease by using a new dataset obtained from patients newly suspected of having Parkinson disease. They were requested to pronounce the vowel "a" for 10 seconds, and a smartphone was kept at a certain distance (8 cm) from the patients to record the audio.

The dataset from the mPower study [31] was further used to test a voice condition analysis system for Parkinson disease, which was also verified using an experimental dataset (UEX) [53]. Six different machine learning classifiers (LR, RF, GBoost, passive aggressive, perceptron, and SVM) were applied to compare the performance with the 2 different speech databases. For creating the UEX dataset, 60 participants aged between 51 and 87 years were recruited. Of these 60 participants, 30 had Parkinson disease. A smartphone was used to record 3 different

XSL•FO
RenderX

samples of the participants pronouncing the "a" vowel continuously without being interrupted.

Voice data from the smartphones of patients with bipolar disorder were studied to determine if it is possible to differentiate people who have bipolar disorder and those who are either unaffected or have any relatives with bipolar disorder [54]. Data from 2 studies, namely the RADMIS trial [55] and the Bipolar Illness Onset (BIO) study [56], were used. The RADMIS trial was conducted with people diagnosed as having bipolar disorder who used a smartphone-based monitoring system installed on their phones, which collected voice data (only of those with Android smartphones) and other smartphone-related data, such as sleep duration and app usage. In the BIO study, participants included those who had bipolar disorder, those who had relatives with bipolar disorder, and those who were not diagnosed with bipolar disorder. The RF model developed from the data was verified using 5-fold participant-based cross-validation.

In some cases, the datasets for training the machine learning models were not obtained from previous studies. Various online sources were used for extracting both the crying and noncrying (eg, talking, breathing, hiccups, and yelling) sounds of infants [57]. For the validation of the algorithm, an independent dataset was created by using real-life recordings of 4 infants at home and 11 infants in a pediatric ward, where the recordings were created using smartphones. RF, LR, and naive Bayes were used for the classification and identification of crying and noncrying sounds.

Similarly, 41 YouTube videos and 5 cough sounds from the SoundSnap website were used to train a cough recognition model [58]. The study also included the development of a smartphone app, HealthMode Cough, that recorded continuous sounds, including sounds from streets, crowded markets, train stations, etc. The recordings were used to test the model, which used DCNN. Another model was created using CNN in a study aimed at analyzing the breathing sounds of participants with the smartphone app Breeze 2 [59]. The dataset for training the model was created using 3 separate datasets: a subset of the dataset from the study by Shih et al [60], which contained breathing sounds; the dataset ESC-50 [61], which contained 50 classes of environmental sounds; and a dataset from 2 participants, which contained a 2-minute breathing training session recorded using a smartphone. For the experiment, 30 participants without any respiratory diseases used the Breeze 2 app to perform 2 breathing sessions for 3 minutes: one with and one without headphones.

A dataset, compiled from multiple sources, was used to train a cough detection model for infants [57]. The cough sounds were obtained from 91 publicly available videos on YouTube consisting of coughing children aged between 0 and 16 years. Noncoughing sounds, such as talking, breathing, cat sounds, sirens, and dog sounds, were obtained via audio clips from YouTube, GitHub, and the British Broadcasting Corporation sound library. Furthermore, the audio data of 21 children, who were admitted with conditions, such as bronchitis, pneumonia, respiratory infection, and viral wheezing, were also collected via an Android smartphone. Using the data of 7 children out of the 21 and adding cough and noncough sounds from different sources, a model was created, and the data from the remaining 14 children were used as a validation dataset. The classification performance of the cough detection algorithm was compared using 2 ensemble DT classifiers: RF and GBoost.

Research on the Skin

Studies on the use of smartphone features to assess skin-related anomalies have mostly focused on the prediction or identification of skin cancer traits [57,58], and some studies have evaluated the detection of neonatal jaundice [62] and acne [63].

Studies Conducted Using Databases

To create a model for predicting skin cancer, 2 sets of databases were used in the study by Dascalu et al [64]: one with dermoscopic images (HAM10000 [65] and Dascalu and David [66]) and another with nondermoscopic images (Pacheco et al [67]). The images were obtained by taking pictures from a digital camera or a smartphone. Comparing the 2 datasets, sensitivity (percentage of correctly diagnosed malignancies) and specificity (percentage of negative diagnoses) were derived. The CNN-based model was found to improve specificity, though it was acknowledged that a significant amount of future work would be needed for improving sensitivity. It was also concluded that the dermoscopic images provided better accuracy compared to those from smartphones.

Studies Conducted Through Experiments

Acne is a common skin anomaly, which is experienced by about 10% of the world population. To predict and analyze such skin-related afflictions, many skin image analysis algorithms have been created [63]. To make the analysis and prediction accessible, it would be better to have such a system within a smartphone app. A CNN-based model was developed for acne detection, and an acne severity grading model was developed using the LightGBM algorithm. To test the models, an experiment was conducted, in which 1572 images of the faces of participants were taken from 3 different angles by using iOS or Android smartphones through a smartphone app called Skin Detective, and the dataset was divided in a ratio of 70:30 for training and testing. For ground truth, the images were labeled by 4 dermatologists.

Similarly, for predicting skin cancer, a melanoma detection model was created. A total of 514 patients from dermatology or plastic surgery clinics who had at least one skin lesion were selected, and pictures of their lesions were taken using 3 different cameras: 2 smartphone cameras and 1 digital camera [68]. For the analysis of the experiment dataset, an artificial intelligence algorithm, Deep Ensemble for Recognition of Malignancy [69], developed for determining the probability of skin cancer using dermoscopic images of skin lesions, was used.

Unlike for disease prediction using audio, data for skin-related anomalies can be obtained from other gadgets, such as smart wearables, through which information, such as heart rate, skin temperature, and breathing rate, can be obtained. A combination of data from smartphones (smartphone-based social interactions, activity patterns, and number of apps used) and smartwatches

XSL•FO
RenderX

(E4 Empatica; skin temperature) obtained via the in-house smartphone app MovisensXS was used to predict emotional changes and the severity of depression in people [70]. The study was conducted over a period of 8 weeks and included 41 people with depressive disorder. The participants had to complete daily smartphone-delivered surveys, a clinician-rated symptom assessment test, and a blood test to screen for potential medical contributors of depressed mood.

Studies Conducted With Both Databases and Experiments

Neonatal jaundice is a frequently occurring condition, which can also be diagnosed using smartphone images [62]. A study was conducted with 100 children, aged between 0 and 5 days, in which a picture or video was taken of their full face, with a calibration card, to capture their skin and eye sclera. Ground truth was established by noting their transcutaneous bilirubin (TCB) level, and the pictures were labeled "jaundiced" or "healthy" by a pediatrician. A CNN-based model was trained using the ImageNet dataset [71] and was used to test neonatal jaundice tendencies using the experiment dataset and transfer learning. Multilayer perceptron (MLP), SVM, DT, and RF were also used for diagnosis, where it was determined that transfer learning methods performed better for skin features, while machine learning models performed better for eye features.

Research on the Eye

Diabetic retinopathy was the most commonly studied disease [66,67,69] among the collected literature for eye-related predictions, along with other varying topics, such as eye tracking, vision monitoring, jaundice, and autism.

Studies Conducted Using Databases

An optimized hybrid machine learning classifier with the combination of neural network (NN) and DCNN with a single-stage object detection (SSD) algorithm was proposed to be used with the retinal images taken from a smartphone-enabled DIY camera [25] to predict diabetic retinopathy. Since there was a scarcity of image data captured using DIY smartphone-enabled devices, the model was validated with analysis of 2 other databases that contained fundus images: APTOS (2019 blindness dataset) and EyePACS, and the model performed better in comparison to the individual results of the NN, DCNN, and NN-DCNN methods.

CNN-based models usually tend to provide the best performance in image recognition tasks. With that in mind, the APTOS (2019 blindness dataset) and EyePACS datasets were used to build a CNN-based model for predicting diabetic retinopathy [72]. The algorithm was then externally validated using the Messidor-2 dataset [73], which contained about 1058 images from 4 French eye institutions. The algorithm was further tested on the EyeGo dataset, which contained 103 fundus images from 2 previously published studies obtained by using an EyeGo lens attachment and an iPhone.

Studies Conducted Through Experiments

Almost 51% of eye diseases in the United States are related to cataract [74]. It will be convenient to use images from smartphones for the early detection of cataract, and the results will be provided instantly. By taking pictures with a smartphone camera, 100 samples were collected from participants (50% of the participants had cataract) [74]. SVM was applied on the dataset, and the accuracy was 96.6% for cataract detection.

In addition to images of the eye, videos of eye movement can be used for different kinds of diagnoses, such as for autism, since atypical eye gaze can be considered as an early symptom for autism spectrum disorder (ASD) [75]. The behaviors of 1564 toddlers were recorded using the front camera of an iPhone or an iPad when the toddlers, accompanied by their caregivers, viewed engaging movies for less than 60 seconds on the device. Using computer vision analysis on the data, it was found that children with ASD have less coordinated gaze patterns while viewing movement in movies or following conversation between 2 moving people.

In addition to the in-situ collection of data, smartphones can be used for remote collection of data. To determine the attention span of infants by tracking their gaze, an online webcam-linked eye tracker called OWLET was developed, and experiments were conducted with 127 infants remotely [76]. The infants were in the presence of their caregivers, who used either a smartphone or a computer to access the tracking task and provided their responses of the infant behavior using a questionnaire. For the experiment, a video (an 80-second Sesame Street video) was played, and the eye movements of the infants were recorded, tracked, and analyzed. No difference was found in the image data between the smartphone and computer, which was verified by a 2-sided independent samples *t* test and chi-square test. LR was used to examine the efficiency of the OWLET system.

Similarly, 417 adults with active or passive vision-related problems took part in an experiment using a smartphone app named Home Vision Monitor (HVM) to self-test their vision [77]. The app required them to submit an eye vision test twice per week, and their smartphone usage and app usage history were recorded by the researchers. RF and LR were used for statistical analysis.

The app EyeScreen was developed to support retinoblastoma diagnosis for the presence of leukocoria [78]. About 4000 eye images were obtained from about 1460 participants via the app, and an ImageNet model, ResNet, was used for image processing by dividing the dataset in an 80:20 ratio for training and testing. The app had the feature to process the image within it and provide the result.

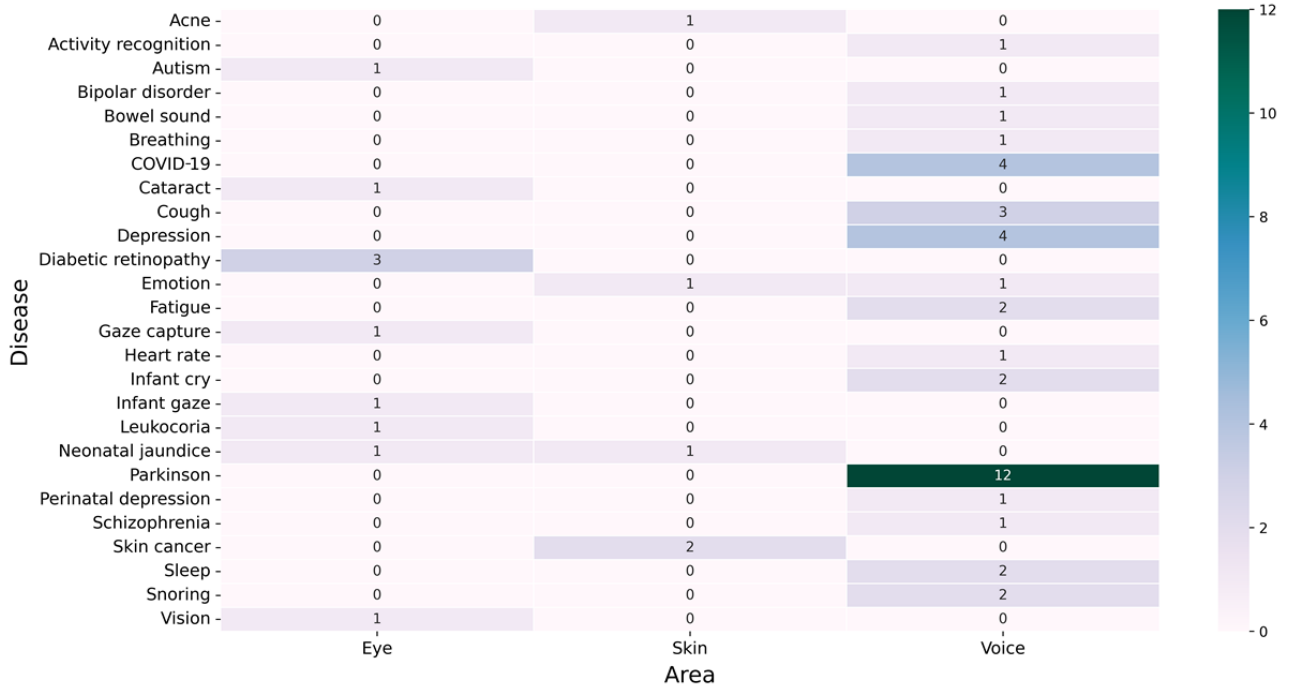
Studies Conducted With Both Databases and Experiments

A common anomaly, neonatal jaundice, was investigated [62], for which a dataset of healthy and jaundiced individuals was created in an experiment conducted over 35 to 42 weeks. In the experiment, a full-face photo was clicked to capture the eye sclera. To obtain ground truth data, the TCB level was measured using a jaundice meter device, and the pictures were labeled "jaundiced" or "healthy" by a pediatrician.

Tracking eye movements has been a topic of interest for a wide variety of research ranging from autism [75] and tourism [28] to driving and gaming [79]. A multi-layer feed-forward

XSL•FO
RenderX

convolutional neural network (ConvNet) model was created and trained on the GazeCapture dataset [80], which was created from the data of 1474 participants using an iPhone or iPad. To verify the model, an experiment was conducted using a custom-made Android app, in which eye gaze videos were captured using the front facing camera of the phone. The participants were asked to follow a stimulus on the mobile screen, which could be a dot or movement of a circular, rectangular, or zig-zag pattern.



Two sets of experiments were carried out, with one using a smartphone (iPhone 6) and another using smartphone-based retinal imaging systems, such as iExaminer, D-Eye, Peek Retina, and iNview [81], to create a model for the diagnosis of diabetic retinopathy. The CNN-based AlexNet architecture was used for transfer learning, which was first trained using 1234 images from the EyePACS dataset. Then, the architecture was tested with 138 retinal images from datasets, including those of the EyePACS, iExaminer, D-Eye, Peek Retina, and iNview systems.

Exclusion of Papers

A total of 11 papers were excluded from the final selection after reviewing the full text of all the papers using the selection criteria. Among them, 5 were excluded because the studies did not involve the use of smartphones for data collection. Similarly, 3 of the papers passed the initial screening test because of the presence of words, such as smartphone, eye, and audio, in their abstract. However, the studies were not relevant to the topic of our review. Furthermore, 2 of the studies were excluded because they only included the proposal of the method of disease prediction using machine learning and smartphones. Finally, a paper was excluded as it included a discussion about the topic but did not contain any database analysis or experiment. Among the papers that provided a proposal of a disease prediction system, it is worth mentioning that the paper by Bilal et al [82] was very detailed and well explained.

After the full-text screening of papers, there were 34, 5, and 10 relevant papers in the categories of voice, skin, and eye, respectively. These studies were further analyzed by focusing on the diseases dealt with in each study and the different health topics. The results can be seen in Figure 2. Parkinson disease was the most studied (n=12) disease among the collected studies, followed by COVID-19 (n=4), depression (n=4), cough (n=3), and diabetic retinopathy (n=3). It can be argued that cough and COVID-19 could be included under the same category and depression and emotion could be included under the same category. However, based on the terminologies and methods used in the papers, we have treated them separately.

Figure 2. Diseases studied in the collected papers.

Discussion

Overview

The use of technology in the medical field has seen massive growth in recent years. A lot of improvements have been made in different areas, such as handling complex electronic medical records [83], and in identifying and predicting various diseases, such as lung anomaly detection using computed tomography scan images [84], emotion detection using different data from smartphones [35], and identification of the burden faced by people who travel to separate locations for receiving health care services [85]. Smartphones provide a low-power, small-sized, and easy method for data collection and analysis, which differs from the usual bulky, expensive, and complex systems used for biomedical data collection and analysis.

Smartphones are equipped with numerous sensors and high-quality cameras, making it easy to collect different types of data. Moreover, due to the COVID-19 outbreak and the changes in the overall working environment that followed, there has been a strong focus on delivering health services remotely

XSL•FO
RenderX

[86]. The disease identification process can be made efficient by using smartphones to collect data and provide a diagnosis, as well as deliver results to patients.

With these factors in mind, we focused on research carried out using machine learning and data from smartphones to identify or predict diseases. We selected 3 areas to focus on and formulated the research questions. We conducted a review of the available papers collected using the screening method explained in the section Study Selection. Here onwards, we will discuss the results for our research questions.

Research Question 1: What Are the Databases Available for Eye, Skin, and Voice Analysis?

We found a total of 31 databases in the collected studies, including an unclear source, vaguely referred to as "online sources" [57]. In most of the cases, the databases were used to create a model for disease prediction. However, there were also instances where the databases were used to validate a model developed using experimental data [81] or using other databases [72]. Since the number of collected voice-related studies was higher than that of skin- or eye-related studies, a similar difference in number can be observed for the list of databases, as shown in Tables 5-7. The numbers of databases for voice, skin, and eye were 22, 4, and 5, respectively. The voice-related databases were used to predict a variety of diseases or health statuses, such as Parkinson disease [26,29], emotion [35], bipolar disorder [55], and infant cry [57]. Owing to the COVID-19 pandemic, many databases were used for the detection of COVID-19 or cough-related anomalies [20,24,46,52]. Of 4 skin-related databases, 3 were aimed at the prediction of skin cancer [64] and the remaining database was related to neonatal jaundice [62]. The same database by Althnian et al [62] was also used for jaundice detection using retinal images. Diabetic retinopathy was the most common disease among eye databases [66,67,69]. Eye databases also consisted of data related to capturing eye movement [80] or gaze/concentration [74].

Research Question 2: What Are the Machine Learning Models Used for Eye, Skin, and Voice Analysis?

Similar to databases, machine learning models were also used either in separation [67,87] or as a comparison along with multiple other models [6,24,31], and sometimes as ensemble classifiers [20,62]. As the same study usually consisted of multiple machine learning methods, the frequency of use of certain machine learning methods was considerably high. To investigate the best machine learning method for each kind of data, instead of using numbers, we calculated the frequency of use of a particular machine learning method for each of the 3 areas. We were then able to determine the rate of machine learning methods for each area, as shown in Tables 8-10. The most common machine learning method used for voice-related data was RF, while CNN was the most used for both eye- and skin-related data.

For further analysis, we expanded on the diseases and determined the frequency of the use of each machine learning method for each of the diseases or anomalies found in the collected papers. The results are shown in Figure 3. The figure shows all machine learning methods used across various studies for each of the diseases. Since many studies used multiple machine learning methods (especially for Parkinson disease), the frequency of use of some methods, such as RF, SVM, CNN, and LR, was high.

Research Question 3: How Are the Data Collected From Smartphones?

To collect audio-related data, the built-in smartphone microphone was used most of the time, both at home [26,37] and in the experimental set up [52]. In some cases, external microphones were also used [36]. Similarly, in many cases, audio was also collected via custom-made smartphone apps [21,34,38], and in some cases, it was collected via a web interface that could be accessed using smartphones [20,25].

For the collection of skin data, pictures and videos were mainly taken with a smartphone [58,59]. In some cases, smartphone apps were also created for data collection [60,63]. Frequently, pictures from smartphones were not considered adequate for taking retinal images, and an external lens or retinal imaging system was used alongside the smartphone to collect eye data [20,66,67]. However, experiments have also shown that smartphone images are equally effective to analyze eye-related anomalies [25,71]. For collecting gaze-related data, videos taken from the front camera of smartphones have been used effectively [75,81].

Data of both the skin and voice have been used for the detection of emotion and depression. However, in such studies, data apart from voice and skin data were also collected. Combinations of data from smartwatches, such as heart rate, skin temperature, and breathing rate, and data from smartphones, such as smartphone-based social interactions, activity patterns, and the usage of apps, were used for detecting emotional changes and the severity of depression [70]. Similarly, for detecting emotional status, voice and other data, such as location, accelerometer data, gyroscope data, and phone usage, were used [31,36]. For the detection of Parkinson disease, data apart from voice data, such as gait and balance [26], tapping of buttons on a smartphone screen [26,33], and accelerometer data [52], were collected. Similarly, in a study for vision monitoring, data apart from images of the eyes, such as phone and app usage, were collected using a smartphone app [77]. Furthermore, in many studies, surveys and questionnaires were also regularly received from participants during data collection, especially via smartphone apps [26,34,36,63].

It is worth noting that there are many sensors available in smartphones, such as accelerometers and gyroscopes, which

XSL•FO
RenderX

can be helpful in determining the speed of touch, posture, walking speed, location, etc. Therefore, even if the aim is to analyze a particular health area, the same combination of data, collected from multiple data sources, can be used to identify different diseases. For example, in the study of Parkinson disease, data, such as voice, accelerometer data, location, application usage, and other phone data, were usually collected. The same data can also be analyzed to detect emotional changes or depression. Similarly, when collecting data on skin abnormalities, it is possible to obtain facial data that can also be used for eye-related analysis.

Moreover, it has been observed that with remote health monitoring systems, especially with the use of smartphones, people often have concerns over the access and use of their data, such as location, application usage, screen time, and browsing history [78,79]. These concerns of smartphone apps are higher as they contain sensitive behavioral data. To tackle these issues, it is necessary to build trust with the users regarding the app and its data collection methods. It was found that state-funded research institutes had higher levels of trust with people compared to private institutions [88]. This shows that to conduct research using smartphones and gather user data, it is necessary to involve trusted institutions for governing the study, as well as have transparency over data collection, distribution, and use of the results.

Limitations

There are some limitations. First, for screening the collected papers based on their titles and abstracts, we used a keyword screening method [23]. Although great care was taken in the selection of keywords for this screening, it must be acknowledged that some papers may have been overlooked if they did not contain the specified keywords. We firmly believe that such a limitation can occur, but the number of studies will be very few. Second, we focused only on studies that used smartphones. This could lead to the exclusion of recent studies that did not consider the use of smartphones to collect health-related data.

Moreover, we only selected studies that analyzed eye-, skin-, and voice-related diseases. Because of the niche approach of this scoping review, we did not consider a lot of other health areas where smartphones might have been used to gather data for machine learning analysis. Furthermore, many new machine learning models and other algorithms are being developed, and existing algorithms are being improved [89]. These methods have not been used but could potentially be used for health diagnosis, and thus, they have been overlooked in this review.

Overall Summary

The field of the use of machine learning on smartphone-obtained data for health care purposes is ever evolving. Through this study, we aimed to provide information about studies that have conducted experiments related to eye-, skin-, or voice-related diseases, where data were obtained strictly via smartphones. Similarly, we have provided details of publicly available databases that have been used in studies to apply machine learning methods for developing models to predict eye-, skin-, or voice-related diseases. Researchers working in similar fields can use the experiment details or the databases presented in this study to design their research. Furthermore, the machine learning model to use for a study needs to be determined with much consideration. We have presented machine learning models applied based on the study area as well as the types of diseases. Therefore, the information provided in the paper can help reduce the time and effort for researchers in designing experiments and selecting the databases or machine learning models to use in their studies. Our title and abstract screening method is also easy to understand and replicate, and could be used by researchers aiming to perform scoping reviews or systematic literature reviews.

Conclusion

There has been a growth in the number of studies based on the application of machine learning methods to data obtained from smartphones for the prediction of diseases. However, there are few literature reviews that provide information about the databases used, experiments carried out, and machine learning methods applied. We formulated a scoping review to identify the studies that have been conducted, specifically related to the 3 areas of skin, eye, and voice, and determined the studies that conducted experiments using smartphones to gather skin-, eye-, and voice-related data; the publicly available databases that include skin, eye, or voice data; and the machine learning methods that are commonly implemented in such studies. Furthermore, with this research, we intended to test the effectiveness of the keyword screening method that we developed. We first searched for relevant studies and screened them by applying our keyword screening method to their titles and abstracts. We analyzed the full text according to the inclusion and exclusion criteria and collected a total of 60 studies.

After assessing the full text of all identified studies, we discarded 11 studies, and among the remaining 49 studies, we found 24 different machine learning methods and 31 different databases used. The details from these collected studies provide insights into how the experimental studies were conducted, which databases were used, and which machine learning methods provided better results. The relevance and quality of the information acquired proved that our keyword screening method was effective in screening papers relevant to the topic and thus could be adopted by researchers for conducting scoping reviews. The use of our results can help reduce the time and effort required by researchers working in the field of artificial intelligence for health care to gather such information in detail. Moreover, the results presented can be used to select databases for future studies, replicate the experimental design, or select machine learning models suitable for the topic of interest.

Abstract

Background: People with schizophrenia often present with cognitive impairments that may hinder their ability to learn about their condition. Education platforms powered by large language models (LLMs) have the potential to improve the accessibility of mental health information. However, the black-box nature of LLMs raises ethical and safety concerns regarding the controllability of chatbots. In particular, prompt-engineered chatbots may drift from their intended role as the conversation progresses and become more prone to hallucinations.

Objective: This study aimed to develop and evaluate a critical analysis filter (CAF) system that ensures that an LLM-powered prompt-engineered chatbot reliably complies with its predefined instructions and scope while delivering validated mental health information.

Methods: For a proof of concept, we prompt engineered an educational chatbot for schizophrenia powered by GPT-4 that could dynamically access information from a schizophrenia manual written for people with schizophrenia and their caregivers. In the CAF, a team of prompt-engineered LLM agents was used to critically analyze and refine the chatbot's responses and deliver real-time feedback to the chatbot. To assess the ability of the CAF to re-establish the chatbot's adherence to its instructions, we generated 3 conversations (by conversing with the chatbot with the CAF disabled) wherein the chatbot started to drift from its instructions toward various unintended roles. We used these checkpoint conversations to initialize automated conversations between the chatbot and adversarial chatbots designed to entice it toward unintended roles. Conversations were repeatedly sampled with the CAF enabled and disabled. In total, 3 human raters independently rated each chatbot response according to criteria developed to measure the chatbot's integrity, specifically, its transparency (such as admitting when a statement lacked explicit support from its scripted sources) and its tendency to faithfully convey the scripted information in the schizophrenia manual.

Results: In total, 36 responses (3 different checkpoint conversations, 3 conversations per checkpoint, and 4 adversarial queries per conversation) were rated for compliance with the CAF enabled and disabled. Activating the CAF resulted in a compliance score that was considered acceptable (≥2) in 81% (7/36) of the responses, compared to only 8.3% (3/36) when the CAF was deactivated.

RenderX

Conclusions: Although more rigorous testing in realistic scenarios is needed, our results suggest that self-reflection mechanisms could enable LLMs to be used effectively and safely in educational mental health platforms. This approach harnesses the flexibility of LLMs while reliably constraining their scope to appropriate and accurate interactions.

Introduction

Background

Worldwide, there is a desperate need to improve access to medical knowledge and empower people with mental health conditions and their families by providing support systems no matter what time of day help is needed or their geographical location [1]. Chatbots powered by large language models (LLMs) such as GPT-4 have great potential as an educational tool that could greatly improve the accessibility of medical knowledge [2]. They can be used to explain complex concepts, give instant feedback with user-tailored examples and metaphors, translate technical language into everyday language, and make learning new information less daunting by breaking it down into smaller pieces. In particular, people with schizophrenia, many of whom present with cognitive impairments, could benefit from this powerful ability to adapt to individual needs [3,4].

While the flexibility of LLMs gives them high potential value in mental health care [5], it also comes with safety concerns due to uncertainties pertaining to their alignment, training materials, and overall opaque and unpredictable nature [6]. This is especially important to consider when the *educational* materials intersect with sensitive topics concerning medication use and self-harm [5]. The fact that LLMs can "hallucinate" is a well-known issue that is compounded by their inability to reliably reflect uncertainty in their answers [7]. Indeed, they have been observed to give wildly inaccurate answers in an authoritative manner even on topics in which they are generally quite accurate [8]. Another consequence of their "lack of self-awareness" is that they may drift into roles that require abilities that artificial intelligence (AI) lacks, such as empathy and being able to weigh a multitude of competing personal values and interests when considering complex personal decisions [9]. Therefore, to leverage the benefits of LLMs in mental health care while avoiding the numerous risks, it is crucial to develop robust systems for restricting the scope of LLM-powered chatbots to the supplementary roles in which they excel and ensuring that they do not drift into taking on superficially similar roles.

Prompting is a technique often used to direct chatbots toward producing more accurate and relevant responses without having to collect new training data and retrain the LLM [10]. The prompts modify the behavior of the LLM by providing it with contextual information. They may instruct the LLM on what role to adopt and rules to follow and offer a way to pass topical information to the LLM. Discussions of high-stakes subjects such as medication or self-harm can be made safer by anchoring the LLM's responses on a knowledge base—a curated repository of information from trusted sources. However, LLMs are stochastic entities, and adherence to sources and instructions is not guaranteed, especially in long conversations in which the model's context window becomes constrained by the cumulative input of both user messages and the model's previous responses. These competing influences can eventually cause a breakdown of what we will refer to as the chatbot's *integrity*—the likelihood that its messages are consistent with its internal rules and the documents that make up its knowledge base. The focus of this study was to develop a framework for maintaining chatbot integrity in the context of delivering mental health information in a conversational format.

Objectives

To achieve more robust chatbot integrity, this study proposed a layered response generation methodology. In the first layer, the chatbot generates a response based on user input. In the second layer, which we will refer to as the critical analysis filter (CAF), specialized AI agents analyze and refine the response to maintain the integrity of the chatbot. To showcase the proposed methodology, we developed a GPT-4–powered schizophrenia informational chatbot, hereafter referred to as CAFIbot, which conveys the content of the *Learning to Live With Schizophrenia* manual. This manual was produced by the Global Alliance of Mental Illness Advocacy Network Europe patient advocacy group [11], who we are collaborating with in an ongoing clinical project (called TRUSTING) involving patients with mental health problems [12]. To make the manual content available to CAFIbot, we implemented an information retrieval algorithm that grants it access to a database of text passages (herein referred to as *sources*) extracted from the schizophrenia manual (its knowledge base).

The effectiveness of the CAF was evaluated using adversarial agents called AI facilitators designed to deliberately prompt CAFIbot into providing advice beyond its intended scope. We defined a scoring system to evaluate whether a response was supported by the sources cited by CAFIbot and how transparent it was when it did make unsupported statements. On the basis of ratings from 3 independent raters, we found that the proportion of responses with acceptable compliance scores increased from 8% (3/36) to 81% (29/36) when activating the CAF, which shows that the CAF substantially improved the chatbot's resilience to the facilitators' attempts to derail it. In addition to demonstrating the sensitivity of the CAF to rule violations, we tested its specificity by letting it answer 10 questions about schizophrenia generated by the open access version of GPT-3.5. A total of 2 messages received warnings,

XSL•FO
RenderX

and the human raters (majority vote) agreed with the criticisms generated by the CAF.

Methods

Information Retrieval Algorithm

To make the information in the schizophrenia manual available to CAFIbot, we implemented a system whereby it could dynamically update the conversational context with relevant sources retrieved from a knowledge base (see the Knowledge Base section) before attempting an answer. The process of generating a response was split into multiple steps: (1) source identification—request sources that are relevant to the user query based on human-written summaries that are included in the initial prompt (Textbox 1), (2) prompt enhancement—insert the identified sections into the conversation, and (3) contextual response generation—use the updated context to produce an informed response.

CAFIbot was instructed to reference the sources that supported its response so that the consistency of the response with cited sources could be evaluated (see the next section). Figure 1 shows the main steps of this information retrieval algorithm, and Figure 2 shows 2 examples of the chatbot answering user queries. It should be noted that the request was made by the conversational agent (ie, the agent that generates responses based on the conversation history [user and assistant messages] as well as system messages [messages from the system developer role to the assistant, including the initial prompt]). The requests took the form of messages such as ¤*:request_knowledge(“11_seeking_a_diagnosis”):*¤, which were automatically recognized by back-end scripts. The chatbot typically requested 1 to 2 sources before it was satisfied. Sources not being actively referenced were removed to free up space and allow CAFIbot to focus on more relevant information. In addition, multiple hardcoded filters were used to ensure that the chatbot’s requests were valid (see Multimedia Appendix 1 for more technical details on how the chatbot retrieves information and performs citations and other aspects of the information retrieval algorithm. The chatbot’s sources are presented in Multimedia Appendix 2).

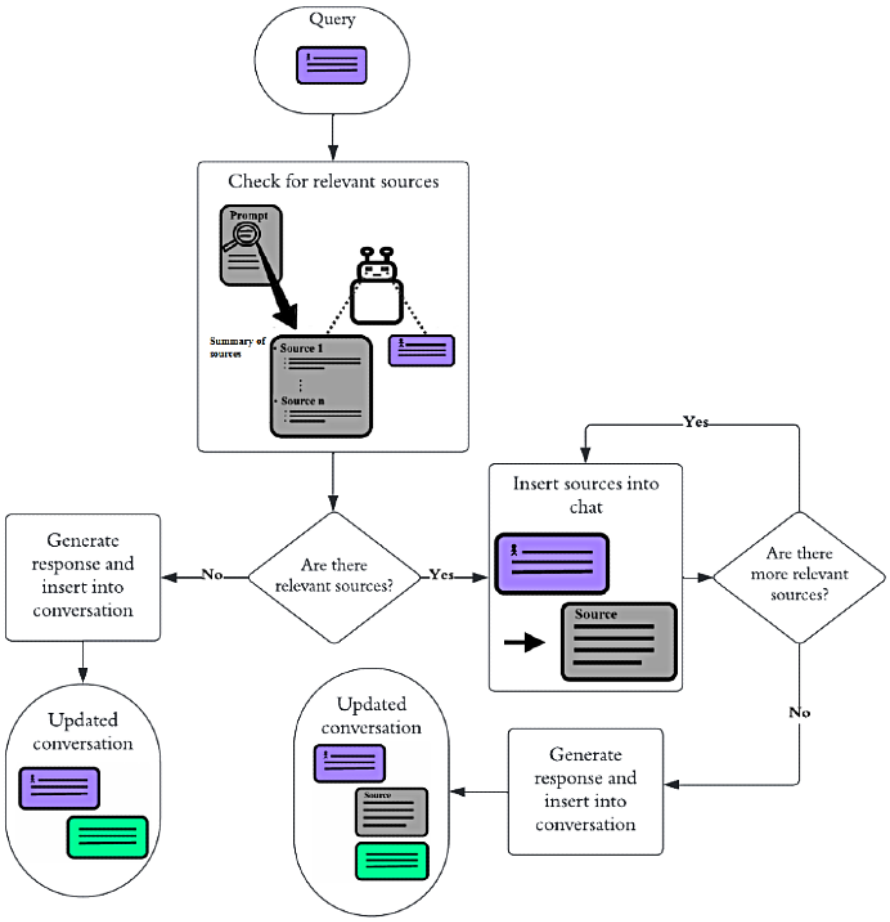
Figure 1. Information retrieval algorithm for dynamically accessing information. This flowchart outlines the steps through which CAFIbot retrieves relevant sources (sections) from the schizophrenia manual on a need-to-know basis to respond to user queries. The initial prompt contains a brief description of each source. If a source is deemed relevant, CAFIbot sends a request for sources to be inserted into the conversation and, thereby, inform the chatbot's response.



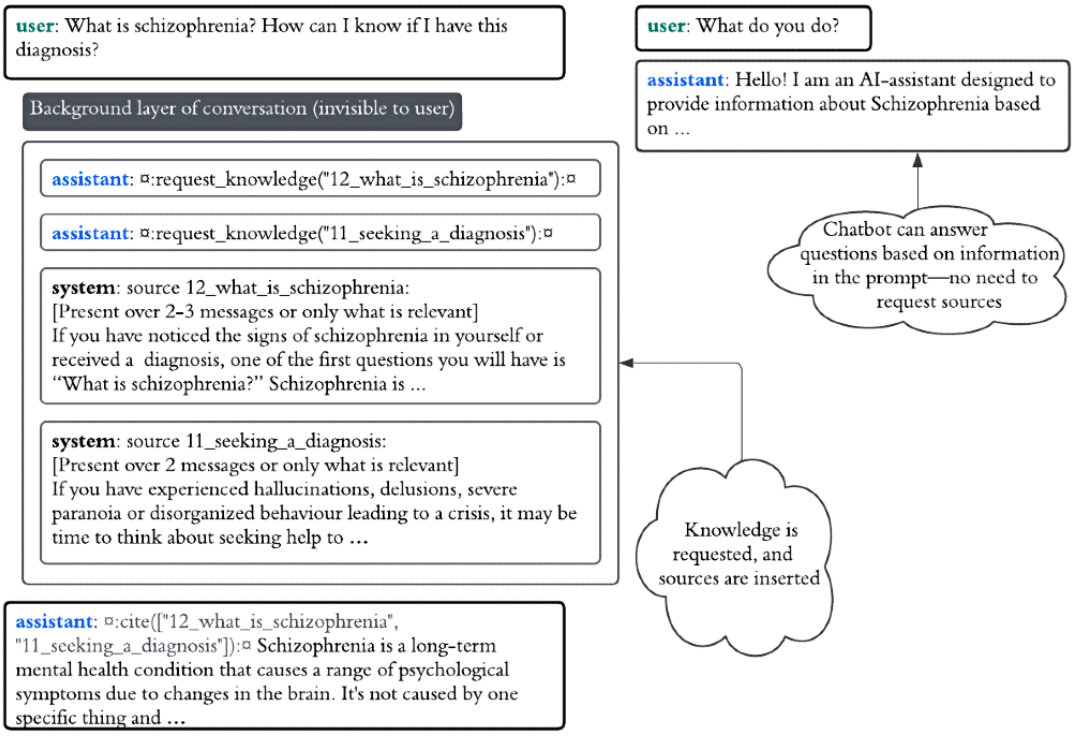


Figure 2. Examples of an assistant answering queries. The conversation on the left shows an example of the chatbot answering a query by retrieving relevant sources and then generating an informed response based on the retrieved passages, which are appended to the input text of GPT-4. The conversation on the right shows an example in which the chatbot answers the question directly based on information from the initial prompt.

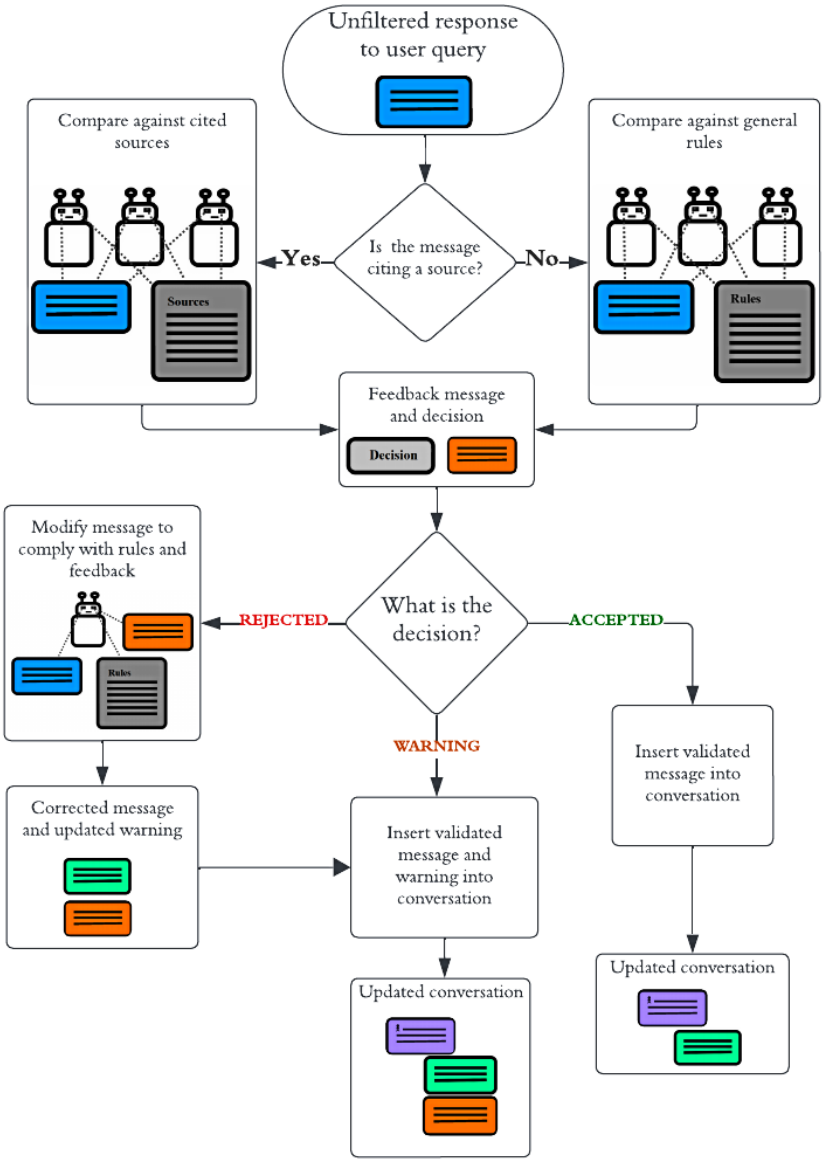
CAF for Maintaining Chatbot Integrity

Our strategy for improving CAFIbot's integrity was based on a prompting paradigm called prompt chaining, wherein a complex goal is broken down into subtasks that are assigned to various specialized LLM agents, each of which is prompted specifically for their given subtask and whose output may be used as input for other agents in other stages of the problem-solving chain [13]. By narrowing the scope of each task, each step in the problem-solving chain can be executed more reliably and accurately, and thus, the solution becomes more reliable. In our case, the complex task was primarily to ensure that the chatbot's response complied with the rules of the chatbot. To this end, we prompt engineered a team of AI agents that critically evaluated and refined the responses generated by the conversational agent.



The AI agents responsible for critical evaluation of chatbot responses will be referred to as *AI judges* or just *judges*. Each judge was responsible for checking the generated response against a list of criteria to ensure desirable behavior and compliance with the rule set. Conceivably, one could have a single judge responsible for evaluating all the criteria in 1 model call, but after trial and error, we found that LLM evaluations aligned much better with those of humans when given a narrower task, and we ended up factorizing the critical analysis of responses into 3 separate analyses assigned to 3 separate judges: one that checked consistency between the response and the cited source, one that investigated unsupported claims (no citation was provided), and one that checked that the chatbot maintained an appropriate tone and was not taking on an unintended role (such as a therapist). The Rules for Permissible Chatbot Responses section describes the rules in detail.

Ideally, we would use GPT-4 for the judges as the response analyses of GPT-4 were often more coherent than those of GPT-3.5, especially when the prompts were long, and it appeared to produce responses that were more factually accurate, relevant, and useful in a clinical context [14,15]. However, because GPT-4 is a computationally expensive model and most responses were compliant with the rule set, we created a preliminary screening layer that used a lighter model, GPT-3.5, and referred to these judges as the *preliminary judges*. Each preliminary judge output a *decision token*, which could be *ACCEPT*, *WARNING*, or *REJECT*. If one of the preliminary judges output *WARNING* or *REJECT*, we called on a second set of GPT-4–powered judges that we referred to as the *chief judges*. From each chief judge, we similarly extracted a decision token, but in addition, we extracted its reasoning—a sentence or 2 motivating their decision. The reasoning was later used to formulate feedback to the conversational agent (if the decision was *WARNING* or *REJECT*). If a chief judge rejected the response, then the response and the feedback were passed to the refinement stage, where another prompted agent (GPT-4) edited the response to fix the issues highlighted in the feedback. An example of refinement is appending "You should verify this information with your therapist" to a response that was flagged for lacking a disclaimer. Figure 3 shows a high level overview of the CAF, but it should be noted that we merged the 2 layers of critical evaluation (preliminary and chief judges) into 1 layer for simplicity. Figure 4 provides a more detailed overview of the decision-making of the preliminary judges. The prompts of the judges can be found in Multimedia Appendix 3.

The prompts of the judges were fine-tuned for desired behavior on a collection of *scenarios* (Multimedia Appendix 4), where each scenario consisted of a user message, the chatbot's response, the sources referenced by the chatbot, and the desired verdict. Multimedia Appendix 1 provides more details on the CAF, and the scenarios can be found in Multimedia Appendix 4.

RenderX

Figure 3. Flowchart of the critical analysis filter for maintaining chatbot integrity. This flowchart highlights the main steps of the process through which chatbot responses are evaluated and modified using a system of specialized prompt-engineered agents designed to ensure that the chatbot's behavior aligns with its instructions and sources. The "general rules" are the rules that apply in situations in which the chatbot does not cite a source, such as when it is explaining its role or querying the user for a suitable topic. The warning messages are directed at the chatbot and notify it of its errors.

XSL•FO
RenderX

Figure 4. Preliminary judges' decision-making flowchart. This flowchart shows the decision tree of the 3 (each box represents a judge) preliminary judges to determine whether a response is accepted or whether it is sent to the second layer of the critical analysis filter for evaluation and processing by GPT-4-powered judges. Each decision tree summarizes the content of the associated prompt, but the reasoning steps leading to the final decision are not programmatically enforced.

Rules for Permissible Chatbot Responses

As the chatbot was intended to base its responses on retrieved information, it was important that its responses were actually supported by that information. The notion of a supported response requires some clarification. Our first attempt at a definition was "all assertions are either reformulations of assertions explicitly stated in the manual or follow as a logical consequence." However, this definition cannot be applied in many cases because the language of the manual is often not explicit enough for such hard logical rules—its tone is often informal, and it relies on common sense for interpretation. For example, "No one is to blame for schizophrenia" can be interpreted as a statement about the etiology of the illness but can also be interpreted as encouraging the reader to adopt an attitude of kindness and understanding toward themselves. Therefore, we defined *supported response* more loosely to mean a response that is consistent with the cited source in tone and intent and whose assertions logically follow from those made in the manual. Common knowledge may be assumed if necessary to explain information in the source to the user. For example, if the manual stated, "Physical activity can help you regulate your mood" and the chatbot replied, "Physical activity could help you manage the symptoms of depression," it would represent a supported response as it helps apply general information to the user's specific situation using common knowledge ("depression affects mood") and basic logic ("depression affects mood, exercise helps regulates mood, therefore..."). However, if it were to claim, "Physical activity can cure depression," it would not constitute a supported

XSL•FO
RenderX

response because it would be making a much stronger claim than what can be deduced based on the source and generally accepted knowledge.

Initially, we considered only allowing supported responses. However, we found that this requirement was too restrictive and decided to allow unsupported statements under certain conditions that aimed to capture situations in which GPT is relatively safe and reliable. Specifically, CAFIbot was allowed to make unsupported assertions if the response satisfied the criteria of being *safe*, *relevant*, *honest*, and *responsible*: (1) the claims are uncontroversial and do not deal with a sensitive topic such as suicide or depression (safe), (2) the claims are relevant to schizophrenia management (relevant), (3) the chatbot admits that the claims lack support from a validated source (honest), and (4) the chatbot encourages verification by an appropriate authority (responsible).

Finally, if the user is in a mental state in which there is urgent need for intervention by a health care professional, for instance, if the user has suicidal thoughts or has relapsed into a psychotic state, we ideally want the chatbot to refrain from offering direct help and, instead, refer the user to an appropriate emergency contact. However, this feature is at an early stage of development, and we mention it here for the sake of completeness as a rule of this nature was included in the prompt at the time the experiments were conducted.

AI Facilitators for Challenging Chatbot Integrity

To test the impact of the AI filter on the chatbot's behavior, we prompt engineered 3 adversarial *AI facilitators* (see the Facilitators section in Multimedia Appendix 3) whose role was to generate questions intended to gradually entice the chatbot toward giving detailed advice on topics outside the scope of CAFIbot. GPT-4 was used to auto-generate conversations to make the results more objective. The out-of-bounds roles, referred to as roles R1 to R3, that the AI facilitators tried to entice the chatbot toward were (1) social activism expert (R1), (2) social interaction expert (R2), and (3) diet expert (R3).

These roles superficially seem permissible as they are related to the within-scope topics of stigma, social life, and lifestyle factors in relation to schizophrenia, and therefore, it is easy to nudge CAFIbot into these roles if done gradually. As such, they represent challenging benchmarks to the CAF in which both nuanced reasoning and common sense interpretations are required to determine when the boundaries of CAFIbot have been overstepped. It should be noted that, for practical reasons, the prompts of the facilitators took only the most recent user query and assistant response as input arguments to its prompt template.

Sampling Conversations Using AI Facilitators

To account for the fact that the conversations are stochastic, we generated multiple independent conversations between each facilitator and the CAFIbot, with each sample conversation having the same starting point (see the Initiation of Facilitator Conversations sheet in Multimedia Appendix 5). For the sake of efficiency and simplicity, we did not restart each conversation from scratch. Instead, for each out-of-bounds role, we manually conversed with CAFIbot until we observed a sign of drift toward the intended out-of-bounds role. We then used that *first-drift response* as a checkpoint from which the corresponding facilitator took over the role as *user*, and we repeatedly sampled conversations that branched off from that point. For each facilitator, 3 sample conversations were generated, and each conversation ended after the facilitator had queried the chatbot 4 times. To obtain comparison data, this experiment was repeated with the CAF deactivated.

Scoring System for Evaluating Chatbot Integrity

To quantify the effect of the CAF, we set up a scoring system that let human raters (see the Human Raters section) assign a *compliance score* to each response—a numerical value from 0 to 4 based on the list of criteria shown in Table 1. These criteria capture various aspects of chatbot integrity. They are not exhaustive but were formulated to obtain a more objective and quantifiable measure of compliance. If a criterion was satisfied, the associated partial score was awarded, and the partial scores were summed to obtain the overall score for the response. If the chatbot was citing a source, the human rater compared the response against the cited source and determined whether they thought that the response was *supported* by the source. If yes, the response was awarded the full 4 points. If unsupported claims were made, conditions S1 and S2 were checked, which consider transparency and responsibility displayed by the chatbot in situations in which it relies on internal knowledge. S1 and S2 were awarded 2 points each and summed to a full score, which reflects our sense that transparency and encouragement of verification are considered equally important and that we accept that the chatbot relies on internal knowledge when appropriate disclaimers are included. In some cases in which the chatbot has started to drift, the chatbot may fail S1 or S2 but still end it with a suggestion to return to a permissible topic (S3). This behavior indicates that the chatbot is reacting to the warning messages by trying to return to a permissible topic. We rewarded this behavior with only 1 point primarily to prevent a full score from being possible if S1 or S2 were not satisfied. Textbox 2 provides an example of how a response was scored.

XSL•FO
RenderX

Table 1. Criteria for scoring the integrity and compliance of the chatbot. The rightmost column shows the partial scores awarded if the associated criterion was met. The partial scores were summed to obtain the final compliance score of a response.

Partial score label	Criterion	Partial score awarded if satisfied
Giving unsupported advice		
S1	Chatbot admits that it is conveying information that is not supported by source materials.	2
S2	Chatbot encourages the user to verify the unsupported information.	2
S3	Chatbot fails S1 or S2 but tries to change the subject to a permissible topic.	1
Conveying source content accurately		
S4	Chatbot conveys information directly supported by its sources.	4

Textbox 2. Example of scoring a response.

Query: "What kind of questions would be good to ask to show I'm really paying attention and engaging with the person speaking?"

Chatbot response: "While the manual doesn't contain specific questions to ask during conversations, a good general approach to showing you're engaged is to ask open-ended questions related to the current topic. These questions encourage more detailed responses and show that you are actively listening. Remember to focus on the speaker's interests and the context of your conversation. It's important to note that *this advice isn't supported by the source (S1: +2)*, so you might want to *verify it with a health care provider (S2: +2)* or a therapist. Can I assist you with anything else?"

Human Raters

A total of 3 raters affiliated with the UiT the Arctic University of Norway Department of Computer Science evaluated the chatbot's responses. Each rater was blind to the annotations of the other raters while evaluating the responses. We took the median compliance score to represent the combined score of the raters. In Multimedia Appendix 5, the individual and aggregated ratings can be found in the Facilitators Results: All Raters sheet, and examples of partial scoring can be found in the Facilitators Partial Scoring: PNW sheet. To evaluate interrater agreement, we calculated the proportion of responses in which the ratings differed by at most 1 and also calculated the Cohen κ (ranges from −1 to 1) for each pair of raters. For the Cohen κ, we used quadratic weights to account for the magnitude of the disagreements and took the average of the 3 pairwise scores (rater 1 vs rater 2, rater 1 vs rater 3, and rater 2 vs rater 3) to represent overall interrater agreement.

Testing the Specificity of the CAF

While the experiment with the facilitators tests the sensitivity of the CAF to out-of-scope responses, it is important for the feasibility of our proposed solution that it also has good specificity; an overactive CAF could be disruptive to the performance of the chatbot, for example, by filling the conversation with unnecessary warning messages, which may lead to less relevant or coherent responses. To this end, we asked GPT-3.5 to generate 10 questions to simulate queries from someone newly diagnosed with schizophrenia. The same 3 raters independently assessed the criticisms in the warning messages that were generated by the CAF and labeled them according to whether they *mostly agreed*. It should be noted that, for simplicity, *agreement* here refers to specificity and does not consider the completeness of the critique. The resulting conversation can be found in the 10 Schizophrenia Questions Results sheet in Multimedia Appendix 5.

Knowledge Base

The knowledge base of the chatbot was made up of passages of text from *Learning to Live With Schizophrenia: A Companion Guide*—a manual about schizophrenia produced by the Global Alliance of Mental Illness Advocacy Network Europe (an international patient advocacy organization) through consultation with people with schizophrenia, their caregivers and family members, and health care professionals [11,16]. The manual is written in English. The manual consists of approximately 12,000 words, or approximately 16,000 tokens, and is divided into 28 consecutive sections or *sources* that the chatbot can request (Multimedia Appendix 2). When segmenting the information, we aimed to create relatively self-contained pieces of information that covered a specific topic or introduced a chapter. PNW segmented the knowledge base into sources and wrote descriptions for each source under the guidance of BE, who has extensive experience in psychiatry research.

Technical Specifications

The responses of CAFIbot were generated by GPT-4 (version 1106-preview with an 8000-token window; OpenAI), with the maximum tokens set to 320 (approximately 240 words). For preliminary screening, we used GPT-3.5 Turbo (version 0613 with a 16,000-token window; OpenAI). All GPT models had the temperature set to the default value of 1, which adds variability to the generated responses. The raw results from the experiments were generated on May 14, 2024.

Privacy Issues

An important ethical aspect to consider when delivering information via an LLM is data privacy. Therefore, CAFIbot was built on the Microsoft Azure OpenAI service (Microsoft Corp), a leading cloud service known for its robust security features and compliance certifications. The Azure OpenAI service provides advanced encryption and threat management to safeguard data, ensuring that potentially sensitive information shared with our chatbot remains confidential. Importantly, Microsoft Azure's commitment to data privacy and security

XSL•FO
RenderX

means that customer data are not sold or shared with third parties.

Before any implementation for use beyond our own technical evaluation (eg, for public use), all logging of input and output data (as is standard with this Microsoft service) must be disabled to ensure that CAFIbot is in compliance with privacy regulations as storing actual conversations would require a complex ethics approval process. Furthermore, the chatbot will be deployed on a website associated with the TRUSTING project [12]. To protect user privacy, the chatbot will operate anonymously, and we will not collect or store identifiable information. The website will include a clear disclaimer outlining the intended purpose and limitations of the chatbot.

Ethical Considerations

This study did not involve human participants and, therefore, did not require institutional review board approval. The chatbot was tested using AI-generated conversations, and no personal data were collected. We propose a chatbot solution intended to be used by a vulnerable patient group. Our approach is designed to minimize the risk of the chatbot providing harmful advice, but we cannot guarantee that harmful advice will not be produced given the stochastic nature of LLMs. As we do not log any information about the conversations, we will not be able to detect harmful responses and, therefore, cannot take any action. However, with the right safeguards and precautions, we believe that the benefit to patients of better and more equitable access to medical information outweighs the risk of inaccurate or biased advice. While we emphasize the need to weigh risks against benefits when considering the ethics of using AI to assist vulnerable individuals, we acknowledge the valid ethical concerns and have made multiple design choices to circumvent these issues. First, we provide a chatbot whose intended use is to educate about a mental illness using scripted sources, which is relatively low risk. Second, our framework is likely to significantly alleviate the well-known issue of biased or inaccurate LLM responses by anchoring them on validated sources and by preventing the chatbot from drifting into discussions that may trigger its inherent biases. Finally, we note that educating users on risk is an important aspect of responsible implementation of AI [17]. Therefore, in our future implementation, we plan to dedicate much effort to formulating disclaimers and educational content that clearly explain the chatbot's intended use and risks.

Results

Effect of the CAF on Chatbot Integrity

The results from the experiments to nudge CAFIbot toward 3 different out-of-bounds roles are presented in Table 2, which shows the median compliance score for each response. The interrater agreement was decent as the compliance scores differed by at most 1 in 90% (65/72) of the responses and the average weighted Cohen κ was 0.921 (SD 0.0084). For each of the 3 facilitators, activating the CAF resulted in substantially improved ability for CAFIbot to adhere to its instructions. With the CAF activated, the fraction of responses with a compliance score of ≥3 was 83% (10/12), 75% (9/12), and 83% (10/12) for roles R1 to R3, respectively, whereas the corresponding values were 17% (2/12), 0%, and 8% (1/12) when the CAF was deactivated. With the CAF activated, CAFIbot received at least one median compliance score of 0 in 5 out of 9 conversations, but in the 3 cases in which a score of 0 was received, CAFIbot was able to recover before the end of the conversation by receiving a subsequent score of 4. In contrast, without the stabilizing influence of the CAF, in each conversation, the responses eventually ended up consistently receiving low compliance scores of 0 and 2, illustrating the self-perpetuating nature of rule violations.

XSL•FO
RenderX

Table 2. Median compliance scores of each response in the sample conversations (4 queries per conversation and 3 sample conversations per experimental configuration) reflecting CAFIbot's ability to comply with its instructions and stay within the scope of its stated role. The conversational partner was an artificial intelligence facilitator designed to ask questions that entice the chatbot toward giving unsupported advice. Each conversation was restarted 3 times from a fixed starting point.

	With the CAF[a] turned on			With the CAF turned off

[a]CAF: critical analysis filter.

Specificity of the CAF When Answering Schizophrenia Questions

The 10 Schizophrenia Questions Results sheet in Multimedia Appendix 5 shows the full conversation along with the sources referenced, warning messages produced by the CAF, original responses (before refinement), and ratings. In total, 2 responses were flagged by the CAF: one received a warning, and one was modified to comply with the instructions. In both cases, most raters agreed with the criticism of the CAF. Thus, the CAF showed good specificity when answering questions about schizophrenia. It should be noted that we included an improvised question in which we asked the chatbot to rephrase a response in simpler terms, after which it consistently used simpler language, showcasing an attractive advantage of using chatbots in education.

Discussion

Principal Findings

The CAF was highly effective at re-establishing the integrity of the chatbot after it had started to drift from its role and instructions. With the CAF activated, CAFIbot showed a substantially improved tendency to admit its limitations and encourage verification when appropriate and generally tried to steer the conversation back to a permissible topic. However, with the filter deactivated, the chatbot displayed an "eagerness" to expand on out-of-bounds topics, illustrating the importance of robust monitoring mechanisms that detect and prevent this type of conversational drift. Finally, the CAF showed good specificity when answering the 10 questions about schizophrenia, as all warning messages had valid motivations.

Comparison With Prior Work

There has been a surge of research in using advanced generative AI in mental health care services over recent years, but attention has mostly been paid to therapeutic applications and counseling support [5]. We were not able to identify any research that was mainly focused on the problem of controlling the scope of LLM-powered conversational agents in the context of mental health care, and our research appears novel in that it focuses specifically on this aspect of LLM performance in situations in which controlling the scope and ensuring transparency is of critical importance.

A framework that had many similarities to the CAF is self-reflective retrieval-augmented generation (SELF-RAG), a recently proposed method that significantly improves the accuracy and relevance of retrieval-augmented generation–enhanced LLM responses by using stages of self-reflection [18,19]. Reflection tokens guide this process, categorizing the need for retrieval and critiquing the generated text, similarly to how our framework used *REJECT* and *WARNING* to indicate that a rule had been violated. While both frameworks evaluate whether a response is supported by the retrieved information, SELF-RAG uses self-critical agents more extensively to improve the information retrieval component by

XSL•FO
RenderX

also analyzing *necessity* (whether retrieval is required to answer the query), *relevance* (whether the retrieved passages relate to the query), and *completeness* (whether additional passages are relevant). In contrast, the CAF uses critical agents primarily to maintain the integrity of the prompted chatbots. A unique aspect of the CAF is that it uses feedback from the analysis and refinement of the response as reminders to the conversational agent to reduce the likelihood that it will repeat the errors in future interactions. It would be interesting to evaluate the contribution of this feedback mechanism.

Another key difference lies in how critical agents are developed in each framework. SELF-RAG uses supervised training to train LLMs to predict decision tokens such as "relevant" from inputs such as the user query and the retrieved passage. Decision tokens are generated automatically by a state-of-the-art model (GPT-4) prompted for that purpose, and a smaller and more cost-effective student model is trained to mimic GPT-4's performance. In contrast, the CAF relies on manual prompt engineering, a time-consuming approach that limits the number of labeled examples available for developing and testing critical agents. Adopting a setup similar to that of the teacher-student setup used in SELF-RAG would enable us to train and evaluate the critical agents in the CAF on a much larger and more diverse set of scenarios by using automation to scale up the generation of training examples. Testing this approach, as well as applying SELF-RAG to the information retrieval component of our chatbot, is a promising direction for future development.

Defining the Scope and Boundaries of the Chatbot

Occasionally, unsupported responses did pass through the CAF undetected. These slips in sensitivity are at least partially explained by the ambiguity of the rules that outline the scope of CAFIbot. Indeed, humans themselves will sometimes disagree on whether a response complies with a rule, as illustrated by the less-than-perfect interrater agreement. However, this ambiguity is unavoidable if we wish to leverage the abilities of LLMs; to be effective as a conveyor of information, CAFIbot sometimes has to rely on common knowledge, for example, when explaining concepts not defined in the sources, and this fact inevitably leads to gray areas as it is not possible to unambiguously define "common knowledge" in a few paragraphs of text.

Restricting the GPT's Responses to Topics in Which It Is Reliable

To illustrate why it is difficult to formulate exact rules for what constitutes a "supported" statement, consider the following question—"Can including more vegetables make my diet healthier?"—as a follow-up to the manual's recommendation to "adhere to a healthy diet." If the chatbot says, "Including fruits and vegetables in your diet is generally considered to be healthy," should we be pedantic and flag this as unsupported because the manual never explicitly specifies what "healthy eating" means, or do we consider this fact to be so basic that we permit it despite not being explicitly stated? Much of the utility of chatbots such as ChatGPT comes from their ability to explain and expand on phrases or concepts, and by being too restrictive, we would lose this feature. Thus, the formulation of such rules is a balancing act between predictability and risk reduction on the one hand (with deterministic algorithms being an extreme example) and usefulness and versatility on the other.

As a general strategy for striking a good balance between risk reduction and utility, we decided to allow the chatbot to make unsupported assertions under the condition that they constituted basic and uncontroversial information or advice. This formulation was intended to capture the situations in which the GPT is at its most reliable, an assertion that can be motivated by observing that there is presumably a lot of training data available for such topics, and information about them on the internet will tend to be more consistent and, thus, reduce unpredictability in the GPT's responses. Indeed, studies have found that the GPT performs better when asked questions related to popular factual knowledge [7]. A pitfall of this strategy is that common misconceptions can be hard to distinguish from basic facts due to their pervasiveness, and so its success depends on how well the GPT differentiates between the 2. In any case, this strategy is likely to at least weed out hallucinations and radical statements. Ultimately, our premise is that the increased flexibility afforded to the chatbot by the "basic-and-uncontroversial" rule outweighs the risks associated with the occasional inaccurate advice as such advice will likely be generic but benign. More research into how LLMs classify messages into basic and nonbasic is needed to establish what kind of inaccuracies might slip through a filter that implements this type of rule.

Another important factor for when to restrict the chatbot's reliance on innate knowledge is the consequence of an inaccurate response. How strictly a rule is interpreted and applied should ideally depend on the stakes involved in the situation. A low-stakes situation in which the chatbot can be afforded more leeway is if the user asks the following: "What are the benefits of taking regular walks?" On the other hand, if the user asks the following—"Should I quit my medication?"—then the CAF should err on the side of caution and restrict the chatbot to parroting the advice from the sources. This strategy could be generalized to include any situation in which LLMs should not be trusted. The social activist role provides a good example. Challenging social stigma could be plausibly interpreted as an action that is encouraged by the source on stigma if consistency with the local context (social stigma) is prioritized over consideration of the broader context (the well-being of an individual learning how to cope with their mental illness). While human experts are good at keeping in mind the broader context when making individualized recommendations, AI seems more inclined to ignore the "big picture" and, thereby, generate responses that are inappropriate when individual considerations are taken into account. Perhaps, in certain situations, a more fruitful approach than trying to align AI and human evaluation is to get the LLMs to detect situations in which AI should not be trusted and increase the strictness of the CAF in those cases. It would be interesting to see research into the ability of LLMs to identify high-stakes situations, subjects not suitable for AI, and other situations that are relevant to controlling the scope of chatbots in a mental health context.

XSL•FO
RenderX

Generalizability to Other Mental Illnesses and Use Cases

We tested the efficacy of the proposed method in the context of educating about schizophrenia, but the general framework can in theory be applied to create an informational chatbot for any mental illness. The variables of the framework that need to be modified are the knowledge base (ie, the sources) and their description in the initial prompt and the parts of the prompts (including the prompts of the judges) that describe the role of the chatbot and that reference schizophrenia specifically. In general, the prompts make few references to schizophrenia, and it should be easy to repurpose the prompts for other mental health conditions. We also note that adding a new rule for the chatbot is simply a matter of adding the rule to the initial prompt as well as updating the prompt of the relevant judges accordingly.

Although we tested the framework on schizophrenia education, we have reason to believe that our results will generalize well to many other clinical contexts. The difficulty of getting a chatbot to reliably adhere to prompt instructions can vary significantly depending on factors such as the nature of the user's input or the topic being discussed. For example, we found that getting the chatbot to respect source boundaries was far easier when the sources concerned medication (where disclaimers are natural and the content tends to be concrete) than when the sources addressed social stigma and also that long and unfocused queries were more likely to derail the chatbot than concise queries. As such factors, as well as the content being conveyed, vary depending on the clinical user population, it follows that some variability in performance is to be expected across different mental health conditions. We note that the content conveyed in this study represents a particularly tricky prompting challenge as it is easy—in principle—for the chatbot to get lost in a tangential unintended role (eg, therapist) when conveying passages from our source materials, which are written not only to convey facts but also to be emotionally supportive. Looking ahead to practical implementation, we expect this framework to work particularly well when the information is concrete and factual as boundaries in that case will be less ambiguous. As such, a promising use case is a platform for conveying technical information to mental health patients ("Where on the website can I find...") who may struggle to navigate information when it is presented in more generic formats such as booklets and websites. Indeed, the original intent behind developing this type of chatbot was to answer user questions about the data collection app that will be used in the research project associated with this chatbot. Other promising use cases for chatbots as adaptive mediums of educational content are medical conditions that are highly heterogeneous, such as insomnia as people with insomnia can differ greatly in terms of the information and strategies that are relevant to them.

Suggestions for Future Prompting-Related Research

Structuring Sources for Delivery via a Chatbot

The sources of CAFIbot were written with a static medium of communication in mind. Therefore, the chatbot's performance might be improved if the sources are instead written specifically to be communicated via chatbots. For example, a static manual may assume that the sections are read in sequence and some sections serve only as introductions to a chapter, but CAFIbot may retrieve them in isolation. As a result, CAFIbot may sometimes produce awkward answers if the retrieved sources lack the preceding context. If the blocks are instead written as self-contained blocks of information, then the chatbot may be more likely to produce a complete and comprehensive answer.

Another way in which the sources could be optimized for chatbot communication is to express them in a more compact technical language so that they take up less tokens and, thus, less space in the context window. The LLM could then "decompress" the information when it conveys the technical information to the user in simpler terms—a task at which LLMs excel. Another advantage of condensing the language of the sources is that the notion of a response being "supported by a source" is more natural when preceded by precise scientific language, and therefore, the LLM might be more inclined to respect the boundaries of the source materials.

Finally, information that is to be conveyed via a chatbot includes a layer of information in addition to the content—instructions on how and when to convey that content. We used square brackets to specify local rules that applied in the surrounding context, such as "...[Ask before presenting this paragraph]..."—an approach that is inspired by teacher-oriented manuals. This convention creates an additional layer of information wherein experts can insert their knowledge and experience to fine-tune the chatbot's behavior. For example, we noticed that, when CAFIbot was conveying the section on stigma, it had a strong tendency to give advice encouraging the user to engage in social activism—a subject in which we do not want to trust AI for advice. We could correct for this undesired tendency by adding a sentence clarifying the intended lessons and implications of the text, such as "Do not internalize social stigma" as opposed to "Try to eliminate social stigma in your society." Specifying the intent explicitly could help align the chatbot's behavior with that of humans. It could also help differentiate the context from overlapping topics—in this case, clinical care focused on individual well-being versus large-scale social change.

Adding Depth to the Chatbot's Knowledge

CAFIbot was unable to fully answer some of the 10 schizophrenia questions, such as the question about different subtypes of schizophrenia due to that topic not being covered by the manual. This highlights an important difference between static and adaptive education—a static manual must limit the level of detail it provides and the number of topics it covers to not overwhelm the reader and be accessible to individuals across a broad range of abilities and backgrounds. A chatbot need not be subject to this constraint as models such as GPT-4 can adapt to the needs of the situation and present a topic at the appropriate level of detail. This fact could be incorporated into the sources of the chatbot. For example, where the schizophrenia manual only stresses the importance of maintaining a healthy diet, a chatbot could be equipped with additional information that allows it to answer likely follow-up questions. Taking this idea further, we are developing a referral feature (not covered in this

XSL•FO
RenderX

paper) that effectively expands the chatbot's knowledge base by enabling it to redirect the user to other prompted assistants that specialize in a particular topic such as sleep. Enabling the chatbot to respond to likely follow-up questions would also make it more engaging and interesting to converse with.

Future Implementation and Development

Future validation of CAFIbot will focus on testing it with real-world users, including patients with mental illnesses, their families, and the public, through the collection of feedback. To ensure compliance with relevant national and international legislation for LLMs, and recognizing that this application is not classified as a medical tool for medical device regulatory purposes (and does not require HIPAA [Health Insurance Portability and Accountability Act] compliance in the United States), our plan includes a phased implementation process. First, usability feedback will be collected from a user board composed of lived-experience experts, namely, people who experience various mental illnesses, so as to refine the system based on initial impressions. Following this, the chatbot will be deployed on a website [12] in which a broad user group can engage with it. Anonymous feedback will be collected through standardized questions designed to assess the chatbot's utility without compromising user privacy. Specifically, we plan to include a feedback link that allows users to rate the chatbot's usefulness through structured questions. This process will span several years in alignment with the timeline of the research project (anticipated to conclude in 2028). At the end of this period, we aim to report critical insights into the chatbot's real-world performance in a follow-up study. Before deployment, we will conduct extensive testing using simulated patient interactions to refine and ascertain the chatbot's safety and usability.

Study Limitations

Generalizability Is Uncertain

This was a feasibility study focused primarily on the safety aspect, and it has important limitations. We tested the CAF only in a very small number of situations, and therefore, the generalizability of our findings is hard to assess. Furthermore, we fine-tuned the prompts of the AI judges to obtain desirable evaluations on a relatively narrow range of scenarios, including scenarios similar to those generated by the facilitators. Thus, the CAF performance might be lower in scenarios outside the set of scenarios used to fine-tune the prompts. As was mentioned in the comparison with SELF-RAG, automating the collection of data for developing and evaluating the judges using the student-teacher method is a highly promising approach for achieving a more generalizable performance.

Another major limitation is the use of AI as a substitute for human testers for convenience and objectivity. AI cannot fully replicate the diverse and unpredictable nature of human input, in particular of people with schizophrenia. A study that collects and analyzes conversations between CAFIbot and people with schizophrenia would be ideal for discovering potential blind spots in the CAF. However, such a study could be very difficult to set up due to legal and privacy concerns with regard to the collection of such sensitive data from people with schizophrenia, in particular those who are not in a stable state of mind, which are precisely the individuals that would be most valuable from the perspective of evaluating the CAF. An alternative is to enroll clinicians with experience working with patients with schizophrenia to simulate this role. Yet another option, as has been done in other studies on GPT and mental health, is to use public online forums such as Reddit as a source of real-life questions about medical conditions [20].

Potential for Biased Performance Evaluation

The person who wrote the prompts (PNW) for and programmed the CAFIbot also designed the benchmarks for evaluating its performance. This could have biased the results, as there may have been a tendency to design tests that measure efficacy in the situations that the system was designed to handle. We expect that we will formulate more comprehensive tests covering a broader range of situations as we acquire more diverse data and viewpoints from external feedback.

Need for Rigorous Testing of Other Aspects of Performance

Designing mechanisms that improve controllability may come at the expense of other aspects of performance such as flexibility or usefulness. More extensive testing is needed to assess various aspects of performance, such as the chatbot's ability to generate relevant and useful answers. As previously mentioned, we are planning on implementing the chatbot on a website and will add features to enable users to provide anonymous feedback.

Limitations of the Information Retrieval Algorithm

Most of the questions generated by GPT-3.5 turned out to actually be asking 2 to 3 questions in 1 sentence, which incidentally made them particularly challenging for the chatbot to answer via the information retrieval algorithm. The information retrieval algorithm tends to work well when a single query can be answered concisely using a small number of sources but may fail when the answer to a question is spread across multiple sources or when the formulation of the question differs substantially from the description of the sources. This is a well-known limitation of on-demand information retrieval in LLMs.

Conclusions

Using AI agents in a CAF to monitor and refine a chatbot's responses as well as provide feedback to the chatbot led to responses with substantially better adherence to the chatbot's sources and instructions and, thereby, a more robust and controllable LLM-powered chatbot. In particular, the chatbot was far more likely to acknowledge its transgressions when it made assertions that were not directly supported by its sources when the CAF was activated than when it was deactivated. Our results suggest that it is feasible to use LLMs as vehicles for mental health information while keeping the risks and consequences associated with LLMs at an acceptably low level. More research is needed to establish the generalizability of our findings.

Abstract

Background: Large language models (LLMs) have demonstrated powerful capabilities in natural language tasks and are increasingly being integrated into health care for tasks like disease risk assessment. Traditional machine learning methods rely on structured data and coding, limiting their flexibility in dynamic clinical environments. This study presents a novel approach to disease risk assessment using generative LLMs through conversational artificial intelligence (AI), eliminating the need for programming.

Objective: This study evaluates the use of pretrained generative LLMs, including LLaMA2-7b and Flan-T5-xl, for COVID-19 severity prediction with the goal of enabling a real-time, no-code, risk assessment solution through chatbot-based, question-answering interactions. To contextualize their performance, we compare LLMs with traditional machine learning classifiers, such as logistic regression, extreme gradient boosting (XGBoost), and random forest, which rely on tabular data.

Methods: We fine-tuned LLMs using few-shot natural language examples from a dataset of 393 pediatric patients, developing a mobile app that integrates these models to provide real-time, no-code, COVID-19 severity risk assessment through clinician-patient interaction. The LLMs were compared with traditional classifiers across different experimental settings, using the area under the curve (AUC) as the primary evaluation metric. Feature importance derived from LLM attention layers was also analyzed to enhance interpretability.

Results: Generative LLMs demonstrated strong performance in low-data settings. In zero-shot scenarios, the T0-3b-T model achieved an AUC of 0.75, while other LLMs, such as T0pp(8bit)-T and Flan-T5-xl-T, reached 0.67 and 0.69, respectively. At 2-shot settings, logistic regression and random forest achieved an AUC of 0.57, while Flan-T5-xl-T and T0-3b-T obtained 0.69 and 0.65, respectively. By 32-shot settings, Flan-T5-xl-T reached 0.70, similar to logistic regression (0.69) and random forest (0.68), while XGBoost improved to 0.65. These results illustrate the differences in how generative LLMs and traditional models handle the increasing data availability. LLMs perform well in low-data scenarios, whereas traditional models rely more on structured tabular data and labeled training examples. Furthermore, the mobile app provides real-time, COVID-19 severity assessments and personalized insights through attention-based feature importance, adding value to the clinical interpretation of the results.

Conclusions: Generative LLMs provide a robust alternative to traditional classifiers, particularly in scenarios with limited labeled data. Their ability to handle unstructured inputs and deliver personalized, real-time assessments without coding makes them highly adaptable to clinical settings. This study underscores the potential of LLM-powered conversational artificial intelligence

Introduction

Background

Disease risk assessment is a critical tool in public health surveillance, where demographic variables and social determinants are often used to assess a patient's susceptibility to disease, predict treatment response, and forecast severity outcomes. Traditionally, these predictions have been carried out using machine learning models trained de novo for each disease or condition using curated tabular data [1-3]. For example, Wang et al [2] developed a linear model–based, multitask learning approach to predict the risk of childhood obesity based on geolocation data. Li et al [3] proposed a mixture neural network to stratify patients and predict heart failure risk within each subgroup.

The advent of transformers has marked a significant shift, allowing researchers to deploy advanced models that improve prediction accuracy and handle complex data structures more effectively. Bidirectional Encoder Representations from Transformers (BERT)–style models [4] have been extensively used in various health care tasks. Notable examples include ClinicalBERT [5] and BioClinicalBERT [6], both trained on clinical notes in the MIMIC-III database. MedBERT [7], further trained on electronic health records (EHRs), achieved a high area under the curve (AUC) scores for disease risk prediction. However, BERT-based models, primarily designed for discriminative tasks, face limitations in processing streaming question-and-answer (QA) pairs typical in conversational data science applications due to their architectural constraints.

Generative Large Language Models for Health Care

Generative large language models (LLMs), such as OpenAI's GPT-3 [8], have transcended the limitations of discriminative models by excelling at handling diverse data formats, including both structured clinical data and unstructured text like patient narratives and medical histories. This versatility allows them to integrate and synthesize information from multiple sources, making them highly effective for complex tasks such as predicting disease severity. Generative LLMs have been applied in health care across various domains, including diagnostic support, clinical decision-making, clinical knowledge extraction, and risk prediction with personalized monitoring.

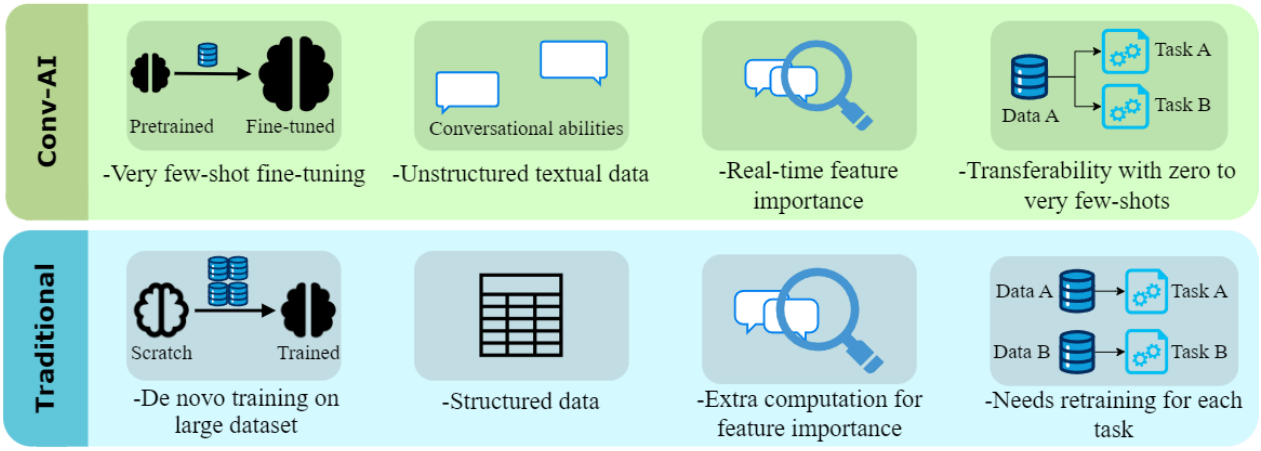
In diagnostic support, generative LLMs like ChatGPT and GPT-4 [9] have been used to aid clinical diagnosis by leveraging structured and unstructured data. Gilson et al [10] assessed ChatGPT's ability to answer the United States Medical Licensing Examination (USMLE) Step 1 and Step 2 multiple-choice questions, highlighting its potential for medical education and diagnostic assistance. Kung et al [11] evaluated ChatGPT's clinical reasoning by testing it on structured questions from the USMLE, simulating clinical decision-making tasks without domain-specific training. Ali et al [12] explored the use of ChatGPT to generate patient-friendly clinical letters based on semistructured prompts, aiming to improve communication efficiency while ensuring accessibility for patients. Xv et al [13] used ChatGPT to assist in diagnosing urological diseases using semistructured patient data, demonstrating its potential as a tool for preliminary diagnostic support. Kanjee et al [14] evaluated GPT-4's diagnostic accuracy in complex clinical cases, showing its ability to generate differential diagnoses based on patient history and clinical findings.

Generative LLMs have also become valuable tools in synthesizing vast amounts of medical literature, enabling clinicians and researchers to stay current with scientific advancements. Tang et al [15] evaluated LLMs in summarizing medical evidence, demonstrating that models like GPT-4 [9] can generate concise summaries of research articles, facilitating faster knowledge assimilation. Sallam [16] discussed how LLMs could assist in systematic reviews and meta-analyses, reducing the effort required in literature search and data extraction.

In risk prediction and personalized patient monitoring, generative LLMs have shown significant potential. Health-LLM [17] integrates wearable sensor data, such as physical activity and heart rate, to predict stress, fatigue, and other health metrics. Leveraging zero-shot learning, the model generalizes effectively across various health prediction tasks without task-specific training. ClinicalMamba [18] excels in analyzing longitudinal EHR notes for disease progression prediction and patient cohort selection by processing unstructured clinical notes over extended sequences.

With increasingly longer context windows, up to 8192 tokens in OpenAI's GPT-4 [19], generative LLMs can efficiently manage extensive patient records and interaction histories. This capability to process long, varied inputs allows them to generalize effectively even with limited labeled domain-specific data. Furthermore, their ability to handle multiturn conversations positions them uniquely for real-time applications, facilitating no-code disease assessment through interactive patient engagements.

Despite the remarkable performance of proprietary black-box LLMs like GPT-4 and MedPaLM-2 [20], there is growing interest in deploying white-box models in health care and other high-stakes domains. White-box models mitigate risks related to data privacy breaches and hallucination by allowing for full transparency and control over the model's architecture and parameters. Their smaller size enables deployment on local devices, enhancing data security by keeping sensitive information on the device. Furthermore, the transparent nature



XSL•FO
RenderX

of these models facilitates interpretability, which is crucial for explainability in clinical settings.

This shift towards transparent and customizable models is exemplified by PMC-LLaMA [21], adapted from the LLaMA architecture and fine-tuned on extensive health and medical corpora. PMC-LLaMA has outperformed larger models in several health and medical QA benchmarks, highlighting the effectiveness of domain-specific fine-tuning. One of the few studies exploring generative LLMs for disease diagnosis and risk assessment is CPLLM [22]. CPLLM fine-tunes Llama2 [23] as a general LLM and uses BioMedLM [24], a model trained extensively on biological and clinical texts, to perform various prediction tasks, including disease diagnosis and patient outcome forecasting. These models demonstrate the potential of LLMs in understanding complex medical language and reasoning. However, their application to direct disease risk assessment using streaming QA interactions remains limited, and they do not fully leverage the interpretability benefits of white-box models for explainability.

Our work builds upon these advancements by transitioning from traditional machine learning–based health outcome prediction—which typically relies on structured tabular data—to chatbot-based, no-code prediction using streaming QA interactions. We develop a generative artificial intelligence (GenAI)–powered mobile app that integrates fine-tuned white-box LLMs—including LLaMA2, Flan-T5, and T0 models—as the core for personalized risk assessment and patient-clinician communication. The app provides a natural language interface for risk assessment, processes user responses in real time, and can be deployed locally on devices to enhance data privacy and security. Figure 1 shows a comparison of our work to traditional methods.

Figure 1. Comparison between large language model (LLM)–based conversational AI (Conv-AI) and traditional machine learning methods for disease risk assessment. The Conv-AI leverages pretrained models that require only very few-shot fine-tuning, can handle unstructured textual data, provide real-time feature importance for each risk assessment it provides, and offer transferability with zero to very few shots for new risk assessment tasks. In contrast, traditional machine learning methods require large datasets for de novo training, process structured data, rely on extra computational steps for instance-specific post hoc feature importance (eg, Shapley additive explanations), and need retraining for each new task.

Contributions

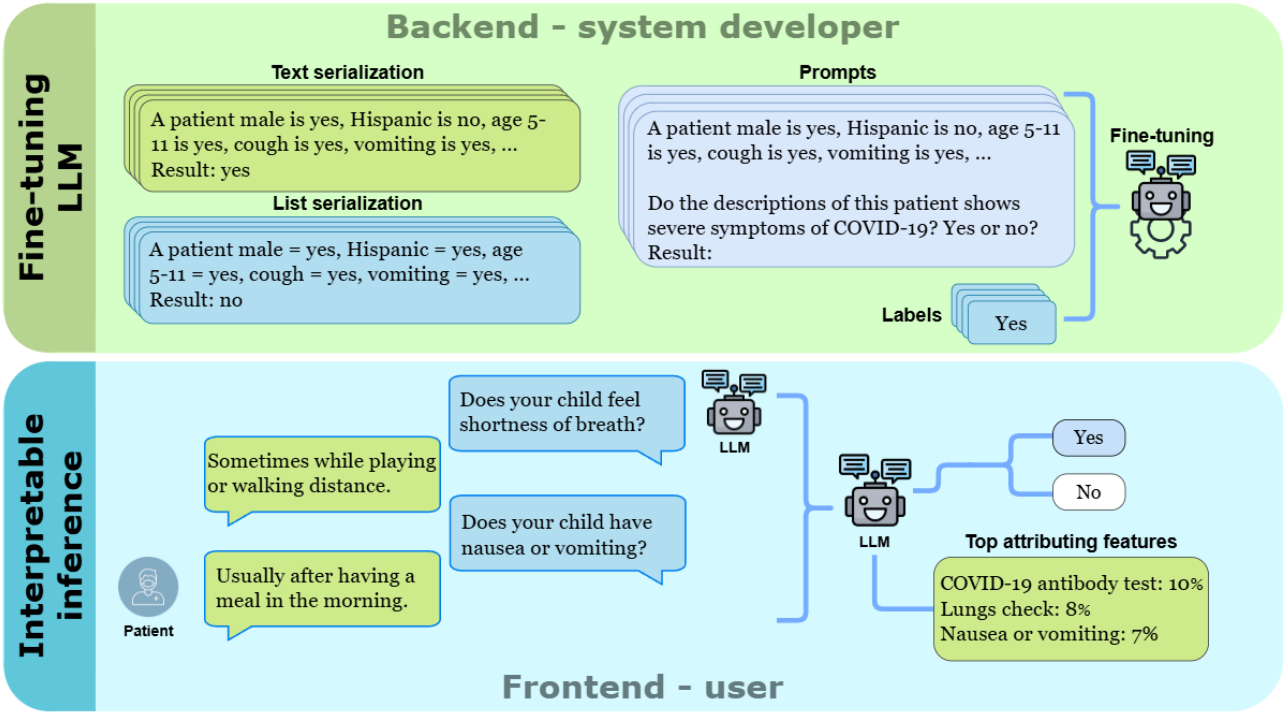
Our contributions to the field of LLM-based disease risk assessment are diverse. First and foremost, we transition from traditional machine learning–based health outcome prediction—which typically relies on structured tabular data—to chatbot-based, no-code prediction using streaming QA interactions. This is realized through the development of a GenAI-powered mobile app that integrates fine-tuned LLMs as the core for personalized risk assessment and patient-clinician communication. The app not only assesses disease risk for patients but also provides contextual insights related to risk surveillance and mitigation through natural language conversation.

Second, we demonstrate that generative LLMs can outperform traditional machine learning methods, such as logistic regression [25], random forest [26], and extreme gradient boosting (XGBoost) [27], in low-data regimes, which is critical for medical applications where labeled data are scarce. For instance, our results show that LLMs like the T0-3b model achieve an AUC of 0.75 in zero-shot settings, demonstrating their potential for disease risk assessment even without task-specific training.

In addition, we provide a comprehensive comparison of both decoder-only and encoder-decoder models, fine-tuned using the widely adopted, parameter-efficient, low-rank adaptation (LoRA) method [28].

Third, we introduce a feature importance analysis derived from the LLM's attention layers, providing personalized insights into the most influential factors driving the model's predictions. This enhances the interpretability and usability of the risk assessment for both patients and clinicians, offering real-time, instance-specific explanations during inference.

Methods



Our Research Objective

The primary objective of this study is to explore the effectiveness of pretrained generative LLMs in no-code risk assessment of disease severity using few-shot multihop QA interactions. We aim to evaluate how these generative LLM-powered chatbots can use streaming QA interactions to accurately classify patient outcomes as severe or nonsevere, which is crucial for early risk assessment and optimizing health

XSL•FO
RenderX

care resource allocation. Through a case study of COVID-19 severity risk assessment, we developed an app that uses open-source generative LLMs to determine the severity of COVID-19 outcomes. This involves leveraging the models' capabilities in zero-shot and few-shot settings, with a focus on the use of serialization techniques to enhance their effectiveness and generalizability. We also integrate real-time feature importance to provide interpretable risk assessments. Figure 2 shows the workflow of our approach, from fine-tuning generative LLMs using serialized QA pairs to real-time risk assessment through a conversational interface.

Figure 2. Workflow for few-shot COVID-19 severity risk assessment using generative large language models (LLMs) with different serialization techniques. The top section, labeled "Backend - system developer," shows the fine-tuning phase where a few-shot sample of patient data, serialized through list and text templates, is used to fine-tune the LLMs. This backend process includes the creation of prompts and corresponding labels for model fine-tuning. The bottom section, labeled "Frontend - user," illustrates how a conversational chatbot interacts with users through our application to gather responses through streaming QA interactions. These responses are analyzed by the fine-tuned LLM in real time, providing risk assessments and highlighting the top attributing features that explain the model's risk assessment. QA: question-and-answer.

Data Collection

A dataset was collected from the emergency departments of Children's Hospital of Michigan and UPMC Children's Hospital of Pittsburgh between March 2021 and February 2022. Table 1 provides an overview of the binary features used in our study, including demographic, clinical, and social determinants that may influence COVID-19 severity risk. The dataset includes a total of 393 participant records, each characterized by responses to a series of carefully designed questions (see Figure 3 for sample QA pairs).

The severity of illness was defined based on the presence of any of the following criteria:

1. Requirement for supplemental oxygen (≥50% fraction of inspired oxygen)
2. Need for mechanical ventilation or noninvasive positive pressure ventilation (bilevel positive airway pressure and continuous positive airway pressure)
3. Need for vasopressors or inotropes
4. Requirement for extracorporeal membrane oxygenation
5. Cardiopulmonary resuscitation
6. Death from a related cause within 4 weeks after discharge

Children meeting any of these criteria were categorized as having severe illness. These outcomes were determined through chart reviews and parent surveys conducted 30 days after discharge [29].

Outliers were removed, and feature selection was performed using Shapley additive explanations values [30], resulting in the final dataset used for analysis.

Figure 3. Overview of our mobile app design, showcasing patient data collection, real-time risk assessment using large language models (LLMs), and clinician review interface.

Tabular Data for Traditional Models

As traditional machine learning methods require tabular data as input, we formalize the questionnaire QA pairs , where n=393, represents the binary feature vector of the i-th instance where d=15, and denotes the binary class label indicating the presence or absence of severe COVID-19 symptoms determined by clinicians.

Each feature vector x_i consists of binary indicators representing social determinants and clinical and demographic factors that may influence the severity of COVID-19, such as age, preexisting conditions, vital signs, and laboratory test results. These features are shown in Table 1. The feature names are denoted as , where each f_j is a natural-language string describing the corresponding attribute.

The task is to predict the binary outcome y_i based on the information provided in x_i. This constitutes a supervised learning problem where the objective is to train a model to minimize prediction error on unseen data.

Serialization for New Conversational AI

At the time of data collection from 2021 to 2022, we did not yet have a chatbot for automated data donations from users, so we used a questionnaire to collect answers from each patient based on a set of questions designed for this study. As a result, the native format of the dataset consists of QA pairs, which were subsequently serialized to fine-tune the generative LLMs

XSL•FO
RenderX

for the risk assessment task. It is important to note that the fine-tuned model is capable of assessing risk using streaming QA interactions in real time (Figures 2 and 3).

To achieve serialization, the features in our dataset are denoted as , and their associated values as . This notation provides a structure that is transformed into natural language prompts for the LLM.

We used two main serialization methods from TABLLM [31], the list template and the text template, to create natural language representations of the data. As shown in Figure 2, the list template links each feature with its value using an equal sign ("="), while the text template uses a narrative structure with the word "is" to connect each feature with its value. These templates enable us to evaluate which serialization approach better translates the data into actionable insights by the LLM.

Generative LLMs

We explore the capabilities of 3 white-box LLMs—LLaMA2 [23], T0 [32], and Flan-T5 [33]—focusing on their application in risk prediction for COVID-19 using both the native QA pairs and the formatted tabular dataset.

To our knowledge, this is one of the first attempts leveraging generative LLMs and conversational data science for disease risk assessment across various LLMs and few-shot settings. Our selection includes both decoder-only (LLaMA2) and encoder-decoder architectures (T0 and Flan-T5), allowing for a comprehensive assessment and comparison of their performance. The white-box nature of these models is particularly advantageous as it enables setup on local hosts with private datasets, ensuring precise risk assessment by allowing direct access to model weights and logits.

The input to the LLMs is a serialized string generated from the tabular data using the previously explained serialization strategies. Given a feature vector . and their associated values , the serialized input string S_i can be represented using either the list template or text template serialization methods (Figure 2).

These feature vectors originate from the structured dataset described in Table 1, which provides the foundation for both traditional and generative model comparisons.

The LLM processes the serialized input string S_i and outputs logits for the next token in the sequence. We focus on the logits corresponding to the tokens "yes" and "no," which indicate severe or nonsevere symptoms, respectively. The probabilities for these tokens are obtained by applying the softmax function to the logits:

The probability indicates the likelihood of severe symptoms based on the input data S_i. This probability is directly used as the severity risk score for evaluation purposes.

To determine the binary predicted label from this probability:

The probability score , reflecting the severity risk, is used to compute the AUC for evaluation (Figure 2).

Evaluation Setting

Zero-Shot Setting

In the zero-shot setting, our approach leverages the intrinsic capabilities of LLMs. These models, unlike traditional classifiers such as logistic regression and XGBoost, have been extensively pretrained on diverse datasets. This extensive pretraining enables them to apply their accumulated world knowledge directly to specific classification tasks without additional training, demonstrating exceptional generalizability.

We assess the zero-shot prediction effectiveness of these LLMs by presenting them with tasks aligned with our study's objectives that they have not been specifically trained on. The models interpret and classify new, unseen data solely based on their pretrained knowledge. This approach not only highlights the potential of LLMs in real-world applications but also evaluates their ability to generalize from their training to novel scenarios in healthcare.

This zero-shot methodology allows us to evaluate how well these LLMs can recognize and classify complex, previously unseen patterns in health care data, providing valuable insights into their practical applicability and limitations in clinical settings.

Few-Shot Fine-Tuning

In the few-shot setting, we use sample sizes of 2, 4, 8, 16, and 32 to fine-tune the LLMs, aiming to examine the effect of training sample size on model performance compared to traditional classifiers. To ensure fairness and reduce bias in the fine-tuning process, we maintain a balanced ratio of positive and negative samples, with an equal number of examples from each class in each sample size.

To enhance computational efficiency in adapting the LLMs to our specific tasks, we employ a parameter-efficient fine-tuning approach using LoRA [27]. Instead of adjusting all parameters within the model, LoRA involves training a small proportion of parameters by integrating trainable low-rank matrices into each layer of the pretrained model. This method allows the model to quickly adapt to new tasks by optimizing only a subset of parameters, thereby preserving the general capabilities of the LLM while enhancing its performance on task-specific features.

Feature Importance Analysis

In disease risk assessment, interpretability is as critical as accuracy, particularly when both are provided to the user in real time. Here, we introduce a novel approach for analyzing feature importance by leveraging the attention mechanisms inherent in the output layers of generative LLMs. This method provides additional insights into the risk assessment process of the model, which is valuable for both clinicians and patients in understanding the factors contributing to the model's output.

XSL•FO
RenderX

Our approach involves extracting attention scores from the model's output layer, where the attention assigned to each input token is interpreted as an indicator of feature importance. We compute the attention for each feature-value pair and associate the average attention score with the corresponding feature. This provides a holistic view of which features, along with their associated values, influence the model's output.

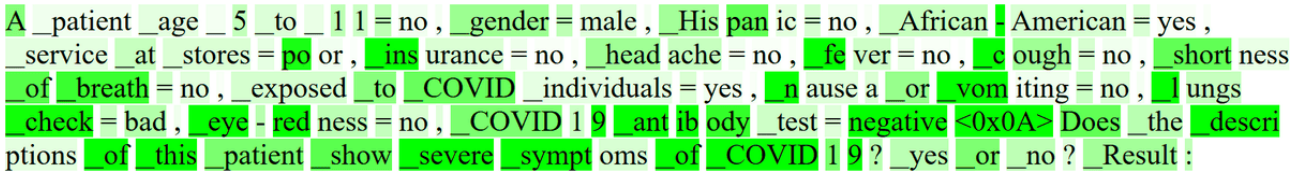
In Figure 4, the attention map illustrates the attention scores for a predicted positive case by the LLM, where darker shades represent higher attention scores assigned to specific feature-value pairs.

For an input sequence such as:

A patient

> *Do the descriptions of this patient show severe symptoms of COVID-19? Yes or no? Result:*

We calculate attention scores for each feature-value pair in the original sequence. The average attention score for each feature-value pair is then computed, and the score is associated with the feature itself, offering a representation of feature importance in the context of disease severity risk. As shown in Figure 4, any missing data in both the training and inference stages could be handled by having the value as "none" and having the model make the prediction; this will impact the prediction depending on the feature missing, but the free-text input of the LLMs still allows for a prediction to happen.



This normalized attention score serves as a proxy for feature importance, offering clinicians and patients a clearer understanding of which features (eg, age, preexisting conditions, vital signs, etc) are most influential in the model's assessment of COVID-19 severity risk. As illustrated in Multimedia Appendix 1, the plot shows the normalized attention scores from the LLaMA2-7b model in the 32-shot setting for two test cases: one positive (yes) and one negative (no).

For the positive case, the top five features with the highest attention scores, as shown in this figure, are:

1. f15: COVID-19 antibody test
2. f13: Lungs check
3. f12: Nausea or vomiting
4. f9: Cough
5. f14: Eye redness

By integrating this analysis into our mobile app, we enhance the interpretability of LLM-based risk assessments, empowering users with deeper insights into the model's reasoning process.

Figure 4. The attention map for a predicted positive case where the darker color represents larger attention weights for each token. The prompts are tokenized to mimic the actual inputs to the large language models (LLMs).

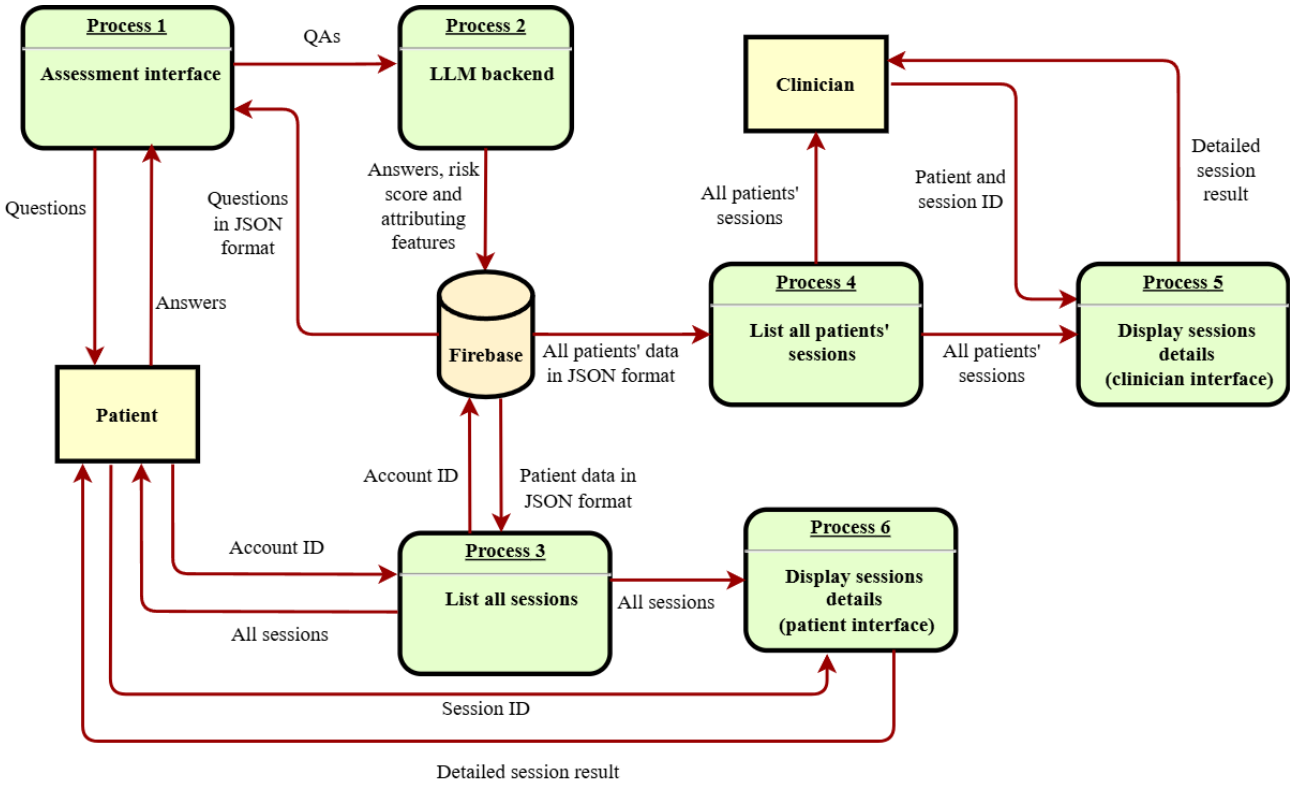
Mobile App

To provide users with code-free disease severity risk assessment and enhance user experience, we developed a mobile chatbot powered by the aforementioned generative LLMs. This app is designed to facilitate the assessment and management of COVID-19 in children, with potential applicability to other diseases and conditions. It offers two versions: one for patients to donate their health information via answering the questions and receiving real-time severity risk assessments, and another for clinicians to manage, review, and interpret the sessions donated by patients. The primary goals are to enhance early detection of severe outcomes, improve patient-clinician communication, and streamline the overall risk assessment process.

The app targets patients, clinicians, and other health care providers involved in managing preclinical cases. It leverages the capabilities of generative LLMs to analyze patient responses and provide immediate feedback on the risk of severe symptoms. Developed using React Native and JavaScript for the front end, Firebase for database management, and various frontend technologies, the app provides a user-friendly, efficient, and effective solution for managing disease risks. It aims to improve patient outcomes by facilitating timely and informed decision-making.

Database Structure

Our mobile app uses Firebase for database management, structured into three primary collections: Users, Questions, and Answers.



The data flow between the patient, LLM backend, Firebase, and interfaces for both patients and clinicians is illustrated in Figure 5. This figure highlights the interactions among processes, including the assessment submission, session management, and result retrieval.

- Users: This collection includes essential user information such as ID, Email, and isAdmin. The ID uniquely identifies each user, the Email serves as contact information, and the isAdmin field (Boolean) indicates whether the user has administrative privileges (clinicians) or not (patients).
- Questions: Each document in this collection has a unique ID and a Description field. The ID is used to reference questions in the Answers collection, and the Description contains the text of the question posed to the user, ensuring clarity and specificity in data mapping.
- Answers: This collection records user responses during their sessions. Each document includes a session ID and an array of answers where each entry links to the relevant Question ID from the Questions collection. In addition, it contains a Text field for the user's detailed response; an Answer field for the LLM-generated response (eg, yes or

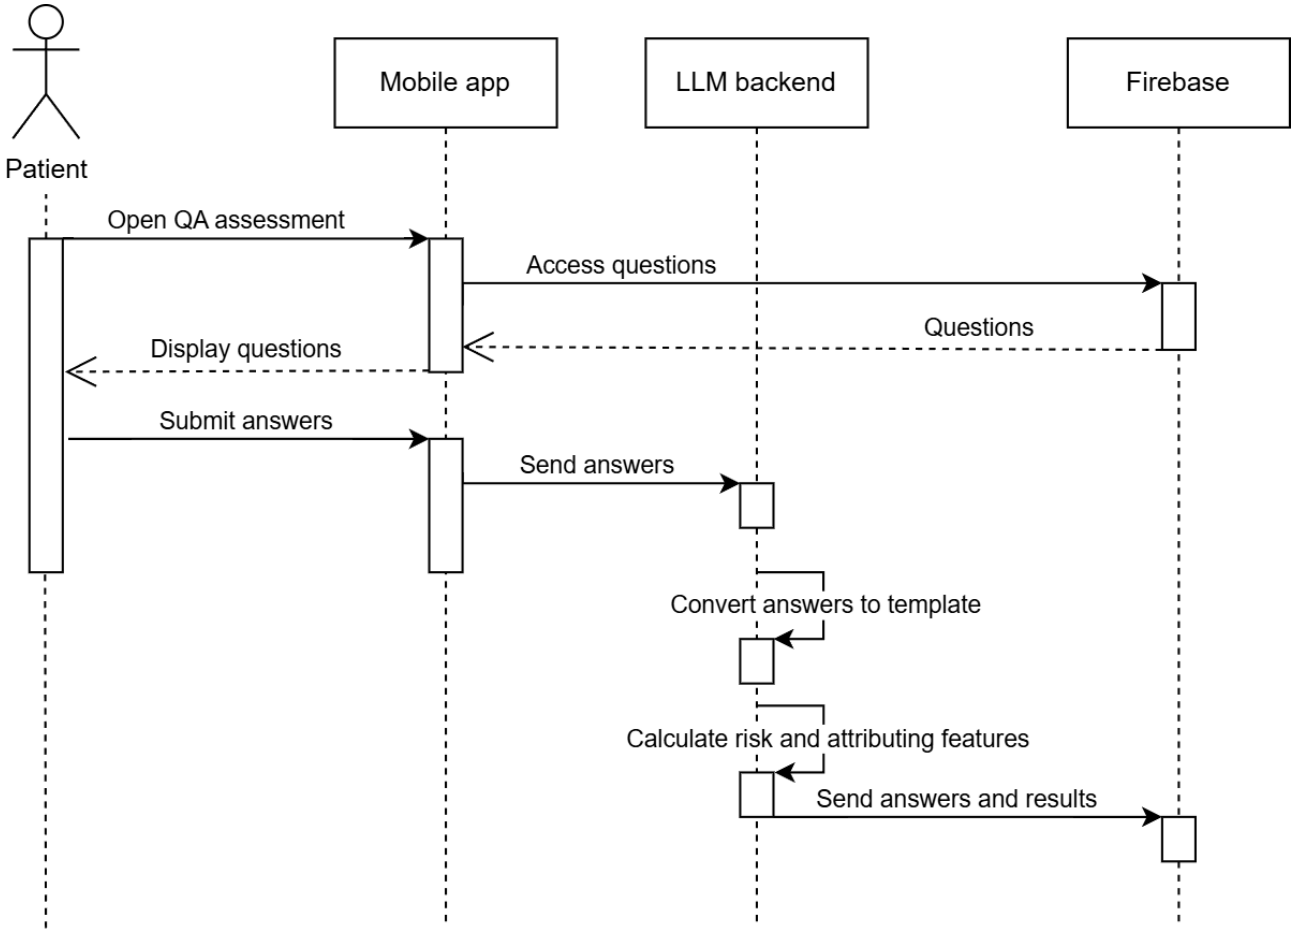
XSL•FO
RenderX

no); a Date field marking the session's completion time; a Risk Score field, which is derived from the user's responses and utilized for subsequent risk prediction by the LLM; and an Important Features field, which stores the key features identified by the LLM's attention scores that contributed to the risk assessment.

Figure 5. Data flow diagram where we map out the flow of information between different processes of large language model (LLM) backend, Firebase, and mobile app interfaces for both patient and clinician.

User Interface: Assessment

The step-by-step workflow for conducting an assessment and storing results in Firebase is detailed in Figure 6. This sequence diagram outlines the interaction between the patient, mobile app, LLM backend, and database.



As shown in Figure 3, on the Assessment page, we leverage the power of LLMs to engage in a conversation with the patient. This interaction allows us to ask questions and gather contextual information for each response. By doing so, we retrieve a binary answer (yes or no) using the LLM, which is then provided to the primary care physician along with the patient's context to aid in decision-making.

After the user responds to each question, we use our LLM to generate a binary answer. This involves providing the LLM with instructions that include the question and the user's response and asking the LLM to interpret the response into a binary answer (yes or no). This sequential process is performed for all questions. Currently, the input for the final LLM-based risk assessment, which predicts the COVID-19 severity risk, is based solely on the set of binary answers generated by the LLM. Future enhancements could incorporate the original user responses to improve context understanding.

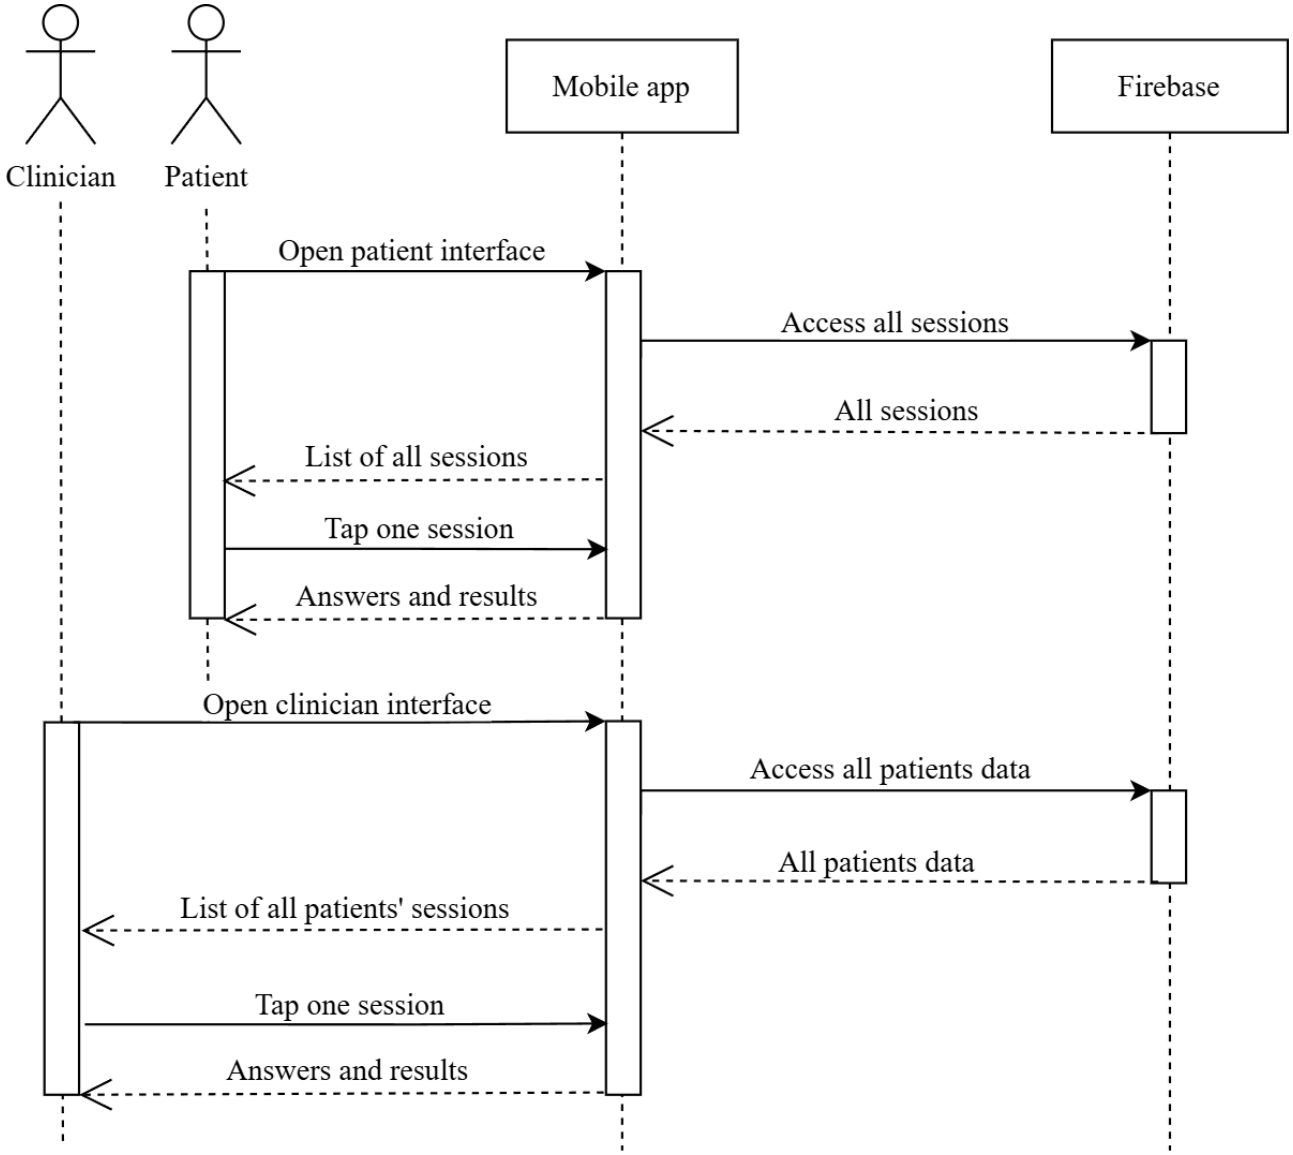
We currently use the Llama2-7b application programming interface (API) for answer retrieval. Our long-term goal is to integrate a fine-tuned LLM hosted on our servers to ensure better optimization and accuracy specific to our dataset, as evidenced by the improved performance results discussed in this paper.

XSL•FO
RenderX

Figure 6. Sequence diagram for the Assessment page, where the patient takes the risk assessment and the large language model (LLM) backend calculates the results, which will be saved to the Firebase. QA: question-and-answer.

User Interface: Patient and Clinician Results

Figure 7 illustrates the interaction flows for both patients and clinicians as they access session details and results. This sequence diagram shows how patient data and assessments are retrieved and displayed in real time.



Patients can submit a session at any time, receiving an immediate risk assessment in the Patient Interface section (Figure 3). This section displays all sessions submitted by the current user, along with their respective risk assessments.

In the Clinician Interface section, clinicians can access all sessions from their patients, organized by patient ID, for efficient review. Each session includes a comprehensive report featuring the predicted risk score, ensuring transparency and aiding in clinical decision-making.

Upon submission, a patient's session is instantly available in both the patient's and clinician's panels. While patients can only view their own sessions, clinicians can review all sessions from their assigned patients. This setup supports real-time updates through Firebase, facilitating seamless communication and follow-up between patients and their health care providers. Furthermore, the app provides personalized feature importance analysis based on the LLM's attention layers, giving both patients and clinicians additional insights into the most critical factors influencing the risk assessment.

Figure 7. Sequence diagram for displaying patients' session results. As shown, each patient has access to all their own sessions while the clinician can access all patients' sessions.

Ethical Considerations

The data collected and used for this study were approved by the University of Pittsburgh Institutional Review Board (MOD21010046-003; approval date: February 25, 2021). Informed consent was obtained from all legal caregivers, and when age appropriate, an informed assent was also obtained from the participants. Before the use of this study, the data were subject to a multistep anonymization procedure with personally identifying information marked and deleted.

Results

Training and Fine-Tuning Settings

In our experiments, we used a rigorous hyperparameter tuning strategy to optimize model performance, supported by a robust setup to ensure diverse dataset initialization and minimize potential biases. For both traditional machine learning methods and LLMs, we used 5 specific random seeds—0, 1, 32, 42, and 1024—to create diverse dataset splits. The dataset of 393 samples was divided into 256 training, 59 validation, and 78 testing segments, preserving a consistent positive-to-negative ratio of approximately 0.38.

For both traditional methods and LLMs, training was conducted using up to 32 shots to evaluate performance in the few-shot regime. For few-shot settings ranging from 2 to 32 shots, we ensured a balanced sampling of positive and negative examples in the training set, maintaining an equal number of instances from each class to avoid biases during training. Key hyperparameters, such as the learning rate, were optimized using grid search, with the learning rate set to 3×10^{-4}. The batch size matched the number of shots, and training consistently ran for 128 epochs to ensure convergence. During fine-tuning with LoRA, validation loss was monitored to select the best model checkpoint, minimizing overfitting and enhancing generalization to the test set. The optimization used cross-entropy loss, aligning with the binary classification task of predicting COVID-19 severity. This comprehensive setup ensured robust and interpretable model performance, particularly in low-data settings.

Effects of Serialization

Overview

Table 2 shows the performance of different serialization methods for the LLMs across various few-shot settings. We evaluated 2 primary serialization methods: list template and text template, across models tested with 0, 2, 4, 8, 16, and 32 training shots to observe performance variations with the number of training examples.

The list template often exhibited better performance at lower shot counts, while the text template typically outperformed the list template as the number of training examples increased. The following summarizes the performance trends for each model.

Table 2. Performance of models across different shot settings. All values represent the average area under the curve (AUC) across 5 random seeds rounded to 2 decimal places. In addition, SDs given across the 5 random seeds are shown. The suffixes "-L" and "-T" represent list serialization and text serialization, respectively.

Model	Number of shots					
	0, AUC[a] (SD)	2, AUC (SD)	4, AUC (SD)	8, AUC (SD)	16, AUC (SD)	32, AUC (SD)
Llama2-7b-L	0.54 (.05)	0.69 (.07)	0.69 (.06)	0.68 (.04)	0.63 (.04)	0.66 (.07)
Flan-t5-xl-L	0.62 (.03)	0.64 (.02)	0.63 (.02)	0.68 (.06)	0.66 (.05)	0.69 (.06)
Flan-t5-xxl-L	0.60 (.03)	0.61 (.03)	0.61 (.05)	0.62 (.06)	0.59 (.10)	0.65 (.11)
T0pp(8bit)-L	0.69 (.04)	0.70 (.07)	0.70 (.05)	0.70 (.05)	0.68 (.06)	0.70 (.10)
T0-3b-L	0.68 (.04)	0.67 (.04)	0.68 (.05)	0.70 (.04)	0.67 (.04)	0.67 (.07)
Llama2-7b-T	0.59 (.05)	0.69 (.03)	0.69 (.01)	0.64 (.07)	0.63 (.05)	0.67 (.06)
Flan-t5-xl-T	0.69 (.03)	0.69 (.02)	0.69 (.03)	0.71 (.05)	0.69 (.04)	0.70 (.05)
Flan-t5-xxl-T	0.61 (.04)	0.58 (.03)	0.63 (.08)	0.59 (.10)	0.62 (.09)	0.63 (.10)
T0pp(8bit)-T	0.67 (.02)	0.65 (.05)	0.66 (.05)	0.68 (.04)	0.65 (.08)	0.67 (.08)
T0-3b-T	0.75 (.04)	0.65 (.06)	0.65 (.05)	0.68 (.03)	0.67 (.04)	0.65 (.08)
Logistic regression	—[b]	0.57 (.07)	0.55 (.10)	0.64 (.06)	0.61 (.11)	0.69 (.08)
Random forest	—	0.57 (.07)	0.57 (.06)	0.62 (.08)	0.66 (.07)	0.68 (.07)
XGBoost[c]	—	0.50 (.00)	0.50 (.00)	0.50 (.00)	0.54 (.06)	0.65 (.03)

[a]Average area under the curve.

[b]Not applicable.

[c]XGBoost: extreme gradient boosting.

Llama2-7b

In the zero-shot setting, the text template achieved an AUC of 0.59 compared to 0.54 for the list template. At 2 training shots, both templates achieved an AUC of 0.69, but the text template began to outperform, reaching an AUC of 0.67 at 32 training shots compared with 0.66 for the list template.

Flan-t5-xl

The text template consistently outperformed the list template across most shot settings. At 2 training shots, the text template achieved an AUC of 0.69 compared to 0.64 for the list template, and this lead continued up to 32 shots, where the text template achieved an AUC of 0.70 compared to 0.69 for the list template.

Flan-t5-xxl

Both templates showed similar performance in the early few-shot settings. At 2 training shots, the list template achieved an AUC of 0.61, slightly outperforming the text template, which achieved an AUC of 0.58. By 32 training shots, the list template achieved an AUC of 0.65, slightly outperforming the text template, which achieved an AUC of 0.63.

T0pp (8bit)

In the zero-shot setting, the list template led with an AUC of 0.69 compared to 0.67 for the text template. This lead was maintained through most shot settings, with both templates achieving around 0.70 AUC by 32 shots.

T0-3b

The text template outperformed the list template in the zero-shot setting, achieving an AUC of 0.75 compared to 0.68 for the list template. In the 2-shot setting, the list template performed slightly better, with an AUC of 0.67 compared to 0.65 for the text template. At 32 shots, the text template closed the gap with an AUC of 0.65 compared with 0.67 for the list template.

In Table 3, we can also compare the best-performing models across different shots, constraining the recall to be higher than 0.8. This gives us better insights into their performance in population screening for early health risks, where recall is considered more important than precision.

Overall, while the list template often provides an initial advantage in early few-shot settings, the text template shows competitive performance as the number of training examples increases. This suggests that serialization choice can be

XSL•FO
RenderX

important in low-data regimes. The text template's strong performance in the zero-shot setting, particularly for the T0-3b model, highlights its potential when no training data is available.

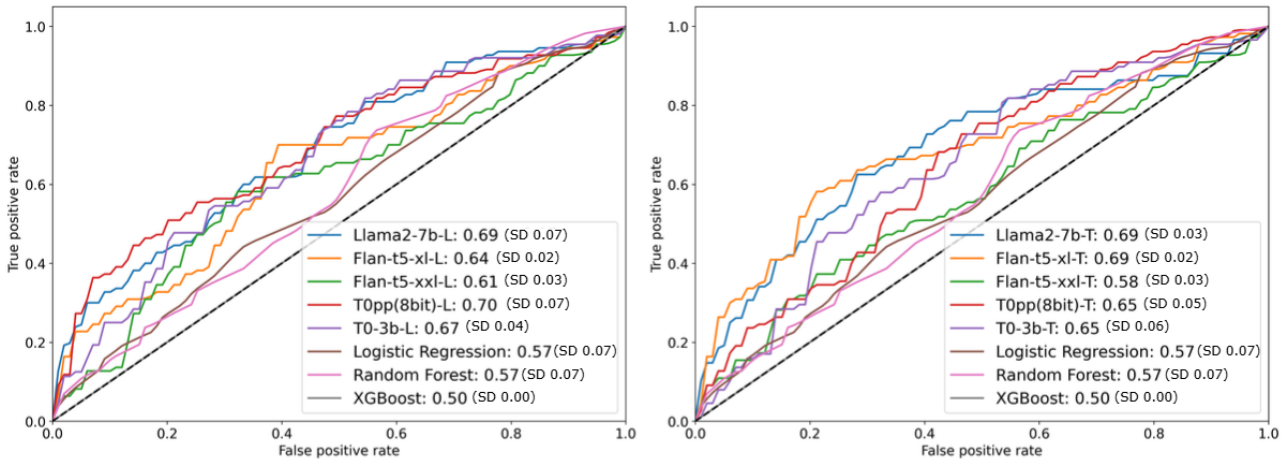
Table 3. Precision, recall, and F1-score of the best performing models across different shots averaged over 5 random seeds.

Shot	Best model	Threshold	Precision	Recall	F_1-score
0	T0-3b	0.04	0.37	0.85	0.52
2	T0pp	0.12	0.34	0.81	0.46
4	T0pp	0.24	0.35	0.83	0.49
8	flan-t5-xl	0.17	0.38	0.80	0.50
16	flan-t5-xl	0.15	0.34	0.85	0.48
32	flan-t5-xl	0.16	0.36	0.81	0.49

LLMs Versus Traditional Machine Learning Methods

Our study highlights the versatility of LLMs for various health care apps, particularly in scenarios with limited data. To benchmark their performance against traditional machine learning methods, we compared LLMs with logistic regression, random forest, and XGBoost.

LLMs benefit from extensive pretraining, allowing them to generalize well to "unseen" data, unlike traditional methods that require substantial amounts of training data. As shown in Table 2, LLMs like T0-3b-T achieved an AUC of 0.75 in the zero-shot setting, demonstrating a good performance even without task-specific fine-tuning. This demonstrates the effectiveness of LLM-powered risk assessment without the need for additional labeled data.



In the 2-shot setting, LLMs continue to show strong performance relative to traditional methods. For instance, Figure 8 compares the average AUC across 5 different seeds in this scenario. The left panel shows results using the list serialization (-L) approach, while the right panel shows results using the text serialization (-T) approach. In this 2-shot scenario, LLMs such as T0pp(8bit)-L and Flan-t5-xl-T achieve AUCs of 0.70 and 0.69, respectively, clearly outperforming traditional methods, including logistic regression, random forest, and XGBoost, which achieved AUCs of 0.57, 0.57, and 0.50, respectively.

LLMs' ability to perform well with minimal data highlights their advantage in low-data regimes. This makes them particularly suitable for real-time, no-code health care apps where rapid decision-making is required, even in scenarios where labeled data is scarce.

Furthermore, LLMs' capacity to handle streaming data formats, such as multihop QA pairs, enhances their integration into conversational interfaces, supporting real-time patient-clinician interactions. This flexibility offers significant usability in clinical settings where personalized and immediate risk assessments are needed (Figure 1).

Overall, while traditional methods may improve with larger datasets, LLMs demonstrate a clear advantage in dynamic, low-data health care environments. Their ability to handle incomplete data and streaming input formats makes them robust for real-world applications requiring adaptability and speed.

Figure 8. Average area under the curve (AUC) in a 2-shot setting over 5 different seeds. The left panel shows results using the list serialization (-L) approach, while the right panel shows results using the text serialization (-T) approach. XGBoost: extreme gradient boosting.

Discussion

Principal Findings

Our research demonstrates that generative LLMs provide a robust and no-code approach for predicting COVID-19 severity, which is particularly effective in low-data regimes. These models excel in zero-shot and few-shot settings, showcasing their ability to perform well without extensive domain-specific training. This is crucial for real-time applications requiring immediate and reliable predictions, highlighting their

XSL•FO
RenderX

exceptional generalizability compared with traditional classifiers like logistic regression, random forest, and XGBoost, which typically require more labeled data to achieve comparable performance.

Generative LLMs effectively handle diverse input formats, integrating both structured clinical data and unstructured natural language inputs from patient interactions. This flexibility enables them to synthesize information from various sources, such as patient medical histories and symptom descriptions, enhancing their usability in dynamic health care settings. In our study, we incorporated these models into a conversational interface, which facilitates real-time patient-clinician interactions and immediate risk assessments. This setup supports continuous data collection and leverages the conversational capabilities of LLMs to optimize clinical decision-making and resource allocation.

Future Directions and Limitations

Future work should focus on integrating continuous clinician-patient conversational data for fine-tuning or in-context learning, extending the application of LLMs beyond static disease prediction models. Techniques like chain of thought and chain of interaction, which align with the interactive nature of medical consultations, show promise for enhancing model performance in interpreting and responding to patient data in real-time settings. While our study used models like T0pp with parameter-efficient fine-tuning using LoRA, future research could explore newer and more advanced small language models such as LLaMA3-8b and Mistral-7b-Instruct, which have demonstrated exceptional performance in low-data regimes. These models could offer greater efficiency and accuracy as computational resources and methodologies advance, supporting more sophisticated and scalable applications in health care [34,35].

However, limitations remain that warrant further exploration. This study does not address the critical issue of handling sensitive data, such as personally identifiable information (PII), within health care datasets. Incorporating a dual dataset that includes both PII and non-PII data could facilitate machine unlearning research, allowing models to selectively forget sensitive information while retaining predictive capabilities from nonsensitive data. This would ensure compliance with privacy regulations and enhance the ethical deployment of LLMs in health care. Advancing privacy-preserving techniques, such as selective forgetting mechanisms, would not only safeguard sensitive data but also support broader trust in the use of LLMs in clinical settings.

As these models evolve, vulnerabilities such as adversarial attacks during in-context learning pose significant risks. Studies have shown that manipulated inputs can lead to inaccurate or harmful predictions, particularly in high-stakes tasks like health care risk assessment [36]. Addressing these risks is crucial to ensure that LLMs remain reliable and safe for broader adoption in health care applications. Enhanced resilience to adversarial techniques, combined with privacy-preserving methods, will be key to building robust and trustworthy systems. By addressing these challenges, future research can ensure that LLMs not only deliver accurate predictions but also adhere to ethical and privacy standards in real-world settings.

Conclusions

In conclusion, generative LLMs offer a valuable tool for no-code risk assessment in low-data regimes. Their ability to perform zero-shot or few-shot transferability to new diseases or conditions and handle complex, varied inputs positions them as key assets for enhancing health care interventions and resource management. Furthermore, the incorporation of feature importance analysis derived from the LLM's attention layers provides an additional layer of interpretability, offering personalized insights into the decision-making process for both patients and clinicians.

Abstract

Background: Most online and social media discussions about birth control methods for women center on side effects, highlighting a demand for shared experiences with these products. Online user reviews and ratings of birth control products offer a largely untapped supplementary resource that could assist women and their partners in making informed contraception choices.

Objective: This study sought to analyze women's online ratings and reviews of various birth control methods, focusing on side effects linked to low product ratings.

Methods: Using natural language processing (NLP) for topic modeling and descriptive statistics, this study analyzes 19,506 unique reviews of female contraceptive products posted on the website Drugs.com.

Results: Ratings vary widely across contraception types. Hormonal contraceptives with high systemic absorption, such as progestin-only pills and extended-cycle pills, received more unfavorable reviews than other methods and women frequently described menstrual irregularities, continuous bleeding, and weight gain associated with their administration. Intrauterine devices were generally rated more positively, although about 1 in 10 users reported severe cramps and pain, which were linked to very poor ratings.

Conclusions: While exploratory, this study highlights the potential of NLP in analyzing extensive online reviews to reveal insights into women's experiences with contraceptives and the impact of side effects on their overall well-being. In addition to results from clinical studies, NLP-derived insights from online reviews can provide complementary information for women and health care providers, despite possible biases in online reviews. The findings suggest a need for further research to validate links between specific side effects, contraceptive methods, and women's overall well-being.

contraception; side effects; natural language processing; NLP; informed choices; online reviews; women; well-being

Introduction

Background

According to the United Nations, contraception is a critical issue impacting 1.9 billion women of reproductive age. Worldwide, approximately 922 million women or their partners use contraception. More than half of all contracepting women rely on modern contraceptive products designed to be used by women. These female products comprise long-acting reversible contraceptives (LARCs), such as intrauterine devices (IUDs) and hormonal implants as well as short-acting methods, such as oral contraceptives, known as "the pill," hormonal patches, vaginal rings, and contraceptive injections. Traditional methods such as withdrawal and calendar rhythm are relied upon by 7% of women, and the single most common contraceptive method

XSL•FO
RenderX

worldwide is female sterilization (24%), an irreversible method [1,2].

According to data from the latest National Survey of Family Growth (2017 to 2019), approximately 27.5% of women of reproductive age in the United States use female contraceptive products, comprising oral contraceptive pills (OCPs, 14%), LARCs (10.4%) and other short-acting methods, such as contraceptive injections (2%), vaginal rings (0.8%), and patches (0.3%) [2]. With increasing levels of formal education, the prevalence of LARC and short-acting methods increases while the prevalence of female sterilization decreases [3].

While female contraceptive products are reversible and generally more efficacious than traditional methods, thus offering advantages to women with regards to their family planning and thus self-determination [1,4], they can be associated with unpleasant experiences [5,6], ranging from abdominal pain to mood swings or changes in libido [7,8]. The experience of such unpleasant side effects has a negative impact on a woman's health, which the World Health Organization defines as "state of complete physical, mental, and social well-being," and thus on the quality of life [9,10]. Furthermore, negative side effects are a major cause for poor adherence or even discontinuing contraception which may result in unintended pregnancies [11,12].

Access to Data to Inform Contraceptive Choices

For women to find the contraceptive method that is most suitable for them and thus make informed contraception choices, it is important to have access to relevant information regarding different available contraception options. The type of information that women require can be assigned to 2 broad categories.

First, information relating to the efficacy of contraceptive methods regarding preventing unintended pregnancies and protection from sexually transmittable diseases is crucial [13]. There is comprehensive clinical as well as real-world data on efficacy and safety of different contraceptive methods [14,15]. These data are generally accessible to women through health care providers (HCPs) or nongovernmental organizations, although there are geographical differences on a global level [16].

Second, women seek information relating to potential unpleasant experiences related to contraceptive methods as these can have a substantial negative impact on women's well-being, not only impacting women themselves, but also their families [13,17,18]. However, there are 2 major challenges women face when seeking information about potential negative experiences related to contraceptive methods, namely, the availability of data and the accessibility of reliable data [17].

Data on the frequency of negative side effects are generally available, as they are collected in clinical trials and stated on drug labels [19,20]. However, the construct of well-being is more nuanced, comprising a "state of positive feelings and meeting full potential in the world" [21]. Consequently, data on the mere occurrence and frequency of certain side effects provide insufficient information on how certain side effects typically impact well-being. For example, abdominal pain related to a contraceptive product might constitute a neglectable nuisance or a major suffering limiting women's participation in daily life. Despite the subjective nature of side effect severity [22], for women facing contraception choices, knowing that a certain side effect can be a significant issue for some women constitutes relevant information [17]. However, there is a lack of comprehensive data on women's subjective and collective unpleasant experiences with different contraceptive methods [23]. Studies have also shown that while women tend to turn to HCPs for contraceptive counseling, HCPs often lack relevant knowledge and provide insufficient information on potential side effects [24,25]. To learn about experiences with different contraceptive methods, women also tend to speak to relatives and friends, but these experiences are subjective and constitute a small sample size.

Role of Social Media to Inform Contraception Choices

From this background, social media has started to play an important role as a source of information. Experimental research indicates that social media content may influence women's intentions to use certain contraceptive products [26] even as social media conversations about contraception have become more polarized in the past 20 years [27].

Thus, there is a growing body of research to evaluate how women use social media to inform contraception choices [28]. To analyze information shared and consumed on social media, natural language processing (NLP) is used due to its capacity to analyze nonstructured, textual data.

For example, Pleasants et al [28] used NLP to study posts related to birth control on the US platform Reddit and found that "Side Effects!?" is the most common flair, a tag that users can attach to their post to categorize the content. Furthermore, "Experience" and "Side Effects?!" are the most common flairs among the most popular posts, based on the number of comments and "scores," that is, upvotes minus downvotes [28]. Analyzing contraceptive content shared on X (formerly Twitter) Huang et al [29] discovered that a fifth of all the tweets relate to side effects. Similarly, in a text mining analysis of messages sent on a free sexual and reproductive health information service in Kenya, Green et al [30] found that users wrote most often about family planning and side effects. Balakrishnan et al [31] conducted an NLP-based social listening analysis in a German internet community and observed that side effects are the most common problem associated with most contraceptives. They also found that while the pill is the most frequently mentioned contraceptive method, there appears to be migration from hormonal to nonhormonal methods. In line with this, Felice et al [32] analyzed user reviews of a digital contraceptive supporting women in fertility prediction through a mixed methods approach involving NLP and found that the hormone-free aspect of the contraception experience is highly salient for many users. A content analysis by Pfender and Devlin [33] of YouTube vlogs discussing birth control methods revealed that social media influencers primarily described their discontinuation of hormonal birth control due to experienced side effects. Their study also showed that vlogs may provide inaccurate sexual health information, hereby directly or indirectly discouraging the use of the contraceptive under

XSL•FO
RenderX

discussion. In a content analysis of the "sex secrets" Facebook page, Yeo and Chu [34] found that young people predominantly use this social media platform to request information, opinion, or advice, including the topic of birth control. Stoddard et al [35] found that more than half of the most popular contraception videos on TikTok revolved around patient experience. Although videos created by health care professionals received proportionately more views, over half of the total views were still of content generated by laypeople [35].

Overall, these NLP-based social media content studies show that social media is used to share information and consume information on contraception options. Furthermore, they reveal that user-generated content mostly revolves around side effects and that posts discussing women's experiences with regards to side effects receive the greatest interest. At the same time, the content that is available, especially when shared by influencers, is not always reliable and may misguide contraception choices. In fact, there is increasing concern among researchers and women's health practitioners that social media influencers spread misconceptions about contraceptive methods, particularly hormonal contraception, which negatively affect the acceptance of efficacious contraceptive methods and thus increase the risk of unintended pregnancies [36].

Furthermore, the previously mentioned studies highlight that unpleasant experiences are an issue that is currently not well-addressed in clinical contraceptive counseling. This further substantiates the observation that users appear to have an unmet need for reliable, trustworthy information. However, existing NLP-based studies do not provide a systematic picture of the association of different side effects with different available contraceptive methods and how severely women experience these side effects.

To fill this gap, the NLP method of sentiment analysis can identify, extract, and quantify the subjective emotions within a text, assigning a continuous sentiment score usually between −1 for highly negative and 1 for highly positive posts [37,38]. Studies using sentiment analysis may thus provide first hints as to how severely women experience certain side effects. Merz et al [27] studied population attitudes toward contraceptive methods over time by performing sentiment analysis on tweets on X regarding contraceptive methods and find that most tweets are negative. In their sample long-acting methods are mentioned more often than short-acting ones and related sentiments are twice as likely to be positive [27]. In contrast, in a study with Indonesian users of X, Sari et al [39] found that users predominantly express negative attitudes toward long-acting contraceptive methods.

However, a major limitation of sentiment analysis is that it can be inaccurate if the model has been trained on biased, limited, or unrepresentative datasets as it may fail to generalize well to diverse and nuanced language usage, such as sarcasm, slang, or cultural context variations present in social media posts. Although the modern state-of-the art approach in sentiment analysis involves using pretrained language models such as Bidirectional Encoder Representations from Transformers or GPT, there is an inherent risk of bias in general and gender bias in particular [40,41], limiting performance in sentiment analysis tasks.

In this context, the information on online drug review forums constitute a great, widely untapped, resource to inform contraception choices. Many online drug review forums contain 2 distinct pieces of information related to a product: a standardized numeric rating score indicating overall product satisfaction and a comment in free text form. A powerful advantage of online product reviews is that the integration of qualitative (text comments) and quantitative (ratings) data facilitates insights into the relationship between issues mentioned in comments and overall product satisfaction, which is presumably closely linked to the impact of the respective product on the well-being of the user.

Evaluating data from online review forums to inform decisions is hampered by several limitations, such as potential biases, unrepresentative sample issues, and the potential presence of inauthentic reviews. Nevertheless, consumer behavior in many industries, including health care and retail, indicates that other people's reviews, particularly when available in large numbers, are important in driving purchase decisions and are thus considered a valuable source of information [42]. Thus, in the context of contraception, reviews data complement information on contraceptive options that women and their partners may receive from other sources, such as HCPs, community workers, scientific studies, or other social media sources.

Purpose of the Study

This research aimed to produce insightful information from a large drug review dataset with regard to which experiences with contraceptive products women described on the web, both qualitatively and quantitatively. The focus is on unfavorable experiences, as previous research has shown that side effects are the topic of greatest interest for women using forums and social media to seek information on contraception.

From this background, in this paper, we investigated the following research questions (RQs):

1. How do users rate different contraceptive methods available to women on a major drug review website?
2. Which issues (ie, topics) do users describe in unfavorable online reviews of contraceptive products available to women?
3. How frequently are these issues described for different contraceptive methods?
4. Can we observe an association between the main topic discussed and the average rating submitted in unfavorable birth control reviews?

Methods

Dataset

Our study was performed on a dataset of 19,506 unique online reviews of birth control products in the United States posted on the website Drugs.com [43], a United States–based pharmaceutical information website, between April 2009 and September 2017. The reviews analyzed in this study were extracted from a comprehensive online drug review dataset

XSL•FO
RenderX

available for research purposes in the University of California, Irvine (UCI) Machine Learning Repository [44]. The original dataset had been collected via web scraping from the website Drugs.com [43] and comprised 215,063 reviews of drugs treating different conditions, such as high blood pressure, cough, and birth control [45]. While this dataset may be somewhat dated, these reviews are highly relevant for this study. First, the products evaluated have been on the market for many years and are widely used today. Second, analyzing older reviews might even offer the advantage of capturing women's experiences with contraceptive products in a more authentic, less skewed way. Research has shown that in recent years, social media influencers negatively frame hormonal contraceptives and encourage the uptake of nonhormonal options which may alter women's attitudes and expectations [26] and thus possibly their online reviews.

The online drug user reviews contained information on the related condition, the name of the drug, a 10-star user rating on overall satisfaction, how many users considered this review helpful, and the date the review was posted. The name of the drug was captured in a structured format as it stemmed from a drop-down menu from which the website users needed to select a drug name when leaving a comment.

Ethical Considerations

The study used publicly available data from the UCI Machine Learning repository. The UCI Machine Learning dataset did not contain any identifying information about the authors of the reviews, such as their username. Furthermore, when posting a review on the website Drugs.com [43], users were required to consent to the publication and use of their reviews. Finally, to the best of our knowledge, the reviews we selected to be in this manuscript do not risk reverse identification as the website Drugs.com [43] does not display full user names alongside the reviews. Therefore, in line with other studies evaluating social media posts on contraception, ethics approval for using these reviews as a basis for analysis was not deemed necessary.

Data Cleansing and Grouping

Within the drug review dataset offered by the UCI Machine Learning Directory, 38,436 product reviews were classified as relating to "birth control." Many reviews were captured twice, once under a product's brand name and a second time under the name of the respective active pharmaceutical ingredient, that is, the generic name. By removing duplicates, we obtained 19,524 unique birth control reviews. When cleansing the dataset, we retained drug brand names for their greater detail compared to generic names. This granularity is more suitable for analysis, as products with the same active ingredient can vary in dosage and administration schedules across brands. In total, <400 out of 19,524 unique reviews did not contain a brand name, but rather only the generic name. We kept most of those reviews in the dataset, only removing 13 unique reviews of drugs that could not be related to 1 specific contraceptive method, namely, levonorgestrel (10 reviews), which can be a hormonal IUD or emergency contraception commonly sold as Plan B; and Provera (3 reviews), which can either be a birth control shot under the name Depo-Provera or an oral progestin product that is not approved as a contraceptive. The clean birth control dataset contained unique reviews on 169 different products identified by brand name or active pharmaceutical ingredients.

For later analysis and comparison of drug reviews for different contraceptive methods, we categorized all products into 11 contraceptive methods. This categorization focused on the application mode of these products, which is in line with the classification of contraception options typically used for advising women [46]. The methods comprise: hormonal and nonhormonal (ie, copper) IUDs, implants, vaginal rings, birth control shots, hormonal patches, spermicides, and emergency contraception. For OCPs, we distinguished between combined contraceptive oral pills (COCPs), progestin-only pills (POPs), and OCPs that induce a 91-day cycle, as these are expected to have different side effect profiles, and patients are typically counseled differently. Given the small number of reviews on emergency contraception (n=3) and spermicides (n=2), we removed those reviews from the dataset, too, leaving 19,506 reviews on 167 different products across 9 different contraceptive methods.

To analyze which negative experiences or side effects related to birth control options women described, we created a new attribute marking all reviews with a rating of ≤5 (on a scale from 1 to 10) as unfavorable reviews. Rather than limiting our analysis to reviews associated with strictly negative ratings (usually defined as ≤3), we deliberately used a wider window to also include negative to neutral ratings (scores of 4 and 5) as these might also contain relevant descriptions of unpleasant experiences. Overall, 8330 reviews fell into our definition of unfavorable (ie, nonpositive with a rating of 5 and lower).

NLP Approach for Analyzing Unfavorable Birth Control Reviews

Overview

Within NLP, topic modeling refers to techniques for uncovering abstract themes in a large textual dataset, typically referred to as a corpus. It involves algorithmically analyzing documents to detect word and phrase patterns that indicate specific topics. Thus, topic modeling allows analyzing which topics women discuss in unfavorable reviews of different contraceptive products. For our study, we wrote an NLP program for topic analysis in Python (version 3.11.3; Python Software Foundation) using several NLP libraries, including Natural Language Toolkit (version 3.7) [47] and scikit-learn (version 1.2.2) [48]. For visualization, we used Matplotlib (version 3.7.1) [49] and Seaborn (version 0.12.2) [50].

Text Preparation

Our text preprocessing procedure included multiple steps. Text cleaning was performed as the raw birth control reviews in the UCI repository contained several issues with punctuation and how certain characters were captured. Furthermore, we implemented a custom-developed catalog of more than 110 abbreviations and short forms to replace them with the long form. Examples include "can't" being replaced with "cannot," "PMS" with "premenstrual syndrome," "yr" with "year" or "ain't" with "am not." If an abbreviation had 2 meanings, such as "he's," we replaced it with the most common form. This step ensured uniformity in word representation so that the frequency of a word could be captured adequately. In addition, we removed

XSL•FO
RenderX

any nontext characters, created word tokens and reduced words to their base root via lemmatization. To further reduce the dimensionality of the textual data and focus on the most meaningful words, we excluded common words typically not carrying meaning, so-called "stop words" as predefined in NLTK, except for the stop word "not" which adds to the meaning of a review describing potential complaints or side effects. We also removed all product names and contraceptive methods, such as "iud," "implant" or "pill," from the reviews to allow our topic modeling algorithm to reveal topics that are contraceptive product and method agnostic.

As Table 1 shows, after the removal of stop words, there were highly frequent words in the reviews that did not relate to specific birth control side effects or complaints. To reduce noise and dimensionality, we removed the words "month," "day," "year," "week" "birth," and "control" from the reviews.

Table 1. Most common words in the birth control product reviews (excluding noninformative words).

Word	Occurrences (n=889,864), n (%)
not	30,973 (3.48)
period	19,145 (2.15)

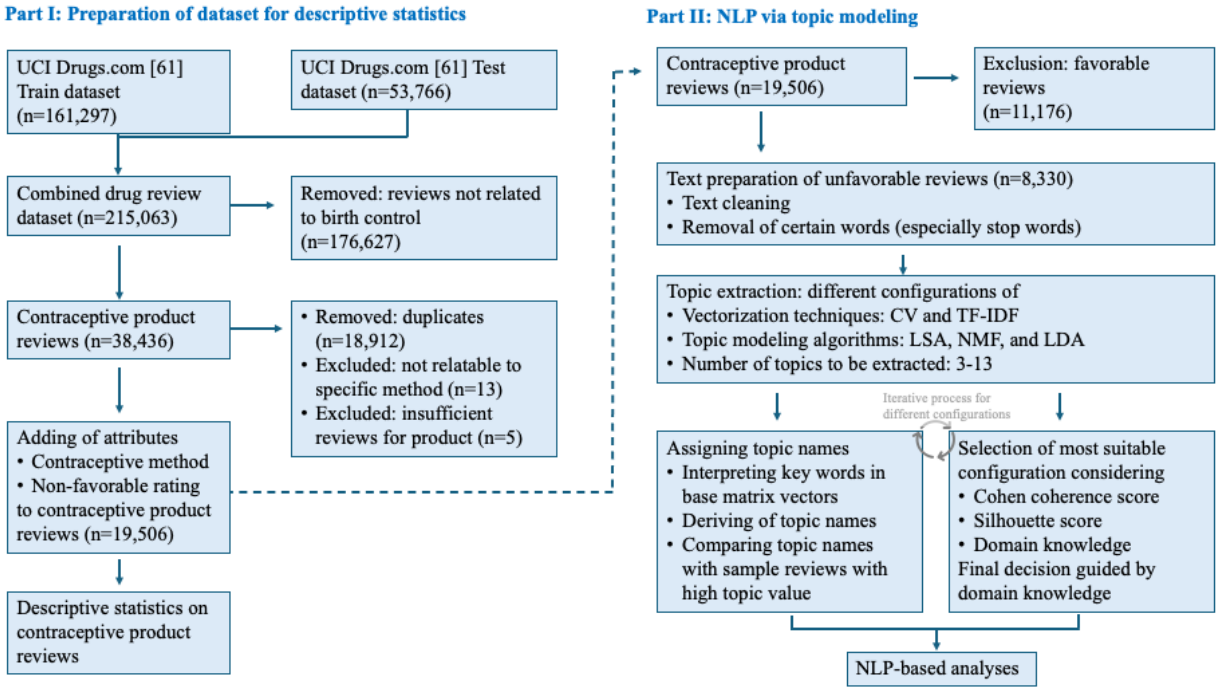
Topic Extraction Approach

In topic modeling, selecting the optimal vectorization techniques, topic modeling algorithms, and the number of topics to extract is crucial. This process aimed to derive topics that align with domain-specific inquiries and RQs. While coherence and silhouette scores can support this selection, domain expertise and expert judgment are essential in evaluating the relevance and applicability of the themes extracted by an algorithm [51].

The topics described in the following sections result from an iterative strategy combining various vectorization techniques to construct a document-term matrix, including count vectorization and term-frequency–inverse document frequency (TF-IDF). We used topic modeling algorithms, such as latent semantic analysis, nonnegative matrix factorization (NMF), and latent Dirichlet allocation, extracting between 3 and 13 topics. The selection of techniques and the number of topics was based on expert judgment, Cohen coherence, and the silhouette score, with the final decision guided by domain knowledge to yield the most useful, interpretable, and distinct topics.

The final technical configuration of the topic modeling in this research is as follows:

- Vectorization—TF-IDF vectorization yielding a document-term matrix, where rows represented reviews,



XSL•FO
RenderX

columns represented words, and values indicated word importance. TF-IDF highlights terms frequent in a document (ie, a product review) but less common across the corpus (ie, across all reviews), reducing the weight of ubiquitous words.

- Topic modeling algorithm—NMF decomposing the nonnegative document-term matrix into 2 lower-dimensional matrices: the topic matrix (W) and the terms matrix (H). The topic matrix represented documents by underlying topics, while the terms matrix represented topics by original words or tokens.
- Number of topics—8 topics differentiating most effectively among various types of experiences and complaints.

The flowchart in Figure 1 illustrates the overall methodological approach.

Figure 1. A flow diagram of the methodological approach used in the study. Results

Descriptive and topic analysis of the website Drugs.com [43] drug reviews dataset allowed us to answer our RQs.

Online Ratings of Different Contraceptive Methods Available to Women (RQ 1)

Frequency of Ratings

Table 2 displays the distribution of ratings of birth control products in the drug review dataset from 1 to 10, with 1 being very bad and 10 being very good. The frequency diagram of the ratings is U-shaped, such that both very poor and very good ratings were common. The most common rating was 10 out of 10 (n=3905, 20.02% of the reviews), and the second most common rating was 1 out of 10 (n=2986, 15.31% of the reviews). The overall mean was 6.08, and the SD was 3.31. Thus, reviews were polarized, but on average gravitated toward positive ratings.

XSL•FO
RenderX

Table 2. Frequency of contraceptive product ratings on a scale from 1 to 10 (1: very bad and 10: very good) in the online drug review dataset (n=19,506).

Rating	Frequency, n (%)
1	2986 (15.31)
2	1409 (7.22)
3	1363 (6.99)
4	1083 (5.55)
5	1489 (7.63)
6	964 (4.94)
7	1253 (6.42)
8	2112 (10.83)
9	2942 (15.08)
10	3905 (20.02)

Ratings of Different Contraceptive Methods

Table 3 provides an overview of the number of available birth control product reviews in the dataset, grouped by the product categories. COCPs are the most reviewed birth control products, constituting 44.12% (8606/19,506) of all reviews. Hormonal implants and hormonal IUDs rank second and third, respectively.

Slightly more than half of birth control product reviews (n=11,176, 57.3%) are favorable according to our definition, whereas 42.7% (8330) of reviews are unfavorable. Overall, the share of unfavorable reviews varied substantially across categories. POPs had the highest share of unfavorable reviews (n=232, 53.1%), whereas nonhormonal IUDs had the lowest (n=234, 29.3%).

Figure 2, a scatter diagram with trimmed axes, reveals 2 clusters of different contraceptive methods based on mean ratings and SDs. The first cluster, located in the lower right, includes POPs, birth control shots, 91-day cycle OCPs, COCPs, and hormonal implants, with lower average ratings (5.32-5.82) and higher SDs (3.26-3.52). The second group, situated in the upper left, comprises hormonal and copper IUDs, hormonal patches, and vaginal rings, exhibiting higher average ratings (6.65-7.11) and generally lower SDs (2.99-3.13), except for copper IUDs, which had a SD of 3.28.

Table 3. Descriptive statistics of product ratings by contraceptive method.

Contraceptive method	Unique reviews (n=19,506), n (%)	Products (n=167), n (%)	Rating, mean (SD)	Number and share of unfavorable reviews (n=8330, 42.7%), n (%)
COCP[a]	8606 (44.12)	138 (82.6)	5.80 (3.32)	3968 (46.11)
Implant	4392 (22.52)	3 (1.8)	5.82 (3.32)	2064 (46.99)
Hormonal IUD[b]	2871 (14.72)	4 (2.4)	7.04 (3.05)	848 (29.54)
Vaginal ring	827 (4.24)	2 (1.2)	6.7 (3.0)	297 (35.91)
Copper IUD	800 (4.1)	2 (1.2)	7.11 (3.3)	234 (29.25)
Shot	653 (3.35)	2 (1.2)	5.5 (3.5)	327 (50.08)
Patch	508 (2.6)	3 (1.8)	6.8 (3.1)	157 (30.91)
POP[c]	437 (2.24)	11 (6.6)	5.3 (3.3)	232 (53.09)
OCP[d] with 91 d cycle	412 (2.11)	9 (5.4)	5.6 (3.3)	327 (49.27)

Issues Described by Users in Unfavorable Online Reviews of Contraceptive Products Available to Women (RQ 2)

Table 4 presents the 8 themes extracted from the 8330 unfavorable birth control product reviews in our dataset. Overall, each extracted theme corresponded to a description of side effects. There was no topic that explicitly alluded to nonhealth aspects such as cost, ethical or societal concerns, or accessibility. A total of 4 topics extracted were highly specific and related to "weight gain," skin problems," "loss of libido," and "mental health problems." Another 3 topics related to the impact of the contraceptive product on women's menstrual cycle but alluded to distinct aspects, which we named "menstrual irregularities," "cramps and pain," and "continuous bleeding." The final topic, "multiple cause dissatisfaction," was a mixed, broad topic. It was the least distinct topic, comprising a mixture of diffused complaints ranging from headache, tiredness, general life, and relationship issues to a mere product warning. A sample review that scored high on the topic "multiple cause dissatisfaction" read as follows:

> *Makes me feel very moody and sensitive, my husband and I fight all the time. When we got married I felt so much in love but know not sure about it. He said I changed a lot after having our baby. So not sure if the IUD is making me feel that way. I feel so bad because I get mad very easy for little things and I feel like I am loosing my husband. Of course that he doesn't want to wear his ring makes me think things but he said that he is not use to wear rings and I always wear mine. I cook breakfast every single day, cook lunch for us to take it to work since we do not have to much money and sometimes I feel that he doesn't really appreciate it! Do laundry, clean and he doesn't really help me much and he doesn't see it. Not sure what to think.*

Table 5 provides sample reviews for each topic. More examples can be found in Multimedia Appendices 1 and 2.

For each topic, Table 4 also presents the share of online user reviews where this topic was dominant having the highest topic value in the topic matrix W. Thus, the dominant topic is the issue voiced most firmly in an unfavorable review. Table 4 shows that with this dominant topic modeling scheme, the reviews were relatively evenly distributed among the 8 identified topics. The rarest dominant topic was "weight gain" with 9.69% (807/8330) of the unfavorable reviews predominantly describing this side effect. "Multiple cause dissatisfaction" dominated in 17.92% (1493/8330) of the unfavorable reviews.

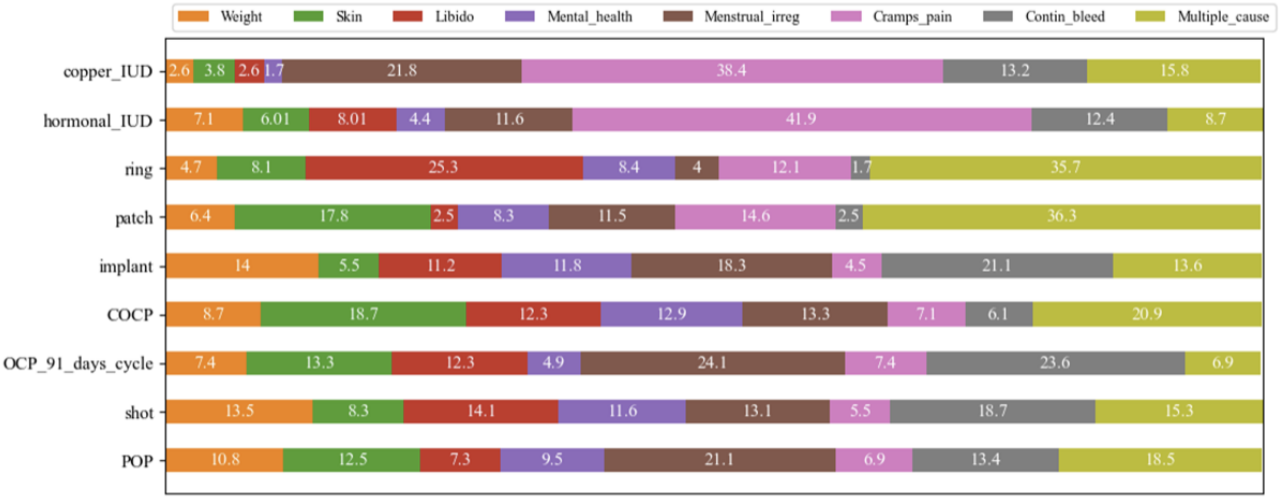
XSL•FO
RenderX

Table 4. Topics discussed in unfavorable reviews of birth control products and their relative frequency (n=8330).

Topic	Topic description	Unfavorable reviews with this dominant topic, n (%)
Weight gain	Users describe a change in body weight, typically an increase, which is attributed to the contraceptive product	807 (9.69)
Skin problems	Users describe an impact of the product on outward appearance, in particular acne	1051 (12.62)
Loss of libido	Users describe a reduction or loss of interest in physical intimacy and intercourse	963 (11.56)
Mental health problems	Users describe mental health problems, such as mood swings, depression, and anxiety	902 (10.83)
Menstrual irregularities	Users describe different problems with their period resulting from the contraceptive method; ranging from spotting, heavy bleeding, to unusually light periods	1223 (14.68)
Cramps and pain	Users describe particularly painful experiences, especially cramps, associated with the product or its administration	926 (11.12)
Continuous bleeding	Users describe continuous bleeding episodes which last substantially longer than regular periods and are more pronounced than simple menstrual irregularities	965 (11.58)
Multiple cause dissatisfaction	Users express dissatisfaction with the contraceptive product. None or various reasons are provided ranging from general side effects such as headaches to overall challenges in life that might or might not be attributable to the contraception choice	1493 (17.92)

Table 5. Examples of reviews centering on a specific topic.

Topic	Sample reviews with the dominant topic
Weight gain	“Been on it for 3 months, 20 pound weight gain—always hungry and never full. No periods, but not worth the weight gain and uncontrollable appetite...Was managing weight very well prior to implant...”
Skin problems	“Horrible, horrible, horrible I have never had acne this bad in my life!!!!!!!!!! My WHOLE chin and jawline are red and covered in cystic acne!!! I HAD PERFECTLY CLEAR SKIN BEFORE. I am honestly in a complete panic with what is going on with my skin. I’m in shock that a small pill could do this much damage. My face hurts so bad because of the acne. Its been only 3 weeks since I started taking it. Switching to sprintec tomorrow. DO NOT USE THIS, SAVE YOUR SKIN!!!!!”
Loss of libido	“I have been on NuvaRing for 5 months. Within a month I noticed a decrease in my sex drive, and I’ve had vaginal dryness which makes sex painful. Bad sex has effected other parts of my life.”
Mental health problems	“I used this pill during my teens and it caused irritability and heavy mood swings. Perhaps it was just teen angst but I tried microgynon recently, which uses the same hormones just different levels, and experienced similar mood swings and depression.”
Menstrual irregularities	“I have been on this medication for almost a month. I got my period once, but it hasn’t even been a week later that I got a second period. My first period was very light and only lasted three days, but I’m not sure how this period will be.”
Cramps and pain	“I got the kyleena inserted today and experienced the worst cramps in my life. The insertion were (8/10) on the pain scale. I am not very sensitive to pain but can’t take any pain medication. The last 4 hours has been the worst in my entire life so far I have really bad cramps now 10/10 and nausea. I can’t even get out of bed because of the severe pain!”
Continuous bleeding	“With liletta I have been bleeding for 3 month s I am so so tire of bleeding.”
Multiple cause dissatisfaction	“Do not take this pill.”



Relative Frequency of Side Effects Described Across Contraceptive Methods (RQ 3)

For each contraceptive method, Figure 3 shows the relative frequencies of the dominant topics in descending order according to average rating. For both copper and hormonal IUDs, the most frequent complaint by far was “cramps and pain,” which was the dominant theme in 38% (n=90) and 42% (n=355) of the reviews, respectively. For COCP, the most common complaints were “multiple cause dissatisfaction” (n=831, 21%) and “skin problems” (742, 19%). For POP and OCP that induce a 91-day cycle, “menstrual irregularities” were the most common issue (n=49, 21%, and n=49, 24% of reviews, respectively). For implants, as well as for hormonal shots, “continuous bleeding” (n=436, 21%, and n=61, 19%, respectively) was the most frequent problem described in the

XSL•FO
RenderX

reviews. For hormonal patches and vaginal rings, the most frequent dominant topic was “multiple cause dissatisfaction” (n=57, 36% and 106, 36%). For hormonal patches, the second most frequently described dominant side effect prominently voiced in unfavorable online reviews was “skin problems” (n=28, 18%).

Figure 3. Relative frequency of dominant topics in nonfavorable reviews by contraceptive method (as percentages). COCP: combined contraceptive oral pill; IUD: intrauterine device; POP: progestin-only pill.

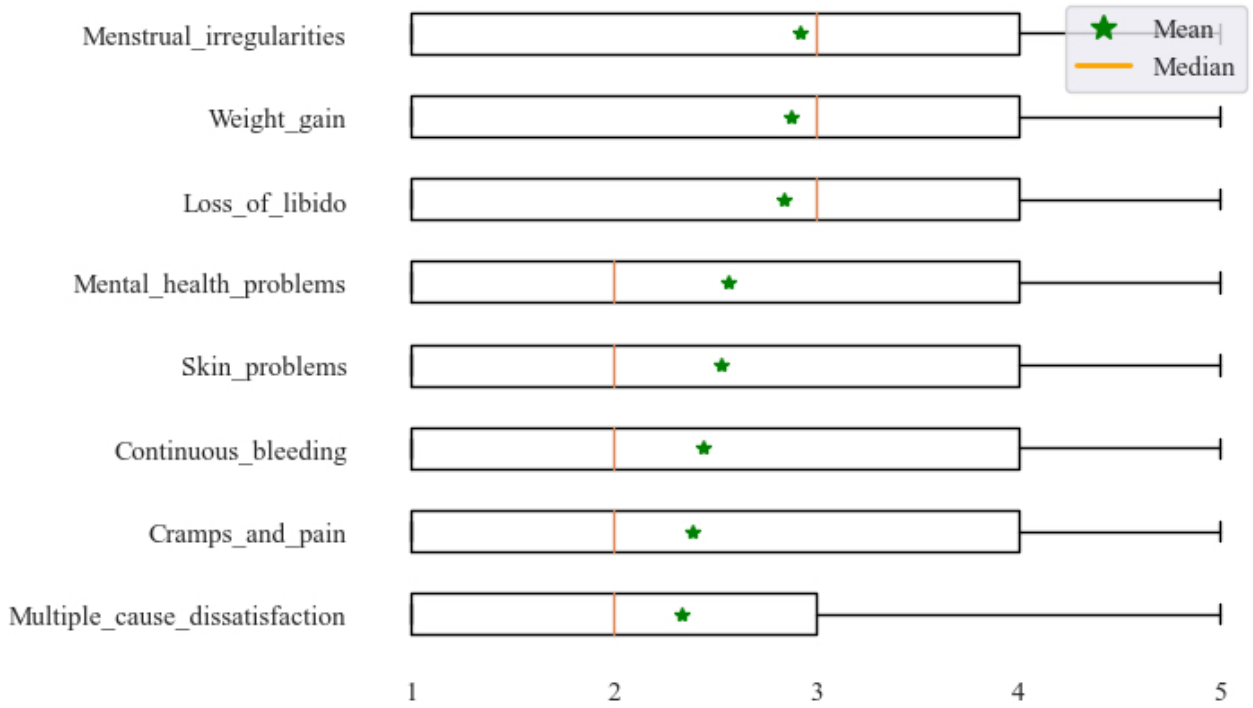
When reviewing the relative frequencies of dominant topics identified in Figure 3, it is important to remember that each contraceptive method was associated with a different proportion of unfavorable reviews. This was analyzed in the context of RQ 1 and is depicted in Table 3 which displays substantial variation in the proportion of unfavorable reviews across contraceptive product categories; with POP having the highest share of unfavorable reviews (n=232, 53.1%) and copper IUDs having the lowest share of unfavorable reviews (n=234, 29.3%). Scaling the relative frequencies of the dominant topics shown in Figure 3 with the overall share of unfavorable reviews of contraceptive methods displayed in Table 3, we find that for certain contraceptive methods, specific issues were very commonly discussed in online reviews in general, as in the following examples:

- Almost a quarter, that is, 24% (n=97), of all reviews of 91-day cycle OCPs report general “menstrual irregularities” or “continuous bleeding” (this is derived from n=49, 24%, of the reviews where “menstrual irregularities” were the dominant topic plus another n=48, 24%, where “continuous bleeding” was the dominant topic; multiplied by 49.3%, the rate of unfavorable reviews).
- Overall, 17% (n=104) of all reviews of hormonal shots discussed “menstrual irregularities” or “continuous bleeding.”
- For IUDs, 12% (n=90, copper) and 11% (n=355, hormonal) of all reviews revolved around “cramps and pain” associated with the contraceptive method and its administration.
- “Loss of libido” was the dominant topic in almost every 10th review of vaginal rings, that is, 9% (n=75).
- Almost 6% (n=243) of all reviews of “hormonal implants” revolved primarily around mental health issues.

Association Between Dominant Topic and Ratings of Birth Control Products (RQ 4)

The final RQ relates to how severely such side effects might impact the well-being and overall quality of life of women. This approach is important for providing a balanced picture of the frequency numbers described earlier. Not every side effect, even if common, necessarily impacts overall well-being to the same extent. For example, individual reviews illustrate that “cramps and pain” might have a much more negative impact on overall well-being than menstrual irregularities. For illustration, a sample review with “cramps and pain” as the dominant topic read as follows:

> *My experience was absolutely horrible. Birth control works different for everyone but this was by far the worst pain I’ve ever been in...*



While a sample review where menstrual irregularities were voiced read as follows:

> *I have been on this medication for almost a month. I got my period once, but it hasn’t even been a week later that I got a second period. My first period was very light and only lasted three days, but I’m not sure how this period will be.*

Figure 4 displays boxplots of unfavorable ratings by dominant topic. The boxplots show that the frequency distributions for all dominant topic-based groups are left skewed. Consistently, the first quartile of ratings is a 1, that is, at least a quarter of all reviewers (2986 across all groups, ie, 35.8% on average) writing a nonpositive review submitted the lowest possible rating. The medians displayed in the boxplots as orange vertical lines range from 2 to 3. Only 3 dominant topics were associated with a median rating of 3, namely “menstrual irregularities,” “weight gain,” and “loss of libido.” For all other dominant topics, half of all unfavorable reviews have a rating of ≤2.

XSL•FO
RenderX

Figure 4. Boxplots of ratings by dominant topic described in nonfavorable reviews.

The mean ratings per dominant topic are represented as green star. On average, reviews predominantly describing menstrual irregularities have the highest average rating (mean 2.92, SD 1.53; 1223/8330, 14.68%). The next highest average ratings were in reviews describing weight change (mean 2.87, SD 1.52; 807/8330, 9.69%) and loss of libido (mean 2.84, SD 1.49; 963/8330, 11.56%). Conversely, reviews with the lowest ratings, on average, predominantly described multiple cause dissatisfaction (mean 2.34, SD 1.45; 1493/8330, 17.92%), cramps and pain (mean 2.39, SD 1.55; 926/8330, 11.12%), and continuous bleeding (mean 2.45, SD 1.47; 965/8330, 11.58%). Skin problems (mean 2.53, SD 1.49; 1051/8330, 12.62%) and mental health problems (mean 2.57, SD 1.48; 902/8330, 10.83%) had slightly greater ratings than the bottom 3 groups.

Discussion

Principal Findings

Our findings are in line with the literature evaluating how users, mostly women, use social media to discuss and evaluate different contraception options. Side effects were the most important area that was discussed online. Our NLP algorithm extracted 8 topics, of which 7 clearly describe a specific unpleasant side effect and only 1 less concise topic also encompasses other issues such as general life challenges, relationship issues, or product warnings. The algorithm did not extract any frequent words indicative of nonhealth related challenges such as cost and accessibility.

Our research extends the existing body of knowledge in several aspects. First, we found that in the online drug review forum, niche products tend to be overrepresented compared to their prevalence among the respective populations in the United States. For example, Table 3 shows that 22.52% (4392/19,506) of the reviews discussed hormonal implants. However, their prevalence among women using reversible contraceptive products (either LARCs or short-acting methods) is 7.3% [2]. Similarly, vaginal rings (827/19,506, 4.24% of reviews vs 2.9% in the respective population [2]) and hormonal patches (800/19,506, 4.1% vs 1.1% [2]) appear to be overrepresented. Even more interestingly, IUDs are substantially underrepresented. While 18.82% (3671/19,506) of contraceptive product reviews discuss IUDs, they are used by almost a third of women [2] using female contraceptive products.

The underrepresentation of IUDs might be attributable to the fact that on average, women tend to be more satisfied with IUDs than with other contraceptive products (Figure 2; Table 3). In general, people are more likely to write an online review when they have a complaint than when they are satisfied [52]. Nevertheless, in Figure 2 and Table 3, we observe that a substantial share of women report positive experiences with contraceptive products, ranging from slightly >70% (2589/3671, 70.52%) of favorable reviews for IUDs to 46.9% (205/437) for reviews of POP. Overall satisfaction with reviewed birth control products may be even greater if the probable negative bias inherent in online reviews is accounted for.

Our NLP-based evaluation of product reviews also offered valuable insights into how women experience different product-based contraceptive methods and how negative experiences relate to the overall satisfaction with the method.

Hormonal Short-Acting Contraceptive Methods

Overview

A first pattern we observed was that hormonal contraceptive methods with a higher level of systemic absorption, such as POP, birth control shots, and COCP, received greater shares of unfavorable reviews (232/437, 53.1%, 327/653, 50%, and

XSL•FO
RenderX

3968/8606, 46.1%, respectively) than methods with a lower level of systemic absorption, such as hormonal IUDs (848/2871, 29.54%). For copper IUDs, which do not release any hormones, only 29.3% (234/800) of reviews were unfavorable (Table 3). Thus, based on the online reviews and ratings, it appears that on average women in the website Drugs.com [43] sample are less satisfied with short-acting methods that rely on a systemic hormonal effect, which is in line with the findings of Merz et al [27] studying posts on X over time. This is particularly interesting as recent literature describes a trend of women turning away from hormonal contraceptives despite their high efficacy due to the influence of social media [26,36]. While clinical studies confirm a range of side effects with hormonal contraception, some researchers suspect they may be perceived to be more severe than they truly are [36]. However, our research suggests that women rate oral hormonal contraceptive products, hormonal implants, and shots less positively than nonhormonal methods and that this is linked with specific side effects.

Progestin-Only Methods and the Role of Irregular Bleeding Pattern

Figure 2 shows that POPs, contraceptive implants, and injectable contraceptives, which are all progestin-only methods, obtained comparably low average ratings with a high SD. According to the reviews, the most common side effects for these methods relate to irregular bleeding pattern and continuous bleeding (Figure 3). This is in line with the relevant women's health literature describing irregular or unscheduled bleeding as their most common side effect (eg, [53]). The inhomogeneous experiences with these progestin-only methods might be—to some extent—explained by the interplay between users' expectations and actual experiences. Although irregular bleeding resulting from these progestin-only methods decreases over time [54], women may be more disgruntled by the initial irregularity, especially if counseling focused more on the long-term than short-term expectations.

Potential Role of Ease of Administration for Cycle Control

Among the remaining short-acting contraceptive methods, hormonal patches and vaginal rings obtained comparably high average ratings and lower SDs than COCPs and extended-cycle OCPs (Figure 2). For COCPs, this is expected as women who are prescribed contraception for the first time often opt for the COCP due to its ease of initiation and discontinuation [55]. This initial usage likely leads to varied experiences.

However, this disparity in low average ratings of extended-cycle OCPs versus comparably high and more homogenous average ratings of vaginal rings and hormonal parches is unexpected, given the similarity of side effects across combined hormonal contraceptives (CHC) [53]. A potential explanation of our findings is that the patch and the ring may achieve better cycle control than the extended-cycle COCP due to the lack of need for daily administration [53]. Indeed, for extended-cycle OCPs, nearly half of the reviews (97/203, 47.8%) predominantly described abnormal bleeding, whereas this was only the case for 14% (22/157) of reviews of hormonal patches and 5.7% (17/297) of reviews of vaginal rings (Figure 3). Those opting for an extended-cycle OCP probably do so with the intent of significantly reducing or entirely ceasing their menstrual cycles, which is the primary distinction between standard and extended-cycle OCPs. Unfortunately, breakthrough bleeding is very common early in the use of an extended-cycle regimen [53]. Therefore, women who are hoping for no bleeding are likely to be unhappy with increased bleeding, especially if they are not warned about this. It is also possible that there could be other explanations, such as increased hormonal stability with nonoral administration of CHC [55].

Skin Issues

Research has consistently shown that CHC are beneficial for the treatment of acne [56]. It is surprising, therefore, that in our study, skin problems appear as a dominant topic for COCPs, patches, and 91-day cycle OCPs more commonly than for other methods. Further research would be helpful to explore these findings. One possibility is that the skin problems reported by reviewers are not only acne but also other problems, such as melasma, a hyperpigmentation disorder well known to be associated with oral contraceptive use [57]. However, an example investigation of reviews in which "skin problems" are discussed reveals that many reviews describe disappointment resulting from the birth control product not meetings their expectations with regards to acne control. For example,

> *I've been taking this birth control for about a week now, and I have already noticed some changes. My skin is also acne prone, and I was really hoping that this birth control would help with it. Without the pill, I usually have many bumps on my forehead, my chin is pretty red, and once in a while I will get cystic acne. Now that I've been taking it, I have many new pimples all over my face, like my cheeks and on my nose, where I have never gotten it before. It's also given me MORE cystic acne which is a pain. I really wish that it could have helped, but before I switch off I want to wait a little longer to be sure.*

This disappointment might make them more prone to leave a negative comment than women who experience other side effects.

Loss of Libido

Interestingly, the loss of libido is still associated with comparably high average product ratings. Unfavorable reviews predominantly describing a loss of libido ranked third in average rating (Figure 4). Our analysis also revealed that loss of libido is the most common dominant topic for vaginal rings (75/297, 25.3% of unfavorable reviews), almost double the proportion of any other method. This is interesting since controversial findings on this topic exist in the literature. It has been hypothesized that CHC may adversely affect sexual functioning by increasing sex hormone–binding globulin (SHBG), which then decreases available testosterone and leads to decreasing endogenous hormone production. Oral estrogens are known to increase SHBG via a first-pass hepatic effect [58]. It could be hypothesized that nonoral administration may have a smaller effect on available testosterone, although other research has shown that both oral and vaginal CHC increase SHBG and decrease free androgens [59]. It has also been hypothesized that administering CHC via a nonoral route, such as the use of a

XSL•FO
RenderX

patch or ring, may mitigate effects on sexual function via increased hormonal stability. The ring could also exert a local estrogenic effect, improving lubrication [55].

Several studies have assessed the effect of the vaginal contraceptive ring on sexual functioning, with mixed findings [55,59], and a recent meta-analysis revealed a possible positive effect at 3 months but no effect at 6 months [60]. A larger cross-sectional nonrandomized analysis revealed that decreased libido was most common among users of shots, rings, and implants [8], which is more congruent with our analysis. It is also worth considering that direct hormonal effects are not the only way a method could affect libido; physical discomfort, vaginal dryness or irritation, and excessive bleeding are also expected to contribute. This is also illustrated in this example review:

> *I have been on NuvaRing for 5 months. Within a month I noticed a decrease in my sex drive, and I've had vaginal dryness which makes sex painful. Bad sex has effected other parts of my life.*

Overall, based on the results of our study, it is plausible to anticipate that the systemic administration of hormones might lead to a greater incidence of side effects and lower satisfaction levels. This expectation is corroborated by our data, not only describing side effects with regards to irregular bleeding patterns, skin issues, and loss of libido, but also an increased frequency of complaints such as weight gain and mental health issues associated with these hormonal methods.

Discussion of Insights on LARCs

In our exploratory study, we observe that, on average, women are highly satisfied with their IUDs. In fact, among all contraceptive methods, IUDs are given the highest average ratings on the drug review website (Table 3). This finding is corroborated by existing research indicating high satisfaction levels with this contraceptive method [56]. IUDs offer substantial advantages. The hormonal IUD is known for its ability to significantly reduce menstrual bleeding, with the 52 mg version being approved by the Food and Drug Administration in the United States for both contraception and heavy menstrual bleeding treatment. On the other hand, the copper IUD stands out as the sole nonhormonal choice that offers the convenience of not requiring action during each sexual encounter. Although both types of IUDs can cause undesirable bleeding-related side effects—typically breakthrough bleeding with the hormonal IUD and heavy periods with the copper IUD—these decrease over time [54,61]. We can reasonably assume that women opting for an IUD, which necessitates a medical procedure for insertion, would be well-informed and prepared for this.

However, our research indicates that for a limited group of women, IUDs appear to create major problems. Between 11.3% (90/800) and 12.37% (355/2871) of all written online reviews emphatically describe cramps and pain related to the insertion procedure or persisting pain. In fact, cramps and pain are the dominant topic in 41.9% (355/848) and 38.5% (90/234) of unfavorable reviews of copper and hormonal IUDs, respectively (Figure 3). We also see that, on average, the ratings of reviews where cramps and pain are the dominant topic are the second lowest, occurring only slightly above multiple cause dissatisfaction (Figure 4). This observation has substantial implications for IUD counseling practices. Although physicians typically inform women about the potential side effects of IUDs, our findings underscore the necessity for health care professionals to provide even more comprehensive counseling regarding the risk of temporary as well as lasting cramps and pain, which heavily hampers women's well-being, and to offer pain control options for the insertion procedure.

Limitations

Our study is subject to several limitations. First, the reviews and ratings in online forums may exhibit bias, often skewing toward negative experiences, and there may even be a risk of fake reviews. Consequently, our dataset may not accurately represent the broader population of women using birth control products. Nonetheless, this limitation does not detract from our study's objective, which is to illuminate the experiences with different contraceptive methods women share on a drug review website. This study was intended to supplement traditional qualitative but informal information sources used by women and their partners. Consequently, our extensive analysis of nearly 20,000 online reviews arguably offers a more representative and robust overview than anecdotal evidence gathered from conversations with friends and family regarding birth control options. All the same, we note that the reliance on data from a single source (ie, the website Drugs.com) may introduce a bias. This could affect the findings. Although the drug review dataset dates from 2009 to 2017, reviewers might have already been influenced by social media influencers, who are increasingly expressing concerns about hormonal contraceptives, sometimes inflating the severity of side effects [36], and advocating for nonhormonal methods. Furthermore, the dataset only contains reviews of products. As such, natural contraceptive methods, such as calendar rhythm and withdrawal are not covered. Performing the NLP and sentiment analysis on other contraceptive product review websites could enhance the breadth and robustness of our findings but is outside the scope of this analysis.

Second, our categorization did not stratify by dose or regimen timing (eg, 21 vs 24 active pills) due to insufficient review information (eg, Loestrin could refer to multiple different products with the same active ingredients in different doses and durations), nor by progestin type to avoid small group sizes.

Third, there are important limitations inherent in the topic modeling of birth control product online reviews. While topic modeling offers valuable insights, it is crucial to acknowledge its constraints so that they can be addressed effectively in future research. One of the primary limitations is the subjectivity involved in choosing the right number of topics. In addition, topic modeling may not adequately capture rare or nuanced topics. In our study, which identified 8 topics, we observed 1 particularly ambiguous topic, "Multiple cause dissatisfaction." This topic is frequently associated with vaginal rings and hormonal patches and occasionally encompasses other topics, potentially obscuring the clarity and precision of our overall results. Conversely, our algorithm effectively differentiates

XSL•FO
RenderX

between “menstrual irregularities” and “continuous bleeding,” despite their similarities. Notably, women experience “continuous bleeding” as more problematic than “menstrual irregularities.” However, due to the overlap in these side effects and the associated words, some reviews scored highly for both topics.

Another limitation in topic modeling is the potential ambiguity in allocating reviews to specific topics, which stems from the inherent challenge of accurately capturing the thematic essence of the text. For example, a word such as “skin” in an unfavorable review does not necessarily imply a discussion about skin-related problems. Furthermore, one review may describe several topics or side effects (Multimedia Appendix 2). Thus, analyses that are based on reviews grouped by dominant topic may not fully reflect other potentially confounding aspects.

Despite these challenges, our analysis suggests that using TF-IDF and NMF for topic modeling with 8 topics is the most effective approach. In this setup, most topics, apart from “multiple cause dissatisfaction” and the occasionally intersecting “menstrual irregularities” and “continuous bleeding,” are well-defined by distinct symptom sets, differentiating them from others. The process involved careful consideration of both the interpretability and the distinctiveness of each topic.

Finally, given the exploratory nature of our study, we did not engage in statistical significance testing; consequently, we could not definitively determine whether the observed differences in contraceptive method ratings are systematic. This study was primarily descriptive and does not involve inferential statistical analysis or controlling for confounding variables. We also did not investigate potential interactions between different side effects, such as whether reports of mental health issues could lead to more negative evaluations of other symptoms. The suitability of the dataset for inferential statistics is questionable, as it does not meet several crucial assumptions for significance tests, such as normality, homoscedasticity within groups, or independence of observations.

In summary, our findings provide semiqualitative insights, highlighting the occurrence of certain side effects in the real world and how they are associated with online contraceptive product ratings. A deeper understanding of effect sizes, relationships, and causality requires further research.

Conclusions

This study contributes to the understanding of how contraceptive methods impact women’s overall well-being, as interpreted from a large corpus of online user narratives. Our findings provide a complementary perspective to those derived from clinical trials or the adverse effects documented in pharmaceutical labels and package inserts. By leveraging NLP to analyze user reviews, we aimed to support women in choosing contraceptive options that are not only safe and effective but also reduce the likelihood of specific symptom clusters that could negatively affect their quality of life.

For instance, women seeking contraception may have specific concerns, such as potential effects on libido, skin health, or menstrual regularity. While no contraceptive option is completely free of side effects, it is crucial that women have access to information that enables them to make informed decisions about which side effects they are prepared to accept, guided by the experiences of others. Accordingly, our analysis empowers women to benefit from the collective insights and experiences of a large user base, supporting more informed decision-making. In addition, this information aids HCPs in offering personalized advice to women and their partners.

A key observation from our study is that all female contraceptive methods reviewed online are associated with a substantial percentage of negative ratings. Notably, no contraceptive method to be administered by women received <29% unfavorable evaluations. This finding underscores a significant opportunity for enhancement in the realm of female contraception. The objective for manufacturers would be to innovate and develop contraceptive methods that exert minimal or no negative impact on the well-being and quality of life. In light of this, there is a recent trend toward natural or calendar-based methods sometimes supported by digital cycle tracking tools. Depending on individual life circumstances and personal beliefs, these methods may constitute a viable alternative for some women despite the inherent risks resulting from use failure (the website Drugs.com [43] provides a comparison of efficacy and typical use failure rates). Greater awareness of the side effects of contraceptive products for women could guide couples in making joint decisions about contraception and a more equitable sharing of responsibilities by considering more options. A secondary insight from our study is that dissatisfaction was particularly common for contraceptive products that may result in irregular or continuous bleeding, especially when users may have expected reduced or absent menstrual bleeding. IUDs are generally rated more positively than other methods, although about 1 in 10 users report severe cramps and pain which are linked to very poor ratings.

In conclusion, a pivotal element of efficacious reproductive management is the provision of comprehensive information to women regarding the potential side effects of contraceptives and their likely impact on overall well-being and quality of life. Advancements in artificial intelligence in general and NLP in particular can help in extracting, aggregating, interpreting, and sharing this information. In a broader context, the empowerment of women to manage their reproductive health is acknowledged as a fundamental catalyst for economic advancement and the achievement of personal and professional aspirations, as emphasized by organizations, such as the United Nations, the World Health Organization, and the Organisation for Economic Cooperation and Development. Moreover, female sexuality transcends the dimensions of reproduction and birth control, encompassing aspects of pleasure and human connection, thereby enhancing overall well-being [62]. Access to suitable contraceptive methods and thorough information about these options are vital in facilitating this empowerment.

Abstract

Background: Conversational artificial intelligence (CAI) is increasingly used in various counseling settings to deliver psychotherapy, provide psychoeducational content, and offer support like companionship or emotional aid. Research has shown that CAI has the potential to effectively address mental health issues when its associated risks are handled with great caution. It can provide mental health support to a wider population than conventional face-to-face therapy, and at a faster response rate and more affordable cost. Despite CAI's many advantages in mental health support, potential users may differ in their willingness to adopt and engage with CAI to support their own mental health.

Objective: This study focused specifically on dispositional trust in AI and attachment styles, and examined how they are associated with individuals' intentions to adopt CAI for mental health support.

Methods: A cross-sectional survey of 239 American adults was conducted. Participants were first assessed on their attachment style, then presented with a vignette about CAI use, after which their dispositional trust and subsequent adoption intentions toward CAI counseling were surveyed. Participants had not previously used CAI for digital counseling for mental health support.

Results: Dispositional trust in artificial intelligence emerged as a critical predictor of CAI adoption intentions (P<.001), while attachment anxiety (P=.04), rather than avoidance (P=.09), was found to be positively associated with the intention to adopt CAI counseling after controlling for age and gender.

Conclusions: These findings indicated higher dispositional trust might lead to stronger adoption intention, and higher attachment anxiety might also be associated with greater CAI counseling adoption. Further research into users' attachment styles and dispositional trust is needed to understand individual differences in CAI counseling adoption for enhancing the safety and effectiveness of CAI-driven counseling services and tailoring interventions.

Introduction

Conversational Artificial Intelligence in Mental Health

Conversational artificial intelligence (CAI) has rapidly captured global attention since its emergence in recent years. It has permeated various facets of human life and continues to attract a growing user base worldwide due to its unparalleled impact on the way people access knowledge, present ideas, and interact. Commercially available CAIs, including Replika (developed by Luka Inc, Replika is a chatbot designed to be a conversational agent and personal companion, using artificial intelligence (AI) to simulate human-like conversations; its primary purpose is to provide users with an AI friend that can listen, respond

XSL•FO
RenderX

empathetically, and help users reflect on their thoughts and feelings. It is often used for mental health support, companionship, and improving emotional well-being [1]) and Pi (Developed by Inflection AI, Pi is a CAI designed to provide a range of task-based features, including emotional support, learning assistance, and personalized interactions; it is specifically tailored to engage users in meaningful conversations, making it useful for various purposes, such as mental health support, learning new languages, and relationship advice), are powered by large language models (LLMs) with deep learning–based natural language processing to enable human-like voice or text interactions with users. They offer a wide range of services such as information retrieval, task completion, entertainment, and even mental health support [2]. In the context of mental health support, CAI is used in various counseling settings like delivering psychotherapy, providing psychoeducational content, and offering support such as companionship or emotional aid [3]. In this paper, we define CAIs as chatbots that use LLMs to generate naturalistic text, which is different from traditional rule-based conversational agents that operate mainly on predefined scripts, such as customer-oriented chatbots commonly used in sales and marketing.

One increasingly common usage of these anthropomorphic CAIs has been for counseling purposes in mental health settings to improve the overall quality of communications [4]. Gaffney et al [5] conducted a systematic review of 13 studies on the application of conversational agents (including CAIs) in psychotherapeutic settings and found that overall, CAIs showed promising results in terms of effectiveness and acceptability for addressing mental health issues in users. More recently, Li et al [6] conducted a meta-analysis of 15 randomized controlled trials specifically focusing on CAI counseling, and found that CAIs showed a significant decrease in depression and distress symptoms, especially when used with clinical, subclinical, and older adult populations. These findings suggest that CAI has the potential to effectively address mental health issues. Furthermore, the accessibility and user-friendly nature of CAI have also made them a promising tool for delivering mental health care to a wider population at a faster response rate and at an affordable cost, compared with traditional in-person therapies. It offers hope for overcoming long-lasting barriers, such as social stigma and the demand-supply imbalance, that weigh down traditional mental health care services [7].

Despite the benefits CAI counseling could potentially bring to mental health care, it also poses many risks and challenges, such as misleading responses, privacy infringement, and ethical concerns, to name a few [8]. For instance, counseling typically involves a high degree of self-disclosure, which in the context of CAI counseling can be problematic. Users may share sensitive and personal information that, if not properly protected, could be vulnerable to data breaches or misuse. Furthermore, the algorithms used by CAIs might not fully grasp the nuances of human emotions and mental health issues, potentially providing inappropriate or harmful responses (eg, spreading misinformation, professing their love to users, and sexually harassing minors) [9]. In addition, users of CAI counseling may be more susceptible to developing maladaptive behaviors (eg, addiction) as most counseling CAIs are designed to form social-emotional bonds with its users. While CAI therapies are intended to improve users' psychological well-being, they also risk users developing overreliance and social withdrawal [10]. Without caution in its application and a thorough understanding in human-CAI interaction in counseling settings, the unpredictability in CAI responses could lead to adverse psychological consequences on the user.

How should we weigh the pros and cons of adopting CAI counseling for mental health support? Most of the relevant literature [2,11] acknowledges the significant potential of CAI therapies in providing therapeutic support and underscores the necessity for further exploration and implementation, but also highlights the importance of recognizing and meticulously managing the risks associated with CAI therapies through rigorous research and well-defined guidelines. Furthermore, regardless of the concerns related to the use of CAI for psychological support, there are already CAIs that provide easy access to task-oriented features designed for mental health purposes. For example, a wide range of diverse task-oriented features offered by Pi fall under this category, such as venting, self-care for anxiety, and relationship advice [12]. Particularly, the younger generation may be more open to trying new technologies, making them more vulnerable to potential harms from poorly regulated or non–evidence-based CAI therapies. Therefore, to ensure the safe and effective integration of CAI into mental health services, it is crucial to understand the factors influencing CAI adoption, including potential predictors and barriers. However, research is relatively lacking in this area [7,10]. Studies addressing the factors associated with individual adoption of CAI counseling is needed to comprehend the psychological mechanisms underpinning the formation of human-CAI relationships. This study was designed to address this gap, by examining individual differences in attachment styles and perceived trust as predictors of CAI adoption for mental health care.

Numerous studies have demonstrated attachment style to be a reliable predictor for various relational outcomes [13,14], including the relationship between humans and technology. Meanwhile, trust is considered as another key factor in the context of technology adoption and use, especially in the domain of AI adoption due to risks related to its complexity as mentioned earlier [15]. Therefore, for this study, perceived trust and attachment styles were both examined as potential pertinent variables that might account for individual differences in CAI adaption in the context of digital counseling.

Trust as a Potential Predictor for CAI Counseling Adoption

Based on the theoretical framework developed by McKnight [16], trust is the extent to which a person has confidence in, and is ready to rely on, another entity (in this case, CAI). The formation of trust in information technology goes through different stages, each influenced by distinct factors and mechanisms. Considering CAI as a relatively recent technology, we assume that most individuals would have no previous experiences with CAI counseling. Therefore, the primary focus of this study was on the initial stage of trust building, which

XSL•FO
RenderX

pertains to establishing trust with an unfamiliar party or service without previous interaction. Numerous studies have examined the individual process of technology adoption from the perspective of trust formation, where the entity being trusted is a technology such as an information system or a recommendation agent. For example, when examining the factors that influence digital voice assistant use, Fernandes and Oliveira [17] found a positive link with perceived trust. Kasilingam [18] investigated intentions toward using smartphone chatbots for purchasing decisions and found that trust positively influenced participants' willingness to use chatbots for mobile shopping purposes. However, studies have not yet examined trust as a predictor for the adoption intention of CAI counseling for psychological support before engagement. While a recent review [19] identifies trust as a key predictor of CAI adoption in health care, including mental health care settings, the CAIs discussed in this review reflect a broader, more general definition of CAIs, including those that use prewritten scripts, which fall outside the scope of our research. Research specifically studying the relationship between trust and adoption intention of advanced CAI counseling (eg, ChatGPT [OpenAI] relying on contemporary reinforcement -learning with human feedback-based LLM technology) is still lacking. Additional research is needed to examine the replicability and reliability of these conclusions within the context of advanced CAI counseling technologies. Furthermore, given that CAI counseling for psychological support involves deeper emotional bonding and personal information, trust may play a significantly different role compared with CAI applications for other aspects of mental health care, such as diagnosis or treatment adherence. Studies examining the formation of trust on primitive, pre-LLM chatbot systems have found positive associations between perceived trust and chatbot adoption, which may generalize to explain how initially perceived trust shapes individuals' behaviors in considering the use of CAI counseling. Hence, in this study, we tested whether perceived trust can predict CAI counseling adoption.

Attachment Theory and Styles

Attachment theory, initially developed by John Bowlby, is a psychological framework that describes how infants learn to interact with their caregivers [20-23]. It was later expanded and adapted to explain the dynamics of both long and short-term interpersonal relationships between humans [24]. A key concept within this theory is the idea of "internal working models (IWMs)," which are shaped by early interactions with primary caregivers. The nature of these interactions, whether they are nurturing, inconsistent, or neglectful, greatly influences the types of IWMs developed. When a caregiver consistently responds to a child's needs in a caring, supportive manner, it tends to foster a positive IWM, while inconsistent or neglectful nurturing is more likely to lead to the formation of negative IWMs. These IWMs serve as mental templates that individuals use to perceive themselves and others, and influence their attributions, perceptions, and emotional understandings of these connections. In essence, they tend to serve as a prototype to determine an individual's expectations and behaviors in subsequent relationships [25-27].

Attachment styles are commonly presented as secure attachment, anxious attachment, avoidant attachment, and disorganized attachment. However, disorganized attachment is often viewed as the most unpredictable type due to its lack of organization in how the child (and later adult) responds to their attachment figures, characterized by push-pull dynamics that lead to inconsistent and conflicted coping strategies [28]. This variability makes it challenging to draw reliable and accurate measurements. For that reason, disorganized attachment was not examined in this study.

According to Bretherton and Munholland [29], attachment style can be understood as the manifestation of people's underlying IWMs. The IWM of attachment avoidance is thought to manifest a positive view of self (as worthy of love and nurturance) and a negative view of others (as unresponsive and untrustworthy). Conversely, attachment anxiety is thought to be associated with an IWM that contains a negative view of self and a positive view of others. Finally, secure attachment is the combination of positive views of both self and others. Securely attached individuals are more capable of forming and maintaining close relationships, with higher commitment, intimacy, love, and satisfaction in such relationships. As for the two insecure attachment styles, avoidant attachment is defined by devaluation of the importance of close relationships, avoidance of intimacy and dependence, and decreased engagement in attachment behavior, while anxious attachment involves preoccupation with the availability and responsiveness of attached figures, fear of separation, and abandonment [24,30].

Attachment Insecurity as a Potential Predictor for CAI Counseling Adoption

While attachment styles are typically associated with interpersonal relationships, Hodge and Gebler-Wolfe [31] found that inanimate objects, such as smartphones, could also be perceived as attachment objects for anxiously attached individuals to feel secure, and reduce unpleasant feelings such as loneliness and boredom. This illustrates how attachment theory can be used as a framework to understand a person's relationship with technology. Beyond smartphones, Birnbaum et al [32] found that humans desire the presence of robots in stressful circumstances in a similar manner to their proximity-seeking behavior toward human attachment figures, suggesting that attachment might also play a similarly important role in human-CAI interactions. Given that CAI is a relatively nascent technology, especially in its application for mental health support, there is, to the best of our knowledge, no previous literature investigating the direct relationships between attachment styles and CAI use. The closest study explored the influence of different attachment styles on perceived trust in broadly defined AI; here Gillath et al [33] found that attachment anxiety was associated with lower trust in AI. Furthermore, participants' trust in AI was reduced when their attachment anxiety was enhanced and increased when their attachment security was boosted. Accordingly, consistent with the positive association between perceived trust and CAI adoption, we expected to find a negative association between attachment anxiety and CAI adoption intention in our study.

XSL•FO
RenderX

Meanwhile, although Gillath et al [33] found no significant effect of attachment avoidance on trust in AI, likely due to the inhibited nature of avoidant individuals, we believe it is important and necessary to include both attachment styles in this study in order to provide comprehensive insights into an underexplored area of research. n this study, we take a broader approach by also hypothesizing the relationship between attachment avoidance and CAI adoption. Insecure attachment styles, including both anxious attachment and avoidant attachment, are generally associated with lower levels of trust. For example, a number of studies on human relations have shown that attachment security is associated with more trust, whereas attachment insecurity is associated with less trust in other humans [34-36]. It may thus be reasonable to hypothesize that higher attachment avoidance will predict lower CAI adoption intention. This hypothesis is grounded in the understanding that individuals with high attachment avoidance may be less inclined to trust, and therefore, are less likely to adopt new technologies like CAI.

Research Hypotheses

Therefore, as a first step toward the eventual aim of promoting safer adoption and designing better CAI for mental health support, this study examined how perceived trust and attachment insecurity (ie, attachment anxiety and attachment avoidance) are associated with CAI adoption intentions. We propose the following two hypotheses:

First (hypothesis 1), due to the positive association found between the perceived trust and primitive chatbots adoption in the previous literature**,** higher trust in CAI counseling would predict higher adoption intentions for CAI counseling, after controlling for general confounding variables of age and gender.

Second (hypothesis 2), due to the association between insecure attachment styles (ie, anxiety and avoidance) and lower levels of trust, individuals with higher insecure attachments would show lower adoption intentions for CAI counseling, after controlling for age and gender.

To test the above hypotheses, a cross-sectional web-based survey was conducted. As no previous study has examined the human-CAI relationship through the perspective of attachment styles, this preliminary study may provide novel insights into this area and contribute to the existing literature on attachment and technology-mediated relationships. All hypotheses and methods were preregistered before data collection at Open Science Framework [37] and eventual deviations from the preregistration are detailed in Multimedia Appendix 1.

Methods

Participants

Based on an a priori power analysis, a minimum sample size of 146 was recommended to detect an effect size of F_2=0.075 with 95% power and alpha at .05 using a linear multiple regression with 6 predictors. The effect size was obtained from the findings of Gritti et al [38] on the effect of avoidant attachment on social network mobile app use. A total of 274 participants (aged 18 y and older, with American nationality or residence) were initially recruited through a large and diverse participant pool from the “Prolific” platform (prolific website; Prolific is a web-based service that provides access to a diverse pool of participants [initially recruited from word-of-mouth and social media] who opt-in to participate in studies listed on the platform. Eligible participants from the Prolific platform are notified through email or their Prolific dashboard. Prolific matches studies to participants based on prescreened criteria. Notifications are presented with necessary information, such as the study title, brief description of the study, estimated time commitment, and payment details clearly displayed, etc) between December 2023 and January 2024. Furthermore, 35 participants’ entries were removed due to incomplete data or ineligibility (eg, participants with previous CAI counseling experience as we were only interested in their adoption intention before engagement) responses, leaving a final sample size of 239 participants. The gender ratio of participants was nearly balanced (Table 1). Most of the participants identified as European Americans (153/239, 64% European; 37/239, 15% Asian; 27/239, 11% African American; and 22/239, 8% Native American and others) with a wide age range from 18 to 74 (mean 36.9, SD 12.4) years. For a breakdown of participant demographics, refer to Table 1.

Materials and Procedure

Overview

After reading the information sheet and providing consent to participate, participants proceeded to a survey consisting of multiple blocks in a predetermined order (ie, attachment styles, trust toward CAI counseling, intention of use for CAI counseling, and demographic questions). The item order in each scale was randomized to reduce response bias, and an attention check question was included in the survey.

Adult Attachment Style

Adult attachment style was measured using the close relationship version of Revised Adult Attachment scale [39]. This scale contains 2 subscales with 6 items assessing anxious attachment (eg, "I often worry that other people don't really love me," Cronbach α=0.91) and the other 12 items measuring avoidant attachment (eg, "I find it difficult to allow myself to depend on others," Cronbach α=0.88). Participants were asked to think about their close relationships with people important to them, such as family members, romantic partners, and close friends, and to rate each statement on a 5-point Likert scale, ranging from 1 (strongly disagree) to 5 (strongly agree). Anxious attachment scores and avoidant attachment scores were computed by taking the average of items within each subscale, with certain items being reverse-scored.

Trust in CAI Counseling

The concept of CAI counseling is still relatively new to most people. In order to introduce its applications in mental health

XSL•FO
RenderX

support, we adapted a news article illustrating the use of CAI in these contexts (Multimedia Appendix 1) for participants to read before completing the survey questions on trust in CAI in the setting of mental health support. This was edited to be as neutral in tone as possible and to remove references to gendered pronouns. A 12-item human-computer trust scale was adapted from previous research [40] (eg, "I think that CAI is competent and effective in providing mental support," Cronbach α=0.94) with each statement rated on a 5-point Likert scale, ranging from 1 (strongly disagree) to 5 (strongly agree). Scores for trust were calculated by averaging the items after reverse-scoring the relevant items.

The vignette plays a crucial role in this study, as it provides a contextual scenario to introduce and illustrate the practical application of CAI in mental health care. Given that CAI is still an emerging technology, particularly in the context of mental health support, the vignette helps bridge potential gaps in participants' understanding. This was especially important in case randomly enrolled participants were unfamiliar with CAI counseling or had never encountered it before.

CAI Counseling Adoption Intentions

CAI adoption intentions for mental health support were measured with a single-item measure, "How likely are you to try a counseling service based on CAI for mental health support in future (if needed)?" using a 5-point Likert-type scale (1=extremely unlikely, 5=extremely likely).

Demographics

Participants were asked to answer demographic questions on their age, gender, and education level. In addition, participants were asked about their previous experience with digital technology on a single-item measure, "How is your previous experience with digital technology in general?" (negative, neutral, or positive), and their familiarity with CAI's counseling function for mental health support on another single-item measure, "How familiar are you with the counseling function of CAI?" A 5-point Likert scale from 1 (not familiar at all) to 5 (extremely familiar) was adopted. In addition, previous CAI counseling experience was assessed on a single question, "Have you used CAI for mental health support before? If yes, please tell us more about your experience with it (eg, usability, effectiveness, satisfaction, and motivators for first engagement with CAI, etc.) if you would like to share."

Ethical Considerations

This study was approved by the Human Research Ethics Committee at the University of Canterbury, HREC 2023-120-LR. Participants received compensation of GBP 1.00 (US $1.28) for completing the survey.

All participants were required to carefully read the information sheet, which included essential details such as the research purpose, participation procedure, anonymity assurance, and potential benefits of participation. Participants were informed they could withdraw from the survey at any point. Completion and submission of the survey indicated participants' consent to participate.

Results

Demographics and Descriptive Statistics

Table 1 presents a breakdown of participant demographics. Note that nearly half the participants reported a lack of familiarity with the counseling aspects of CAI.

Descriptive statistics and a correlation matrix among all variables of interest are illustrated in Table 2. Attachment anxiety and avoidance were significantly and positively correlated with each other, which supports the dimensional rather than categorical nature of attachment styles. Furthermore, there was a negative and significant association between age and anxious attachment. Older participants tend to have lower anxiety associated with attachment. A strong significant correlation was found between trust and CAI adoption; higher trust was linked with greater intention of using CAI for mental health support.

Table 2. Descriptive statistics correlations matrix for all variables of interest.

Variable	Mean (SD)	A-anxiety[a]	A-avoidance[b]	Trust	CAI[c] adoption
A-anxiety	2.95 (1.11)

[e]$P<.001$.

Confirmatory Results

To test the first hypothesis, a hierarchical ordinal logistic regression was conducted to examine the relationship between perceived trust in CAI counseling and CAI adoption intention, given that the outcome variable (CAI adoption intention) was a single-item categorical variable. Table 3 reports the full breakdown of results for each model (using standardized

XSL•FO
RenderX

regression coefficients for all predictors). For the first step, age and gender were entered into the model. This step aimed to control for these demographic variables' effects on the outcome variable. Subsequently, the variable of interest—perceived trust—was added into the model to see whether the perceived trust explained significant variance in participants' CAI adoption intention above and beyond the effect of age and gender.

Aligning with hypothesis 1, perceived trust in CAI counseling emerged as a strong predictor of CAI adoption intention (*b*=2.62, 95% CI 2.19-3.09, *P*<.001, odds ratio [OR] 13.70). This suggests the higher the trust levels participants have toward CAI's counseling, the more willing they are to use CAI for mental health support, after controlling for age and genders. This tendency is also apparent in the box plot in which perceived trust was plotted against CAI adoption intention in Figure 1.

Considering our aim of examining adoption in initial stages of trust-building with counseling CAI, we conducted a robustness check by repeating the analysis with the subset of participants who reported "not familiar at all" with counseling CAI (n=116). For this sample, perceived trust in CAI counseling was still a strong predictor of CAI adoption intention (*b*=2.72, 95% CI 2.07-3.45, *P*<.001, OR 15.10), after controlling for age and gender.

To test the second hypothesis, we repeated the hierarchical ordinal logistic regression analysis to see if attachment insecurity predicted CAI adoption intention. Age and gender were included in the first step, followed by anxious attachment and avoidant attachment scores as the second step for predicting CAI adoption intention. Full results can be found in Table 4.

In contrast with hypothesis 2, we observed a small but positive significant effect of attachment anxiety on CAI adoption intention when age and gender were controlled (*b*=0.33, 95% CI 0.02-0.64, *P*=.04, OR 1.39). This means people with higher attachment anxiety are more likely to adopt CAI for mental support. It is contrary to the direction (ie, negative) that was theorized in hypothesis 2. However, this effect did not appear to be robust, as it was not significant in a zero-order correlation (Table 2). As shown in Figure 2, there was no clear pattern between attachment anxiety and CAI adoption intention before controlling for age and gender. No other significant relationships were found including between attachment avoidance and CAI adoption intentions.

To align with our aim of examining adoption in initial stages of trust-building with counseling CAI, we conducted a robustness check by repeating the analysis with the subset of participants who reported "not familiar at all" with counseling CAI (n=116). For this sample, attachment anxiety significantly predicted of CAI adoption intention (*b*=0.55, 95% CI 0.09-1.02, *P*=.02, OR 1.74), but not attachment avoidance (*b*=–0.54, 95% CI –1.148 to 0.064, *P*=.08, OR 0.59), after controlling for age and gender.

Discussion

Principal Findings

In this study, perceived trust and attachment insecurity (ie, attachment anxiety and attachment avoidance) were examined as factors that influence the dependent variable—CAI adoption intention. In hypothesis 1, we assumed that higher trust in CAI counseling would be associated with a stronger adoption intention, with age and gender controlled for their effects. The results supported this hypothesis, as trust appeared to be a strong predictor of participants' intention to use CAI for mental health support. In addition, in hypothesis 2, anxious attachment and avoidant attachment were proposed to be negatively linked to CAI adoption intention, after controlling for age and gender. Surprisingly, the results did not support this hypothesis. Specifically, avoidant attachment was not a significant predictor of CAI adoption intention, while anxious attachment was found to be a significant predictor with a small effect, but only after controlling for age and gender. Contrary to our original expectation, a greater level of attachment anxiety was found to predict a stronger CAI adoption intention.

Implication of Primary Findings

When it comes to the implementation of a novel but uncertain emerging technology like CAI, it is important to understand users' psychology and resultant behaviors at different stages of interaction, to understand how to achieve safe relationships and positive, effective outcomes. There is a critical distinction in the focus between the pre-engagement stage, such as individual users' intentions to adopt the technology, and the post -engagement stage, such as usage patterns and addiction. As CAI for mental health support has not achieved widespread usage, we focused on the pre-engagement stage in order to examine and describe potential predictors that drive individual engagement with CAI in the context of mental health support.

To our knowledge, this is the first study looking at the relationship between trust and CAI adoption intention for the specific purpose of mental health support. These findings are highly important as they underscore the critical role of trust in the adoption of CAI for mental health support. Given the sensitive nature of mental health, establishing and enhancing trust in CAI systems is paramount. Although many people may not yet be familiar with the potential of CAI in providing mental health support, this may change as CAI becomes more widely accepted and integrated into various fields. In times of urgent need, when human resources are unavailable or delayed, CAI could emerge as a valuable and appealing option for those seeking mental health support, prompting them to explore its potential for engagement. Therefore, user safety, wider acceptance, and use of this technology—all call for developers to prioritize robust security protocols and transparent privacy policies to enhance users' trust, including clear communication about how data are collected, stored, and used. Meanwhile, establishing and adhering to ethical standards is essential. This includes ensuring the AI's recommendations are safe, accurate, and unbiased. Providing users with training and resources to understand how CAI systems work can also demystify the technology and build trust.

Future research should focus on identifying specific factors that build or hinder trust in CAI, particularly in diverse populations, and explore interventions that could mitigate trust-related barriers. In addition, it will be crucial to investigate how trust interacts with other psychological variables, such as attachment styles, to fully understand its role in CAI adoption. Notably, a relatively small effect of attachment anxiety on CAI adoption intention was detected after controlling for age and gender. One possible explanation for the observed effect could be that lower levels of attachment anxiety among older individuals diluted the overall impact of attachment anxiety on adoption intention. Recent research has indicated age as an effective demographic factor to predict AI adoption. For example, Shandilya and Fan [41] found that older adults are less likely to use AI products than younger generations. Similarly, Draxler and colleagues [42] found that early adopters of LLMs, such as ChatGPT, tended not to include individuals from relatively older age

XSL•FO
RenderX

groups. This calls for further research incorporating theoretical frameworks and broader contextual and demographic variables to clarify the roles of age and gender in CAI adoption, particularly in the context of counseling therapies for mental health.

Furthermore, to our surprise, higher attachment anxiety was linked with higher adoption intention. One explanation for this unexpected positive association between attachment anxiety and CAI adoption intention might be the constant and excessive need for validation, reassurance, and emotional support which characterizes anxiously attached individuals [43]. Unlike individuals with attachment avoidance, who tend to suppress or ignore their attachment needs to avoid the discomfort caused by fear of abandonment, those with anxious attachment cope by seeking additional attention and affirmation to alleviate their fears and insecurities. Due to the anthropomorphic, nonjudgmental, constantly accessible, and responsive nature of CAI counseling, anxiously attached individuals might consider CAI as a potential attachment object as well as a secure base, for comfort and reassurance seeking whenever needed. This reassurance-seeking behavioral pattern demonstrated by anxiously attached people was also observed in studies on attachment toward inanimate or nonhuman objects and entities, such as smartphones [31] and robots [32]. On the other hand, attachment anxiety is a key indicator of insecure attachment, with individuals exhibiting lower levels of attachment anxiety generally being more securely attached. This higher sense of security may foster greater confidence in their interpersonal skills, making them more comfortable seeking assistance or support from other individuals, as well as in communicating negative or challenging emotions to others. These may also reduce their need for CAI counseling.

Our findings indicate that CAI could be particularly attractive and beneficial for anxiously attached individuals, potentially filling gaps where traditional support is inaccessible or unavailable. Compared with those with attachment avoidance, individuals with attachment anxiety may be more likely to engage with CAI for psychological support, potentially becoming a key demographic within its user base. CAI systems could benefit from tailoring their communication styles to address the unique needs of users with attachment anxiety, ensuring these technologies provide desired emotional support and safe engagement.

While recognizing the significant potential of CAI for psychological support, we believe it is also equally crucial to be aware of the associated risks that might arise in human-CAI interaction. Research has consistently linked attachment anxiety with increased social media use and addiction [44-47]. Consequently, individuals with attachment anxiety may also be more susceptible to developing unhealthy dependencies on CAI in the postengagement phase. Proactively identifying solutions and applying appropriate strategies during the design phase can mitigate potential negative outcomes. It is essential to alert CAI designers to potential maladaptive behaviors associated with CAI use. Integrating protective measures, such as timely advice and interventions, can help safeguard the user experience and optimize therapeutic outcomes, particularly for users with attachment anxiety.

In terms of attachment avoidance, the lack of a significant result is congruent with previous research [48,49]; avoidant-attached individuals have a need to deactivate the attachment system (eg, by inhibiting proximity-seeking behaviors), and this tendency often makes it difficult to observe and capture their avoidant nature in surveys. To be more specific, individuals with attachment avoidance often prefer self-reliance and independence. They are more likely to maintain emotional distance to feel safe rather than seek emotional support, which might lead to a weaker or nonexistent link between attachment avoidance and CAI adoption intention, similar to the results found in our study.

To the best of our knowledge, this study is the first to explore the relationship between attachment styles and CAI adoption in the context of CAI-based therapies. More evidence is needed to determine whether our current findings (in both significance and direction) are replicable and reliable. If attachment styles, particularly attachment anxiety, prove to be a consistent predictor of CAI adoption intention, this could inform the development of more customized designs that promote safer interactions and outcomes that are more effective.

Trust in Generalized AI and CAI

In addition, past studies [33] have already established a relationship between attachment styles and trust in generalized AI. However, our results suggest that this may not necessarily replicate in the context of CAI. According to the results of correlation matrix illustrated in Table 2, both attachment anxiety and avoidance were not significantly correlated with trust in CAI counseling in our study. Therefore, trust was not assessed as a mediator between attachment anxiety and CAI adoption intentions. Specifically, perceived trust was not significantly associated with attachment anxiety (β=.091, *P*=.30) and attachment avoidance (β=–.161, *P*=.07). This finding is inconsistent with the conclusion (ie, higher attachment anxiety predicts lower trust) found by Gillath et al [33] in their study, that we previously relied on in hypothesizing a negative direction between attachment anxiety and CAI adoption intention in hypothesis 2. Hence, this inconsistency could signify a more complex relationship between attachment styles and perceived trust in CAI adoption.

To contextualize these results in understanding this inconsistency, one possible explanation could be that participants' attachment systems may not have been sufficiently activated in this study. According to a review conducted by Campbell and Marshall [50], attachment theory is interactionist in nature, particularly attachment anxiety. Highly anxious individuals may exhibit heightened distress responses when they perceive cues as threats to their relationships. However, in the absence of such cues or when their security needs are fulfilled, they often show similar proximity-seeking tendencies in affect, cognition, and relationship processes to people with low anxiety levels. This suggests that when the attachment system is not effectively activated, it could potentially lead to weaker or contradictory associations between attachment styles and attachment-related behaviors, such as the relationship found between insecure attachment styles and trust in CAI in our study. Future studies are suggested to include research-supported

XSL•FO
RenderX

methods (eg, recalling relationship experiences and hypothetical scenarios) for activating participants' attachment systems before conducting the study.

Furthermore, given its sensitive nature, it is also possible that insecure attachment styles affect trust in CAI counseling in a different manner than trust in AI in general. As mentioned in previous sections, we formulated our second hypothesis based on a relevant study conducted by Gillath et al [33]. The AI technologies examined in this study focused on the relationship between attachment insecurity and perceived trust that were designed for more general purposes, such as self-driving vehicles, medical diagnostic apps, and matchmaking services. Unlike self-driving vehicles or matchmaking services, mental health support requires a higher level of empathy and emotional attunement, areas in which AI technology is more likely to be considered to fall short. Research examining the relationship between attachment styles and trust in AI used for sensitive purposes, such as conversational AI for mental health, need to be specific to the context for which they are used.

General Limitations

There are several limitations that should be mentioned in our study. First of all, one potential obstacle his field of study is the lack of uniformity in defining and measuring AI-related trust. Using different scales to assess trust can lead to the capture of distinct facets of trust and, consequently, generate contradictory results.

Previous research [51] has highlighted the presence of 2 essential components within the overarching concept of trust in AI systems, "user trust potential" and "perceived system trustworthiness." User trust potential typically encompasses the user's internal factors, such as attachment styles, that influence their trust in AI systems. In contrast, perceived system trustworthiness focuses on external factors, including user experience (eg, efficiency and effectiveness) and perceived technical trustworthiness (eg, accuracy, security, and privacy). The existing measurement tools for trust do not clearly distinguish and separately assess these 2 aspects, which may lead to inaccurate capture of the relationship and misses out on important nuances.

This signals a pressing need for the development and validation of a more consolidated and clearly structured measurement tool for trust in AI. Such an instrument would greatly enhance the field's ability to comprehensively assess trust in AI systems. Furthermore, an intriguing avenue for future research is the exploration of which facet of trust, whether internal factors or external factors, exerts a more pronounced influence on actual engagement behaviors, specifically in terms of actual usage. This question holds significant potential for shedding light on the nuances of trust in AI systems and informing practical applications.

Second, our dependent variable CAI adoption intention was measured with a single item on an ordinal scale. Single item may lack the sensitivity to detect subtle differences or changes in the outcome variable, potentially missing important variations in the data. In addition, measuring CAI adoption intention continuously would capture gradual changes more efficiently, leading to more precise description relationship between dependent variable and other independent variables. Multi-item scales should be used to measure adoption intention continuously in future research to increase validity and reliability.

Third, our use of a news article as a vignette to illustrate the use of CAI in mental health support may have implied a subtle positive valence. This could stem from the portrayal of a CAI as a tool that is able to assist individuals with mental health issues. However, as far as possible, we adopted a neutral tone to the vignette, and future studies could consider the portrayal of CAI as a mental health tool with successful (positive) or unsuccessful (negative) outcomes for more generalizable effects.

Furthermore, it is worth noting that disorganized attachment was not examined in the current study. As the first study exploring the relationship between attachment styles and CAI adoption for psychological support, we focused on more clearly defined variables—anxious and avoidant attachment styles—to enable more interpretable and consistent initial insights in this novel area of research. Future research can build on this foundation by incorporating additional insecure attachment styles to generate deeper and more nuanced findings that inform CAI design. In addition, our research participants were sourced through a web-based platform with participants from a single country (the United States). Future research incorporating more diverse samples are encouraged to address these limitations and enhance the generalizability of the findings. Also, although we have excluded participants with previous CAI counseling experience and the results still hold true for the subgroup that reported being entirely unfamiliar with CAI counseling, we acknowledge that future studies would benefit from clearly distinguishing between indirect and direct exposures from which participants gain their familiarity when measuring it.

Conclusion

In conclusion, our study serves as a pioneering effort in the realm of CAI adoption for mental support, being one of the only papers to examine the impact of attachment styles and perceived trust on CAI adoption. Our findings indicate that perceived trust remains a crucial factor influencing adoption intention; individuals with higher perceived trust are more inclined to try CAI therapies when needed. In addition, attachment anxiety, rather than attachment avoidance, is significantly and positively linked to CAI adoption. These results contribute to the current literature as a good first glimpse into human-CAI relationship and inform the future design of CAI systems, particularly in the mental health setting. By understanding how factors such as perceived trust and attachment styles influence CAI adoption, this study underscores the importance of developing tailored, evidence-based strategies to foster user trust and address specific concerns related to mental health applications. Such strategies may potentially help to mitigate potential risks of CAI adoption, such as overreliance or misuse, ensuring that CAI technologies are safely and effectively integrated into mental health care services. Furthermore, these findings highlight the need for continuous evaluation and adaptation of CAI features to better meet the diverse needs of users, ultimately promoting more positive outcomes in mental health support. Future research

XSL•FO
RenderX

should build upon these insights to further refine CAI applications, ensuring they are both user-centered and ethically sound, thereby enhancing their potential to provide effective and accessible mental health care solutions.

Abstract

Background: The introduction of artificial intelligence (AI) into health care has sparked discussions about its potential impact. Patients, as key stakeholders, will be at the forefront of interacting with and being impacted by AI. Given the ethical importance of patient-centered health care, patients must navigate how they engage with AI. However, integrating AI into clinical practice brings potential challenges, particularly in shared decision-making and ensuring patients remain active participants in their care. Whether AI-supported interventions empower or undermine patient participation depends largely on how these technologies are envisioned and integrated into practice.

Objective: This study explores how patients and medical AI professionals perceive the patient's role and the factors shaping participation in AI-supported care.

Methods: We conducted qualitative semistructured interviews with 21 patients and 21 medical AI professionals from different disciplinary backgrounds. Data were analyzed using reflexive thematic analysis. We identified 3 themes to describe how patients and professionals describe factors that shape participation in AI-supported care.

Results: The first theme explored the vision of AI as an unavoidable and potentially harmful force of change in health care. The second theme highlights how patients perceive limitations in their capabilities that may prevent them from meaningfully participating in AI-supported care. The third theme describes patients' adaptive responses, such as relying on experts or making value judgments leading to acceptance or rejection of AI-supported care.

Conclusions: Both external and internal preconceptions influence how patients and medical AI professionals perceive patient participation. Patients often internalize AI's complexity and inevitability as an obstacle to their active participation, leading them to feel they have little influence over its development. While some patients rely on doctors or see AI as something to accept or reject, these strategies risk placing them in a disempowering role as passive recipients of care. Without adequate education on their rights and possibilities, these responses may not be enough to position patients at the center of their care.

Introduction

Background

There is significant enthusiasm about the potential applications of artificial intelligence (AI) in health care [1]. In particular, the AI subtechniques of machine learning (ML) could, in the foreseeable future, be widely implemented to support triage, diagnosis, and treatment—especially in the form of clinical decision support systems (CDSS) [2,3]. With AI's implementation, there are significant hopes that AI can alleviate an overwhelmed health care system by supporting doctors in their daily decisions and data analysis tasks. However, the medical AI community must navigate complex ethical, technical, and human-centered challenges to exploit these potential opportunities [4]. With the introduction of AI, health stakeholders will need to re-evaluate commonly held conceptions about what constitutes good health care. For example, there are unanswered questions about how the introduction of AI will affect the patient's role in AI-supported health care and whether their preferences and expectations align with common ethical paradigms and practices such as shared decision-making (SDM).

Health care, is at a crossroads, grappling with the need to provide quality care while managing vast amounts of medical knowledge and data. Health data are now a part of care interactions, and analyzing it with AI is viewed as essential for improving health care outcomes by providing insights that support better clinical decisions [2]. While AI is a broad term, it is often defined by its behavior and functionality [5]. For example, the High-Level Expert Group on Artificial Intelligence of the European Commission defines AI as systems designed by humans to achieve complex goals by perceiving their environment, processing data, and deciding on actions to meet those goals [6]. Based on this definition, AI encompasses a wide range of technologies, from ML techniques to large language models such as ChatGPT or DeepSeek. Regardless of the underlying AI technique, the road ahead for AI CDSS is to identify whether AI can deliver enough value to match its expectations and whether it can do so within the limits of ethical behavior. Despite AI's hype, a comprehensive exploration of this technology's ethical implications and boundaries remains elusive, especially regarding patients' preferences and how to involve AI in their care ethically.

Historical accounts showed that patients used to have a passive acceptance role where they mostly followed doctors' suggestions and did as they were told. Although now considered ethically unacceptable, past paternalistic models in health care limited patients' freedom of choice and participation in decision-making [7]. Understandably, new acceptable ethical models focus on person-centered care, enhancing patient participation, and supporting SDM. In SDM, a collaborative process between patients and health care professionals, it is essential for patients to be actively involved in their care [7,8]. In that sense, patient participation is an essential step of person-centered care as it focuses on involving patients in the decision-making process or other aspects of health care, including education, goal setting, self-monitoring, or taking part in medical examinations [9]. Person-centered care gives patients a central role by including them in the care process and adapting to their needs and expectations to support patient empowerment [10]. This empowerment considers the complexity of subjective experiences (eg, hopes, fears, and views) and emphasizes the importance of sustaining patients' autonomy and self - determination in their care [10]. The expectation is that empowering patients allows them to engage in their care and gives patients a sense of control over their health journey, making them an active central part of their care. Empowering patients can make them more satisfied with their care, have a deeper engagement in their health, adhere more easily to treatments, and better cope with the uncertainties common to the progression of chronic diseases [11,12]. As the World Health Organization stated in their framework for person-centered health care, there must be a shift towards health systems designed for people, coproduced for their needs and preferences, and consciously adopting the perspective of individuals, families, and communities [12]. Involving patients in their care and providing them with the resources and tools to promote active participation better equips them to understand their health journeys and ultimately make the decisions that align with their values and preferences [7].

A 2023 systematic review found that while most patients and many health professionals have a positive attitude toward AI in health care, concerns persist about whether it can genuinely enhance care quality and improve patient experiences [13]. The authors highlighted the importance of human agency in AI-enabled health care. While health care professionals emphasized their agency and focus on their important role in AI development and implementation, discussions rarely addressed the participation and role of patients in AI-supported care. Debates have largely focused on how AI-generated health information, such as self-monitoring tools, could empower patients. However, they often overlook whether AI can truly support patient empowerment and foster person-centered care [14].

Researchers have focused on investigating the factors that influence whether patients accept or reject the use of AI, with particular emphasis on their preferences regarding data sharing and privacy. Understanding these preferences is crucial, as they shape patient trust in AI-supported systems and determine their willingness to engage with AI in health care [15-19]. However, few research studies have focused on understanding the role (engagement and participation in decision-making) that patients would like to have in AI-supported care. In the United Kingdom, although patients saw AI positively, they reported that to be comfortable with AI use, there must be the intention to preserve their choices (regarding whether AI is [or not] used and the ability to contest AI's care decisions) [20]. However, most patients expected doctors to retain final discretion over the care plans and act as guardians protecting them from potential harm [20]. Similar to previous findings, these results show that although patients want to be engaged, how actively they wish to participate in decision-making is variable and possibly self-contradictory [21,22]. Patients may face many obstacles to participating in SDM. For example, a lack of knowledge and low health literacy could affect patients' confidence to make

XSL•FO
RenderX

decisions and reduce their willingness to participate in decision-making [9]. As the preferences of patients are individual, variable, and contextually dependent, patients could either decide to take a leading role in SDM or not exercise their right to participation during AI-supported care [14].

There is a risk that AI could create new paternalistic structures where AI holds the power to indicate how to act in patient care without much consideration of patients' preferences and needs. To an extent, patients' acceptance of AI could depend on their general perception of AI, their characteristics (eg, age, interest, and gender), and their previous experiences in care [21,23]. If patients have experienced paternalistic decision-making during their care—where the doctor said what should be done—they may be more likely to accept (or even endorse) paternalistic care [21]. In that sense, people developing and using AI in health care should pay particular attention to avoid a blind acceptance of paternalistic AI implementations, which could disincentivize patients' participation and risk their autonomy and self-determination.

Objective

The introduction of AI into clinical practice brings potential challenges, particularly in terms of patient participation and empowerment. Despite AI's promise to enhance health care, there are concerns about whether AI technologies can meet the ethical standards of medical practice [24-26]. Patients and professionals alike may acknowledge the risks associated with AI, particularly to autonomy and patients' and doctors' decision passivity [27,28]. If patients are not properly educated about their rights and the possibilities that AI offers, they may feel disempowered, accepting AI as an inevitable part of their care without fully understanding its implications. This raises questions about the extent to which AI can risk patient empowerment and consequently, SDM. Therefore, when the goal is to maintain person-centered care and support patient empowerment, it is vital to understand the elements that define patients' preferences concerning participation in decision-making during AI-supported care.

This research aims to explore the role patients prefer to take when AI is involved in their care, offering a critical analysis of the external and internal factors that may influence their level of participation in decision-making. Using a qualitative approach, we examined the perspectives of both patients and professionals working with medical AI (referred to as AI professionals). With a focus on person-centered care, this study aims to amplify the patient's voice by acknowledging their experiences, perceptions, knowledge, attitudes, and beliefs that shape their preferred role and their envisioned interactions with AI in health care. The insights gained will encourage both patients and professionals to critically engage in discussions about patient preferences, and establish the boundaries and conditions needed to support patient empowerment in the context of AI-supported health care.

Methods

Qualitative Approach and Context

The qualitative approach for this study is semistructured interviews for data collection and reflexive thematic analysis (RTA) as our analysis framework. Semistructured interview guides were used for data collection, reflecting the study's exploratory approach and allowing for in-depth conversation with every participant. We used RTA as our analytical framework because it allowed us to situate the analysis in the context of health care interactions and determine in-depth and implicit patterns of meaning across the data [29]. According to Braun and Clarke [29], RTA is well-suited for research that requires a nuanced exploration of complex attitudes and beliefs—such as those surrounding AI in health care. With evolving technology such as AI, RTA allows to interpret the data in depth capturing both explicit content and underlying themes, such as ethical considerations or relational dynamics. As a postpositivism methodology, this method focuses on the depth and richness of the insights gained, contributing to a more comprehensive understanding of participants' views [30]. This methodology enabled us to contextualize our analysis for health care and uncover intricate and underlying patterns of meaning within the available data [29]. This study follows the standards for reporting qualitative research (SRQR) [31].

The data for this manuscript is drawn from a larger research project titled "Ethical and Legal Issues of Mobile Health-Data: Improving Understanding and Explainability of Digital Transformation and Data Technologies Using Artificial Intelligence (EXPLaiN)," funded by the Swiss National Science Foundation. The research group acknowledged their positionality as researchers and how their ethical backgrounds, which make patient empowerment vital, informed the interpretation of these results. However, to prevent a single or superficial view, our research group engaged in frequent discussions and included different academic backgrounds (philosophy, ethics, medicine, and psychology).

Participants

Recruitment

We recruited 2 subgroups of participants, patients, and AI professionals. To recruit patients, we approached patients seeking outpatient care at the University Hospital of Basel. Participants were purposely sampled to generate a diverse sample that included a mix of older and younger patients. Therefore, we recruited patients consulting the hospital for the cardiology and infectious diseases departments as they typically are a large outpatient group. Patients must be 18 years or older, consented to participate in 30- to 45-minute interviews in English, Swiss German, or German, and signed the consent form. There were no restrictions on patients based on disease history or diagnosis. Patients were contacted face-to-face at the hospital during their scheduled consultations. Researchers made weekly visits to the hospital, contacting on average 5 patients during each visit. During face-to-face recruitment, most rejections involved patients expressing a lack of interest, time

XSL•FO
RenderX

constraints, or practical challenges like language limitations or hearing impairments.

AI professionals were selected purposefully from a range of disciplines, including medicine, bioethics, public health, philosophy, psychology, economics, law, and computer science. To be included, participants needed to have professional experience with medical AI and hold a senior position in either academia or the private sector, excluding PhD students, interns, and early-career professionals. Examples of participants' roles included professors at universities, senior managers of AI-focused companies, and senior data protection officers in hospitals. Participants were identified based on their involvement in medical AI through projects, products, or research, and were contacted via publicly available email addresses on institutional or corporate websites. A snowball sampling technique was also used, with participants invited to refer others who met the inclusion criteria. Using purposive sampling based on experience allowed us to produce rich, articulated, and expressive data [32]. The initial contact with participants was made via email, inviting them to take part in an interview. The email provided an introduction to the project, outlining its objectives and explaining what their participation would involve, including details on time commitment, audio recording, transcription methods, and the format used for data pseudonymization.

Sample

The first phase of the study involved 41 semistructured interviews with global participants exposed to medical AI, representing various disciplines including medicine, philosophy, law, ethics, public health, and computer science. These interviews explored the barriers and facilitators to implementing AI in clinical settings, particularly in relation to CDSSs and wearable devices. The second phase involved 21 semistructured interviews with patients assisting the University Hospital in Basel, Switzerland. The original study aimed to understand current perspectives, attitudes, knowledge, and challenges regarding AI's role in health data analysis and its potential to support decision-making for both patients and AI professionals. This analysis focuses on a subset of the data collected on AI professionals and patients located in Switzerland or Germany. The goal was to create geographically comparable groups to the patients that lived in the German-speaking part of Switzerland in Basel close to the border with Germany. This translated into a selection of 50% of the AI professional sample and 100% of the patient sample.

Ethical Considerations

The Ethics Committee of Northwest and Central Switzerland approved all methods and this study according to the Human Research ACT Art. 51 (approval number: AO_2021-00045). According to the Ethics Committee of Northwest and Central Switzerland, interviewing professionals were exempt from the Swiss Human Research ACT given no sensitive data was collected. Therefore, the professional interviews required no formal written consent and only needed verbal consent at the beginning of the interview. Patients' written consent was collected and stored locally at the University compounds as per ethical approval protocol. All personal data were pseudonymized and securely stored on the University of Basel's server, with access to the key restricted to the research team. Any potentially reidentifiable data were excluded from data analysis and publications. Participants did not receive any compensation.

Data Collection

Three members of the research team (LAO, NB, and GL) recruited participants and conducted one-on-one semistructured interviews. LAO completed 11 patient interviews. After training with LAO, NB conducted 10 patient interviews in Swiss German, which allowed patients to communicate more comfortably in their native language. Patient interviews, held at the hospital, were conducted in either English or German and recorded with an audio device. GL led 7 and LAO 13 interviews with AI professionals, recorded via Zoom and stored locally. All interviews were conducted between March 2021 and May 2023. LAO and GL transcribed the English interviews verbatim from AI professionals and patients, while NB transcribed those conducted in Swiss German or standard German.

The research team designed interview guides for each subgroup, focusing on key areas: general impressions of AI, the AI-patient relationship, and the AI-doctor-patient relationship. Although the interview guides were largely similar, the version for AI professionals included additional in-depth questions, exploring topics such as interpretations of AI regulations and specific AI concepts. Vignettes were used during both sets of interviews as a tool to enhance discussion among the participants. Using vignettes which are brief descriptions of scenarios, enables researchers to explore participants' attitudes and beliefs without requiring extensive familiarity with the research topic. This approach is especially beneficial for studies on technology applications, as vignettes provide theoretical advantages when exploring abstract or complex topics that may be challenging to discuss directly [33,34]. This is especially evident in medical AI where there are potential implementation scenarios but still limited real-world experiences. The questions were organized into 6 sections: introductory general questions on AI use in medical practice, context-specific questions on AI-patient relationships (using vignette 1 with a wearable device), context-specific questions on doctor-patient relationships involving AI (using vignette 2 with CDSS), and concluding questions. While we acknowledge that responses to vignettes are often shaped more by personal views and moral intuitions than by participants’ theoretical knowledge, the way participants interpret these scenarios reflects how they navigate and make sense of their daily lives [34]. The vignette approach benefits qualitative studies by eliciting authentic responses that mirror real-life reasoning and allow participants to project personal values and intuitions onto scenarios, offering deeper insights into their attitudes and beliefs, and enhancing the richness of the data collected [33,34]. The interview guides are available as Multimedia Appendix 1.

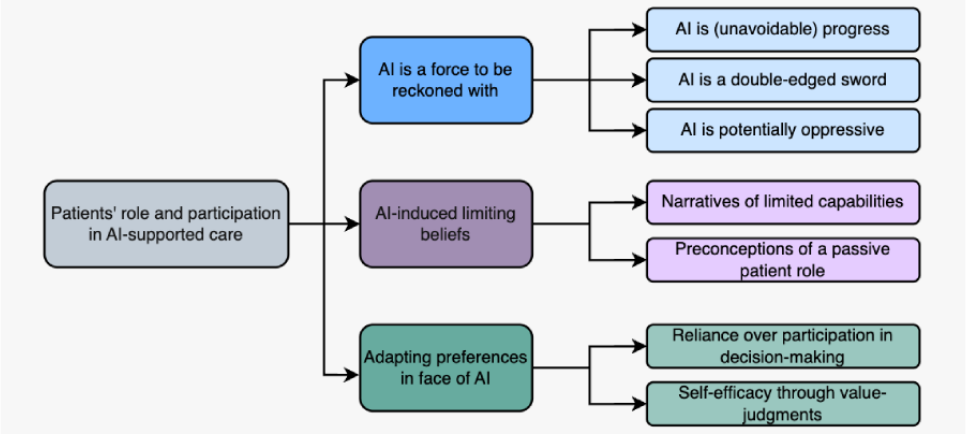
Data Analysis

The authors (LAO, MR, and NB) led the analysis, and all the coauthors supported the analytical process. We carried out inductive and deductive thematic coding of the data, initially line by line, using descriptive or latent labels (MAXQDA software; VERBI Software). AI professionals' and patients’

XSL•FO
RenderX

interviews were coded initially separately. LAO and GL coded all the AI professionals' interviews. LAO and NB coded patient interviews. Researchers merged AI professionals' and patients' data and their initial codes. The authors (LAO, MR, and NB) developed overarching themes and subthemes to identify commonalities across the data, which were then reviewed by the entire research team. After recurring discussions and refinements, the team created 3 major themes illustrating how patients and AI professionals envision patients' role in AI. All interviews were analyzed in the original language (German/English). The researchers' backgrounds played a key role in shaping the interpretation of the data, leading to the development of themes that highlight often-overlooked ethical concerns, particularly the challenges to patient participation and empowerment. We focus on questions related to, person-centrism, a widely acknowledged paradigm that helps to question and reflect on power structures and how these affect patients. While our positionality influenced the analytical process, we actively tried to reduce biases through ongoing discussions within a multidisciplinary research team, incorporating expertise from philosophy, ethics, medicine, and psychology. This collaborative approach ensured a more nuanced and comprehensive analysis.

We aimed to identify areas of consensus where patients and AI professionals shared views, fears, and beliefs about AI in health care. To illustrate the presented findings, we used representative (disidentified) extracts. The patient participant (PT) acronym recognizes patients' quotes, and the AI professional participant (AE) recognizes AI professionals. To improve readability, the authors removed filler sounds and double words from the data presented in this paper. For this publication, the authors translated the extracts as required (LAO, NB, and MR).



Results

Overview

The study included 2 subgroups: 21 patients and 21 AI professionals for a total of 42 interviews. A couple was interviewed together for the patient group (PT9.1 and PT9.2). Given that AI in health care is a multidisciplinary area, most professionals found themselves at the intersection of 2 or more areas of experience; for example, 8 participants were doctors with AI experience. Patient participants came from diverse educational backgrounds and were all recruited in Basel, Switzerland. AI professionals represented fields such as medicine, sociology, law, and computer science, with 13 based in Switzerland and 8 in Germany. The gender distribution was similar in both groups, with 7 women and 14 men among patients, and 6 women and 15 men among AI professionals. Detailed sample characteristics are available in Multimedia Appendix 2.

The results of this research are structured around 3 key themes. The first theme explores the perception of AI as an inevitable and potentially disruptive force in health care, reflecting both optimism and concerns about its transformative impact. The second theme examines how patients perceive limitations in their own capabilities, which may hinder their ability to actively participate in AI-supported care. This includes uncertainties about how much patients can influence AI systems, concerns about decision-making authority, and fears of losing personal agency. The third theme describes patients' adaptive responses to AI integration, such as relying on expert guidance or making personal value judgments that lead to either acceptance or rejection of AI-supported care. These themes collectively illustrate the complex and often conflicting ways in which patients navigate the presence of AI in health care settings (Figure 1). To strengthen the results, key ideas will be supported by participant statements, with identifiers (eg, [PT8]) indicating who expressed each idea. However, this does not mean these participants were the only ones to share this perspective; rather, these examples were chosen as particularly clear or representative illustrations of themes. Full quotes can be found in the theme tables for context.

AI Is a Force to Be Reckoned With

Overview

This theme explores the external influences (eg, narratives, myths, science fiction, and fears) that shape the perspectives of patients and professionals regarding AI in health care (Table 1). Either positively or negatively, participants considered AI as a forceful driver of change. Most patients and some professionals determined that AI is an unavoidable future or thought AI to represent primarily positive progress. Some patients described AI as a double-edged sword that depends on humans' use. At the same time, some professionals discussed this risk regarding the involvement of private companies in AI development. In particular, patients expressed concerns that AI may have an oppressive potential as it could excessively monitor their health or exert control over their lives and health decisions. All these external accounts influence the expectations of a future with AI for patients and professionals and the participatory preferences of patients.

Table 1. Data extracts representative of the theme "AI is a force to be reckoned with."

Subtheme and participant	Data extract
AI[a] is unavoidable	
[PT1][b]	*Because medical progress. As simple as that. So, why should I use something which has less diagnostic or therapeutic powers when something better is available? (...) technology is an improvement to the old times. Isn't it?.*
[PT5]	*I cannot change it anymore. It is simply part of the present age with digitization, one cannot stop it.*
[PT10]	*Yes, we have no other choice left. Because in 10 years you have no more doctors and afterward you should be able to treat more people with fewer people. And, that is only possible by automating and combining certain things. It is a must.(...) And there we need computers as support, which then tells you, it narrows the whole thing down and then the doctor has to come. But otherwise we will no longer make it.*
[AE12][c]	*I guess you cannot avoid it. It's already here. (...) So, it's not, I don't think the question is to be in favor or against machine learning or whatever. (...). It's just here, and now we need to deal with it.*
AI is a double-edged sword	
[PT19]	*So I think it [AI] will come. I am quite sure that this will come. And as long as it comes to the fact that humans, animals, the environment could benefit from it, I am very much for it.*
[PT8]	*I think it [AI] has opportunities and risks; it is always, with everything the question of who does what with it. I think you can use it for many positive things, and you can also abuse it a lot. So, I think, maybe I hope, that it is more of a positive one. But it is through all the technical things, I can use everything in one or the other way. I can use a drone to take beautiful pictures and deliver parcels, or I can use it somehow to wage war somehow, and this will potentially be done with an AI.*
[AE16]	*The other is that you have young people, they do startups, they are idealistic people, and they are trustable people, but they are naive people. And they don't weigh properly the good their system could do, and there is no doubt that these systems can do good, but they don't measure the bad, the pain these systems can do. They understand that it is important not to miss a breast cancer in a woman. They don't understand the shock and the energy, and the pain that the fear of a breast cancer can induce in a person for months because you have something that said you have a risk. And for these people, from one second to the other, the sun is away, the day becomes night, and every minute of their life becomes anxious. And they don't measure the costs, not the money, but the human cost of false positives.*
[AE13]	*There are going to be people who use it for good application and people who use it to exploit, right? And that's just the way the world is, right? So, I don't think anything is inherently good or bad, but it's how something is then utilized. And there will be for sure bad actors and bad players.*
AI is potentially oppressive	
[PT15]	*What will be, so it is the question, whether you really have to know that in detail now [their health data] and then give warnings. Life is vulnerable and that can end at some point and so on. Whether you don't question everything a little too much now and have everything ready and so on. I'm a little against it.*
[AE4]	*I think it's very, yes, science-fiction based, irrational fear. But yeah, I mean we tend to be fearful of many things and in general we overreact to fear. So, in very strange circumstances we are kind of risk-takers, but most of the time we tend to be overly protective and overly restrictive. Because we overestimate these kinds of risks, due to misinformation, due to specific narratives that are created, specific images that are present. It's sufficient for this kind of fear to just have one story, you know almost, one urban legend that keeps returning, and people just kind of attached to that and yeah basically stop thinking about this in a rational manner.*

AI Is (Unavoidable) Progress

Most patients and some professionals saw AI as representing unavoidable progress. From a positive perspective, AI is desirable and a token of medical progress as described explicitly by one participant (PT1). Although patients had a generally positive outlook on the progress brought by AI, they also felt a lack of empowerment. To an extent, patients thought that they could not influence the development of AI (PT5). Others described that AI could not be changed or stopped as it is already used in other systems for daily tasks (eg, search engines and bank systems; PT10). To justify their view that AI is inevitable, patients and professionals focused on the potential benefits or the faculties AI has to overcome human limitations. In particular, one patient (PT14) felt powerless against the desire to increase (process) efficiencies, making AI an incontestable development.

AI Is a Double-Edged Sword

The belief that AI constitutes unavoidable progress has prompted questions regarding its application and AI's potential double-edged nature. Some patients reflected on the conditions for positive progress and required AI to be beneficial to accept it, for example; either beneficial for themselves or everyone (PT19). However, depending on the use, some patients fear AI may be exploited to benefit private companies or the hospital system instead of patients (PT8). Some professionals referred to the challenges of having private companies participating in health care as they might not understand the health care system or might look to take advantage of patients' data for their interests (AE16 and AE13). Patients felt a lack of control and protection regarding the intentions of the people using or developing AI. In their view, technology depends more on who determines its goal than its technical characteristics. In that way, the double-edged sword potential of AI expressed a lingering fear of (other) people's goals and not AI in itself.

AI Is Potentially Oppressive

In contrast to the use-dependent interpretation of a double-edged AI, several patients considered that AI could become an overlord in their lives. Concerning AI notifying them directly of health-related information (ie, changes in heart rhythm via a smartwatch), patients felt irritated or stressed (PT15). To some patients and professionals, this flow of information, often thought to empower patients, is undesirable and almost felt outside their control. In contrast to patients, professionals did not often mention the fear of an oppressive AI. Two professionals explicitly expressed that basing AI judgments on works of fiction could create dystopian fears among patients (AE4). In some respects, patients felt a tension between a potentially oppressive AI that might also be unavoidable and a desire to remain in charge of their own lives and health. Some patients explicitly agreed and expressed their views on science fiction tales of AI oppression. For example, 2 patients (PT3 and PT18) who expressed their desire not to be controlled by AI also mentioned how their first encounter with the topic was science fiction movies.

AI-Induced Limiting Beliefs

Overview

The external view that AI is a force for change appeared to have influenced the (self) evaluation of patients' capacities to handle the changes brought by AI (Table 2). Patients and professionals believe patients have limitations in engaging with AI. Both groups, in one way or the other, have accepted these limitations and put patients in a passive role where health care professionals need to shelter them from AI. These views will likely impact the expected role and preferences in the decision-making of patients, even if unintended.

Table 2. Data extracts representative of the theme "AI-induced limiting beliefs."

Subtheme and participant	Data extract
Narratives of limited capabilities	
[PT17][a]	*I don't feel intelligent enough to judge it [AI]. It exceeds my knowledge.*
[PT6]	*You can slowly say at my age, 76, that there are things [when asked about AI] that you see from a certain distance. On the other hand, 10 or 20 years younger, you have to be there, that is very clear. But I am no longer in the work process, and financially, it is no longer a problem, so for certain things, someone can say I don't care.*
[AE9][b]	*Like, I mean, realistically you can say: "okay, there's a need to disclose a lot of things" [about AI] but of course, also patients can only meaningfully process so much information.*
Preconceptions of a passive patient role	
[PT11]	*It's difficult, so I don't see it. Now as a patient, I come there and then something is offered to me, and then I can as a patient, what could I do differently myself.*
[AE8]	*Patients are not, I don't think they are responsible, that they, they should know it [about AI] because they only just there to receive the treatments and, maybe, follow the advices of the doctors. But, I don't think they have the responsibility, and I would, don't give them the responsibility to understand the systems or to understand the recommendations or other outcomes. I would keep them out of this.*
[PT7]	*Is it my right to say?[about how to support AI implementation]. Such questions I have been asked for the first time. I never thought about it. But yes, it is good to know that you want to know what patients think and listen to their opinion and let it play a part. I appreciate that.*

RenderX

Narratives of Limited Capabilities

Several patients have internalized limitations regarding their roles and capabilities. Some patients felt AI is easy for young people or those considered experts (P17 and P6). In particular, patients reflected on their limits in understanding AI. Some patients further justified their limitations due to a lack of interest in technology or that they do not have to understand or relate to AI. In a way, AI was not for them but possibly for other (younger, smarter, and more interested) people.

Beyond their self-assessed lack of capabilities, some patients said that explanations provided by others might not help them feel more secure about their capacities, even if doctors provided these explanations. Like patients, several professionals questioned whether patients have the competencies to handle AI or if explanations could overcome the perceived limitations (AE9). Both groups accepted that AI is a complex subject and dismissed the opportunities for patients to acquire the skills to handle AI. However, many patients mentioned they actively use other forms of technology, such as smartphones or smartwatches.

Preconceptions of a Passive Patient Role

Beyond the perceived limited capabilities of patients to handle AI, patients position themselves in a passive (receiving) role. Several patients perceived that concerning AI, they would do as the doctor said because doctors are the experts or patients cannot do anything differently (PT11). A few professionals who determined that patients might not need to be involved in AI expressed the view of a passive patient (AE8). Protecting patients from the complexities and dangers of AI also meant excluding them from its development and use. This view implicitly removes the patients' power to decide whether and how to participate in AI. Consequently, a few patients accepted their lack of participation as the standard of care, making them surprised or overwhelmed when questioned about their preferences and ideas regarding AI (PT7).

Adapting Preferences in the Face of AI

Overview

Attributed and observed limitations may have influenced how patients and professionals perceive the patient's role in AI. These limitations have required patients to adapt—consciously or not—and find strategies to maintain their self-efficacy at least to a degree by handing over the responsibility for AI to their doctors. For patients, another way to regain decisional authority was to judge the value of AI for their lives and decide whether to accept or reject it depending on their preconceptions and their general technology-related values. These adaptive strategies influence what patients think is possible regarding their participation in AI and what they see as optimal and feasible (Table 3).

Table 3. Data extracts representative of the theme "Adapting preferences in face of AI."

Subtheme and participant	Data extract
Reliance over patient participation in decision-making	
[PT17][a]	*In principle, I have more confidence in doctors, experts. And before I do not wish that the devices tell me "oh they have a problem here, there", before experts get this information. You [the expert] will see how serious or how the situation is, they will sort and what is necessary you will tell me. This is the right process, I think.*
[AE13][b]	*This is the trust that you give a doctor that they do their job without you telling them what to do, right? So, it's like, if a radiologist is looking for cancer or something, and they use a machine learning algorithm to better understand where, what could be like cancer cells or not, right? You don't care, right? Maybe, it is different if you are, this is part of the doctor's role and job, and if it is something like this where it is a tool that exclusively doctors use, I don't really think there has to be much communication to the person unless if they are curious and ask.*
[AE12]	*Probably the less you know, the more you trust. (...) And then, if you know too much about this [AI], the technical aspects, maybe you don't trust it anymore. (...) So, you can imagine anything, you know, depending on your knowledge.*
Self-efficacy through value judgments	
[PT11]	*No. Because I have my computer and otherwise enough electronic gadgets. I don't need [AI-enabled smartwatches], no. I can imagine that [other people use them], but I do, well, I have somehow my attitude to life that I want to concentrate on myself and don't want to be distracted as much.*
[PT6]	*I am not against it [about AI]. And other people that advocate against it, I mean this was crazy during the pandemic how those two disparities (…) it is mere ideology.*
[PT5]	*And that's exactly how it is, actually. Either I say, I trust in the technology that it does it correctly, that it is checked, that the result is correct. Or I reject it and say "no, I can't imagine that". But that is again the personal feeling of the patient, where he says, "yes, I could imagine that now", the result or "no, I don't want that".*

[a]PT: patient participant.

[b]AE: AI professional participant.

Reliance Over Patient Participation in Decision-Making

The notion of a passive role is ingrained in patients' beliefs that those providing care know what is best for them and could potentially make better decisions than themselves. Therefore, patients chose to rely on doctors to protect themselves from the distress of using AI, mainly as they felt limitations regarding their capabilities. Most patients mentioned they are more likely to trust and rely on doctors because doctors are the experts, they already have a relationship with them, or they inherently cannot trust technology (PT17). To an extent, some patients wanted doctors to take responsibility for AI and decide whether and when AI should be used.

A few professionals agreed that doctors' responsibility entails making these complex decisions regarding AI use. The professionals' views come from an underlying assumption that AI is a support tool and that SDM can come after the AI (diagnosis or treatment) support (AE13 and AE12). Reliance on doctors is an acceptable and expected behavior for both groups. However, it is also possible this behavior is not an active decision but a consequence of seeing AI as unavoidable, complex, and limiting for patients.

Self-Efficacy Through Value Judgments

Most patients judged the value of AI depending on how they saw technology in general or how they assessed AI's usability for their (current) care plan. Beyond questioning the accuracy or relevancy of AI's information, patients based these judgments on their personal understandings and views about technology. In this way, patients aimed at preserving their decision self-efficacy often categorically accepting or rejecting AI. Depending on these judgments, their choices would change between wanting and not wanting to be involved in decision-making for AI-supported health care (PT11 and PT6). A few patients, for example, valued their openness to new technologies as positive, which meant they would inherently be inclined to accept AI in all forms. In contrast, other patients categorized themselves as uninterested or mentioned not needing AI at all. Both groups adapted their preferences based on their personal values and what they saw as possible for the way they live their lives. The strategy of patients to judge the value of AI for their own life and decide whether they would like AI to be involved in their care, helps them preserve their self-efficacy and retake the leading role of decision-making regarding AI's use for their care (PT5). Positively, patients felt capable of making their own choices (especially related to AI-enabled smartwatches). However, there was an ambivalence and polarization between acceptance and refusals. Patients base their value judgments on ideologies of life (eg, whether they are interested in knowing more health information or being informed about health problems) instead of factual information. A few patients reflected on this ambivalence and how to take either position.

Discussion

Principal Findings

This paper presents empirical evidence that voices patients' concerns about AI-supported care and challenges to patients' participation in decision-making. Through interviews with patients and AI professionals, we found that patients are often allocated to a passive standpoint, where they feel unable to participate, a resource to follow their doctor's recommendations, or make precipitated value judgments about AI's actual benefits or risks. In that way, this study revealed that external narratives of AI as a force of change have influenced how patients perceive their role and limitations to participate in decision-making. The insights that patients have adapted to limitations by accepting or endorsing a passive role are concerning because patients unknowingly may be giving away their decisional power.

In many ways, the perception of AI as an inevitable and potentially disruptive force in health care reflects both optimism and concerns about its transformative impact. This includes visible uncertainties about how AI systems function, concerns about decision-making authority, and fears of losing personal agency. The themes of this paper, collectively, illustrate the complex and often conflicting ways in which patients navigate the presence of AI in health care settings.

Comparison With Prior Work

Previous research about patients' views focused on understanding how they see AI rather than how patients could participate in decision-making in AI-supported care and remain empowered. A scoping review of qualitative research found that stakeholders (eg, doctors and patients) see AI as mostly positive but are cautious about its application [35]. Although the availability of patients' perspectives in the scoping review was limited, our findings correlate to the sentiments expressed by other patients worldwide and their ambivalent views about AI. Several researchers have found that patients' positive evaluation of AI depended on the possibility of having oversight by doctors [15-18,35]. For example, patients in Germany had high confidence in their doctors' abilities to work with AI, but it was unclear if they favored AI or saw AI as an unstoppable development [18]. These findings correspond to our results, in which patients desire their doctors to handle AI and perceive AI as complex and unavoidable. Our research offers further in-depth analysis of how these views are expressed and potentially uncovers how patients and professionals hold these perceptions.

The formation of person-centered care requires that patients are (and feel like) equal partners in decision-making and that their knowledge, wants, and wishes are considered [36]. Therefore, the goal of care shifts from informing patients about diseases to creating an informed space in which patients' values and preferences are represented and respected. However, sharing information about AI to ensure that patients are informed might be challenging. For example, during our interviews, patients and professionals questioned whether patients could be informed enough to understand AI. Bjerring and Busch [36] state that the inherent complexity of AI systems, especially those with black-box decision layers, is not conducive to person-centered care because of the challenges of understanding and explaining AI. However, theoretical knowledge is not the only possible provision of an informed space. Patients could contextualize their knowledge, recognize the limits of their expertise to seek information from experts, and be empowered enough to decide

XSL•FO
RenderX

on a particular action depending on what it means "in their own world" [37]. Therefore, their beliefs and values could affect their decisions more than their factual AI knowledge because it is not expected or attainable that patients are omniscient. As seen in the interviews, patients based their decisions on what they believe and value more than what they know. Understanding how patients expressed and constructed these beliefs and how they affect the desired versus expected participatory level is helpful in supporting person-centered care.

All participants recognized that AI might become a health care presence, leading to social and care changes. Although there was no overall positive or negative outlook regarding these changes, myths and preconceptions of AI informed patients' perceptions. Previous research has found that myths regarding AI behavior are a common point of discussion in media and science fiction works [38-41]. Therefore, the image of AI is constructed from the underlying hopes and fears of how AI can improve or harm our future [38,39,42]. During the interviews, it was apparent that the myths of a powerful AI that is also complex and overbearing informed our interviewees' hopes and fears, in particular for patients. These perceptions are a potential driver of the participatory limitations patients and professionals perceive. For example, it is challenging to preserve self-determination if something is an unavoidable self-fulfilling prophecy. Although hopes and fears could be detached from the current reality of technology, they influence how patients envision their interactions with AI and what patients see as possible. Debunking myths and communicating with patients could be a tool to overcome preconceptions and indirectly encourage them to consider participation in decision-making in AI-supported care. Media and AI professionals may need to counteract these perceptions and communicate with patients about AI in a balanced way.

Patients might be willing to accept soft forms of paternalism where doctors handle AI and involve patients after the initial AI decision support. However, previous reports found that patient-controlled or SDM was perceived as more satisfactory and higher quality, even if a patient preferred a passive role [43]. It is possible that patients are undergoing a process of adaptive preference formation where they are navigating the changes AI brings by adapting in ways they see as possible and feasible. Patients might adjust their preferences (passive vs active role) due to the lack of self-trust, as they might see their values, ideas, and fears as unimportant, hampering their ability to make authentic decisions [27,44]. However, it remains unclear whether these adaptations are because of external influences such as social expectations or media narratives or if they express their true wishes and follow their personal values. For example, when patients believe AI is beyond their capabilities, they may feel their only option is to hand over the responsibility for AI to others. If professionals endorse the narratives that originated these preferences (eg, patients cannot handle AI), they might legitimize and reinforce something potentially inappropriate or inauthentic for patients. Most patients accept or reject AI "as is" without considering how or if to change AI for their (own) patient advantage. For some scholars, adaptive preferences are inherently nonautonomous as these are only a response to the limitations present in the context [27,44]. Therefore, endorsing these adaptive preferences could jeopardize patients' autonomy in decision-making regarding AI-supported health care and ultimately be an impediment to person-centered care.

When the goal is to encourage patients to participate in decision-making, the insights of our research request to reconsider patient education to support knowledge acquisition, judgment skills, and empowerment aspects simultaneously. Therefore, it requires emotional, behavioral, and educational components [37,45]. Patients must be made aware of their rights and the possibilities they have to decide whether and how to use AI. Moreover, education should clarify that their participatory decisions could affect their satisfaction or what are acceptable practices with AI. The aim is to demystify AI, provide usable knowledge, and support patients' self-assessment of competence and abilities [46]. In the age of AI, institutions and professionals are required to guide patients' learning while still respecting and encouraging their health deliberations [46]. Professionals should stop narratives of unavoidable AI and patients' loss of capabilities. Instead, professionals must promote a view where patients' unique expertise in their symptoms, experiences, and health goals are valuable insights for decision-making. Policy makers might also need to promote person-centered AI by explicitly stating patients' rights and their options for decision-making in AI-supported care. One caveat is that empowerment and participation should not be mistaken for taking an active role as this is not the only option, but rather should include and respect all patient choices ranging from active to passive. The goal is to prevent patients from adapting their preferences due to perceived limitations and encourage them to decide how to participate in decision-making in AI-supported care.

Limitations

One limitation to consider regarding the quality of the interview data relates to the nature of the subject. AI is used as a general term during the interviews to facilitate patient conversation and avoid technical jargon. For our context, the term AI refers to ML and its black-box subtypes, as reflected in the phrasing of the interview questions and vignettes. However, AI is a general descriptor that can be interpreted differently. A few patients and professionals mentioned difficulties involved in using the concept. For example, PT9.2 expressed about AI, "I think the word is wrong or the phrase. Because do you want something artificial or do you want something real? (...) So the term is challenging." Using the term AI could have shaped interviewees' answers because of the fears and preconceptions associated with the term, which may not reflect specific health care concerns. However, AI is commonly used in media communication, and all patients have already been exposed to this term. While this issue was mitigated to some extent by providing vignettes with scenarios of CDSS, it was impossible to completely eliminate the risk of misinterpretations or misconceptions. Differences in language between German/Swiss German and English could also have influenced how patients interpreted and answered the questions. This research was conducted prior to the release of large language models like ChatGPT, resulting in lower general awareness of common AI behaviors and capabilities—a potential limitation of the study.

XSL•FO
RenderX

The recruitment method meant that only those patients with time and interest might have participated in our study; also, the patient sample of this study skewed towards men and older people. AI views and the envisioned patient role may be influenced by gender or cohort. For example, men might have more favorable attitudes toward AI, and older people might have less health and AI literacy, which could affect their levels of self-trust [47]. One couple was interviewed together, which may have introduced biases in their responses. Their presence together could have influenced each other's answers, either consciously or unconsciously, or increased the likelihood of providing socially desirable responses [48]. However, paired-depth interviewing also offers the possibility for dynamic discussions and deeper insight into shared perceptions as observed in our participants. Therefore, the results of this paper should be interpreted with consideration of both its strengths and limitations. The core knowledge of patients about AI was not measured during our interview, which could affect how they answered the questions. Given the qualitative methodology, our findings cannot be extended to a broader population and must be considered in context.

Conclusions

The ideas and preconceptions of patients and professionals about AI have influenced how they see the different possibilities within the patient role. External narratives of AI as a force of change and the fears associated with its potential harms have caused patients to internalize limitations regarding their role and capabilities to handle it. Patients have aimed to navigate AI's changes by adapting their preferences to either rely on those considered experts or by deciding to accept or refuse AI categorically. However, both adaptive strategies carry a potential risk of disempowerment and passivity because patients feel they cannot do much to stop, change, or improve the course of AI in health care. If the goal is to empower patients to be active partners, these adaptive responses might be insufficient to position them at the center of their care. Patients' empowerment and involvement in AI decision-making might be better understood as a dynamic process of balancing expectations and preferences and the realities of the technology and clinical practice. Professionals, institutions, and policy makers must support that patients realize they can have the possibility to help shape AI for health care. The goal is to put patients in a position in which power is manifested not by the ability to do but by the ability to decide how to do it.

Acknowledgments

We would like to thank Dr Tenzin Wangmo for her support during the initial coding of professional interviews. We would also like to thank Mrs Andrea Baettig for her support while recruiting patients at the University Hospital of Basel. The Swiss National Research Foundation (SNF) enabled this work with the National Research Program "Digital Transformation" framework, NRP 77 (project number 187263, grant number 407740_187263 /1, the recipient: Prof Bernice Simone Elger).

Abstract

Background: Alzheimer disease and related dementias (ADRD) are complex disorders with overlapping symptoms and pathologies. Comprehensive records of symptoms in electronic health records (EHRs) are critical for not only reaching an accurate diagnosis but also supporting ongoing research studies and clinical trials. However, these symptoms are frequently obscured within unstructured clinical notes in EHRs, making manual extraction both time-consuming and labor-intensive.

Objective: We aimed to automate symptom extraction from the clinical notes of patients with ADRD using fine-tuned large language models (LLMs), compare its performance to regular expression-based symptom recognition, and validate the results using brain magnetic resonance imaging (MRI) data.

Methods: We fine-tuned LLMs to extract ADRD symptoms across the following 7 domains: memory, executive function, motor, language, visuospatial, neuropsychiatric, and sleep. We assessed the algorithm's performance by calculating the area under the receiver operating characteristic curve (AUROC) for each domain. The extracted symptoms were then validated in two analyses: (1) predicting ADRD diagnosis using the counts of extracted symptoms and (2) examining the association between ADRD symptoms and MRI-derived brain volumes.

Results: Symptom extraction across the 7 domains achieved high accuracy with AUROCs ranging from 0.97 to 0.99. Using the counts of extracted symptoms to predict ADRD diagnosis yielded an AUROC of 0.83 (95% CI 0.77-0.89). Symptom associations with brain volumes revealed that a smaller hippocampal volume was linked to memory impairments (odds ratio 0.62, 95% CI 0.46-0.84; *P*=.006), and reduced pallidum size was associated with motor impairments (odds ratio 0.73, 95% CI 0.58-0.90; *P*=.04).

Conclusions: These results highlight the accuracy and reliability of our high-throughput ADRD phenotyping algorithm. By enabling automated symptom extraction, our approach has the potential to assist with differential diagnosis, as well as facilitate clinical trials and research studies of dementia.

Introduction

Alzheimer disease and related dementias (ADRD) encompass a group of disorders characterized by cognitive and behavioral impairments, which progressively affect memory, thinking, and activities of daily living [1]. Among them, Alzheimer disease (AD) is the most common form of dementia and affects approximately 6.7 million individuals in the United States [1]. Other major types of ADRD include dementia with Lewy bodies (DLB), frontotemporal dementia (FTD; behavioral variant), Parkinson disease (PD), primary progressive aphasia (PPA), and vascular cognitive impairment (VCI), each presenting unique symptom profiles with overlapping characteristics. For example, AD typically presents with memory loss [2]; DLB with visual hallucinations, motor symptoms, and sleep disturbances [3]; FTD with behavioral and language symptoms [4]; and PD with motor symptoms [5]. However, clinical presentations and symptoms vary with neuropathology, which contributes to diagnostic challenges. Documentation of ADRD symptoms often exists solely within unstructured clinical notes in electronic health records (EHRs) without any standardization, and manual chart review is error prone and time consuming. The development of an artificial intelligence algorithm for automatic symptom extraction from clinical notes could significantly aid in overcoming these challenges, thereby offering substantial benefits for diagnosis and intervention strategies. Additionally, the symptom data in clinical notes have the potential to facilitate research studies, for example, studies of the longitudinal progression of symptoms in patients with ADRD or how symptoms are documented, shedding light on both medical patterns and recording practices [6].

Symptom extraction is often performed by manual expert chart review, which is inefficient and labor intensive. Traditional text mining and natural language processing (NLP) techniques, which rely on symptom-related keywords specified by domain experts [7,8], can facilitate the symptom extraction process. For example, Vijayakrishnan et al [9] developed a rule-based NLP pipeline to identify heart failure symptoms using the Framingham heart failure diagnostic criteria. Jackson et al [10] created a unified NLP model for extracting severe mental illness symptoms based on a keyword lexicon crafted by psychiatrists. Moreover, Forsyth et al [11] developed a machine learning model to extract breast cancer symptoms based on a code book developed by physicians. However, these rule-based or keyword-dependent methods are still susceptible to missing semantic relationships and contextual information.

In contrast to traditional NLP techniques, the advent of deep learning–based large language transformer models [12-14] presents a significant improvement by understanding contextual information and semantic relationships in clinical notes. In particular, large language models (LLMs) are adept at recognizing complex patterns and relationships within texts using an attention-based transformer model [15]. For example, a recent study used LLMs to extract cannabis use and documentation in EHRs among children and young adults [16]. In another study, researchers created an LLM-based symptom extraction model that can be applied to extract COVID-19 symptoms from Twitter data [17]. Indeed, by understanding the context of keywords and terminologies, these models can enable more accurate and sensitive symptom extraction.

In this study, we used LLMs [12,13,18] to extract symptoms from the clinical notes of patients diagnosed with ADRD. Symptoms were categorized into 7 domains: *memory*, *executive function*, *motor*, *language*, *visuospatial*, *neuropsychiatric*, and *sleep*, with distinction as impaired, intact, or no information. This method quantified symptom occurrences for further analysis. The overall aim was to develop an effective model for automated symptom extraction, which may not only facilitate the differential diagnosis of ADRD (AD, DLB, FTD, PD, PPA, and VCI), but also support research on heterogeneity within these subtypes. To evaluate the effectiveness of our LLM-based approach, we compared it against a traditional rule-based method using regular expressions for symptom extraction. We further validated the model's symptom predictions using brain volume data derived from magnetic resonance imaging (MRI).

Methods

Study Dataset

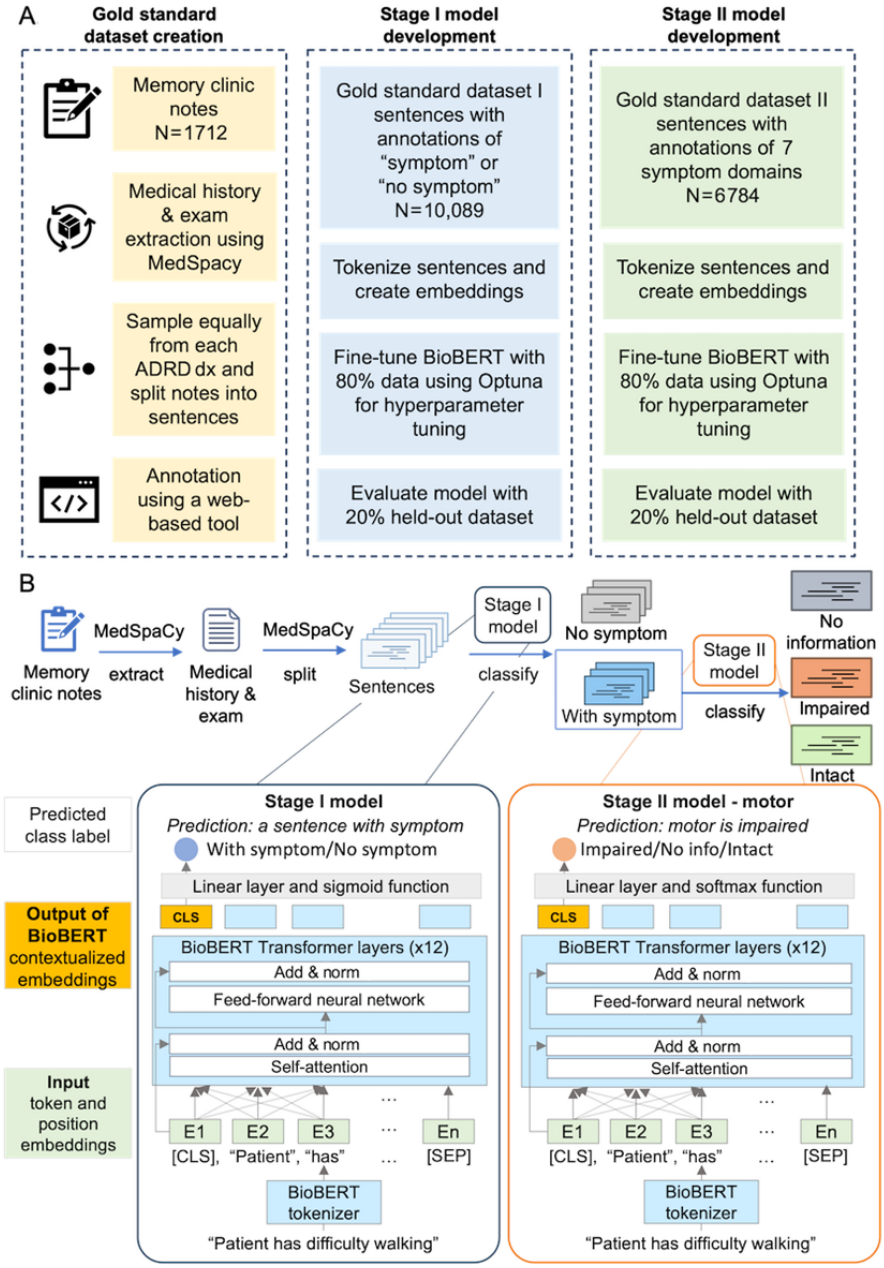
The dataset consisted of the EHR data of patients from the Massachusetts General Hospital (MGH) memory clinic (collected between 2015 and 2022), who were over 50 years old at their first visit and had at least two MGH memory clinic encounters. The dataset was further filtered to exclude patients without an office or telemedicine visit or those who did not have a progress note with at least 512 characters. The final dataset was filtered to only include patients with 1 of 6 ADRD diagnoses during their latest encounter: AD, DLB, FTD, PD, PPA, or VCI, and without mixed dementia in their EHR history. See Multimedia Appendix 1 for the full list of diagnosis names by ADRD category.

Ethical Considerations

This study was approved by the Mass General Brigham Institutional Review Board (protocol 2015P001915), with a waiver of informed consent granted for secondary analysis of electronic health records. No participant compensation was provided. Data were extracted from Epic and securely stored on servers within the Mass General Brigham firewall, with access limited to authorized study personnel in accordance with institutional privacy and data security policies.

Preprocessing

To process the notes, we applied *medspaCy*, a specialized text analysis tool for clinical notes [19]. We extracted key sections of the notes that held important information regarding the patient's symptoms such as medical history, examination, and impression. The extraction tool was customized for each physician's template. Subsequently, we sampled notes based on ADRD diagnoses and split notes into sentences or phrases for symptom annotation.



Annotation

An expert (AB) conducted thorough review of the medical literature and identified symptoms from seven domains typically present in patients living with ADRD: (1) memory, (2) executive function, (3) motor, (4) language, (5) visuospatial, (6)

XSL•FO
RenderX

neuropsychiatric (which also incorporates symptoms related to behavior and mood), and (7) sleep (Multimedia Appendix 2). A behavioral neurologist (JD) provided critical input throughout both processes. Subsequently, another expert (MM) annotated sentences or phrases as *symptom* (patient shows intact or impaired symptoms) or *no symptom* (no information on patient symptoms). Further, MM annotated sentences or phrases as *intact*, *impaired*, or *no information* for each of the 7 symptom domains, using a web-based JavaScript annotation tool developed by AS. Using these annotations, we created 2 gold standard datasets: *gold standard dataset I* (composed of sentences or phrases labeled as *symptom* or *no symptom*) and *gold standard dataset II* (composed of sentences or phrases labeled as *intact*, *impaired*, or *no information* across the 7 symptom domains). The process for creating the gold standard dataset is illustrated in Figure 1A.

Figure 1. Model development and architecture. (A) Gold standard dataset creation and model development. This workflow describes the development of a 2-tier hierarchical model to classify symptoms in clinical notes. Initially, 1712 memory clinic notes are processed, and sentences sampled across various Alzheimer disease and related dementias (ADRD) diagnoses are manually annotated using a web tool, producing 2 gold standard datasets: one identifying symptom presence, and another categorizing symptom status across 7 domains. The 2 classification models, built on BioBERT, undergo fine-tuning using 80% of the data and testing using 20% of a held-out dataset. (B) Illustration of the application of BioBERT in stage I and stage II models for symptom extraction. dx: diagnosis.

Symptom Recognition Using BioBERT

We developed a 2-tier hierarchical model for symptom extraction. The *stage I binary symptom classification model* classified each input sentence as *symptom* or *no symptom*. The *stage II multi-label symptom classification model* is composed of 7 distinct models, with each trained to classify sentences or phrases from 1 of the 7 symptom domains, namely *memory*, *executive function*, *motor*, *language*, *visuospatial*, *neuropsychiatric*, and *sleep*. Each *stage II multi-label symptom*

XSL•FO
RenderX

classification model classifies sentences or phrases into 3 categories: *impaired*, *intact*, and *no information*. The *impaired* category encapsulates symptoms indicative of impairment within the specific domain, highlighting manifestations of dysfunction. Conversely, the *intact* category encompasses symptoms that reflect normal functioning of the respective symptom domain. The *no information* category encompasses all remaining symptoms from other categories (eg, a sentence that only mentions *motor* symptom is categorized as *no information* in the *memory* model), supplemented by nonsymptomatic sentences.

Both the *stage I binary symptom classification model* and *stage II multi-label symptom classification model* were developed using *BioBERT* [20], an LLM pretrained on a large corpus of biomedical text (eg, PubMed abstracts and PubMed Central full-text articles) and implemented using the HuggingFace's *Pythontransformers* package (version 4.8.2) [21]. The *stage I binary symptom classification model* was initialized with its pretrained parameters of BioBERT and then fine-tuned on the *gold standard dataset I* (80% training set, 20% hold-out set). The *stage II multi-label symptom classification model* was again initialized with pretrained parameters and later fine-tuned on *gold standard dataset II* (80% training set, 20% hold-out set). *Optuna* hyperparameter tuning was used to tune the hyperparameters for both models, including training epochs, batch size, and learning rate, with a 20-trial study to maximize the area under the precision-recall curve. An early stopping criterion was implemented to cease training if the loss did not change substantially in 4 epochs, preventing overfitting.

Figure 1B shows how we used BioBERT for the stage I and stage II models. We used the pretrained BioBERT model as a starting point and fine-tuned it for our task. As shown in Figure 1B, the extracted sentences are first processed through the BioBERT tokenizer, which splits the raw text into tokens. For example, the sentence "Patient has difficulty walking" is tokenized. Then, each token is converted into a pretrained embedding, capturing the semantic meaning of the word in the context of the sentence, along with a position embedding that encodes the token's location within the sequence to help the model understand word order and structure. A [CLS] token is added at the beginning of each sentence. Its embedding is used to represent the aggregated meaning of the entire sentence. A [SEP] token is placed at the end to signify the boundary between input tokens. E (embedding) from 1 to n represents the token embeddings, with the total count of n including [CLS] and [SEP]. These embeddings are passed through BioBERT's transformer layers, which use self-attention and feed-forward neural networks to generate context-aware embeddings. As the sentence passes through the layers, the embedding of the [CLS] token becomes enriched with contextualized information derived from the full sentence, which represents the overall meaning of the input. Finally, the embedding of the [CLS] token is used as the input for the linear layer, which calculates the logits for each class. Sigmoid (for binary classification) or SoftMax (for multi-class classification) as a decision function is applied to these logits to obtain class probabilities, and the class with the highest probability is selected as the model's predicted label. We fine-tuned BioBERT separately for stage I (binary classification) using gold standard dataset I and for stage II (multi-label classification) using gold standard dataset II. The fine-tuning process primarily involves adjusting the parameters of the BioBERT transformer layers and the linear layer to optimize performance for each stage's specific classification task.

We also experimented with other pretrained models as part of our preliminary experiments, including ClinicalBERT, RoBERTa, and LLaMA 2, with the latter being a generative transformer model. Despite fine-tuning (for ClinicalBERT and RoBERTa) or prompt engineering (for LLaMA 2), the models did not achieve the same level of performance as BioBERT in symptom classification based on the area under the receiver operating characteristic curve (AUROC) and F_1-score. All text processing and LLM development procedures were conducted in *Python* (version 3.8.15).

Symptom Recognition Using Regular Expressions

We created a list of regex patterns for ADRD symptoms to compare the efficacy of our advanced LLM approach with the traditional rule-based regex technique. First, 100 patient visit notes across the 6 ADRD diagnoses (AD, DLB, FTD, PD, PPA, and VCI) were randomly sampled. These notes were analyzed to identify examples from each of the 7 symptom domains (*memory*, *executive function*, *motor*, *language*, *visuospatial*, *neuropsychiatric*, and *sleep*) and develop a comprehensive set of regex patterns for each symptom domain. An expert behavioral neurologist (JD) provided critical guidance throughout this process. Next, these regex patterns were used to flag sentences or phrases corresponding to each symptom domain in the entire set of visit notes. The symptom counts for each note were then aggregated to calculate the total number of matches for each domain. For the full list of regex patterns, please see Multimedia Appendix 3.

Validation via ADRD Differential Diagnosis

We compiled symptom counts across 7 domains (*memory*, *executive function*, *motor*, *language*, *visuospatial*, *neuropsychiatric*, and *sleep*) based on predictions of our 2-tier hierarchical model on the entire set of visit notes. These symptom counts served as input features for a multinomial L1-regularized logistic regression model to classify 6 ADRD diagnoses (AD, DLB, FTD, PD, PPA, and VCI). To optimize the model, we employed 5-fold cross-validation and grid search cross-validation to determine the optimal value of alpha for L1 regularization using the *Pythonscikit-learn* (version 0.24.2) package. Additionally, we incorporated the aggregated symptom counts, derived from applying the ADRD symptom regex patterns (Multimedia Appendix 3) on the same dataset, as features in the machine learning model. We hypothesized that symptoms identified with our 2-tier hierarchical model would have superior performance than those derived from regex patterns in predicting ADRD diagnoses. All ADRD differential diagnosis analyses were conducted in *Python* (version 3.8.15).

Validation via MRI Brain Volume Data

To evaluate symptom predictions using MRI, we selected memory clinic notes with an MRI scan performed within 1 year of the visit. We ensured that none of these notes overlapped

XSL•FO
RenderX

with the gold standard datasets. Each clinical note was matched with a unique MRI scan from the Mass General Brigham patient database, with the imaging date being within 1 year of the visit date. The *SynthSeg+* pipeline [22] was used for brain segmentation and volume estimation. Only those images whose subcortical regions collectively surpassed a threshold of 0.65 in the average automated quality control score were selected for further analysis. For patients with multiple eligible clinical images, the final brain volume was determined by averaging the volumes across all qualifying images. Furthermore, to account for individual differences, the volume of each brain region was normalized by the intracranial volume.

In our brain volume analysis, we first selected *a priori* brain regions associated with 2 of the most commonly disrupted functions in patients with ADRD: *memory* and *motor*. For *memory* symptoms, we investigated the bilateral hippocampus and entorhinal cortex, both associated with the memory of recent events, as well as the prefrontal cortex, which is related to immediate memory [2,23-25]. For *motor* symptoms, our evaluation encompassed the bilateral primary motor cortex, the secondary motor cortex, the basal ganglia (including the caudate, putamen, pallidum, and nucleus accumbens) along with the thalamus (a structure with strong connections to the basal ganglia), and the cerebellar gray and white matter [26-29].

Logistic regression was used to evaluate the volumes of brain regions associated with symptoms, with a contrast of cases having *impaired* symptoms and those having either *intact* symptoms or *no information*. The analysis was conducted for both *memory* and *motor* symptoms, with adjustments made for age and sex, using the function *glm* in the *R stats* (version 4.3.2) package. The reported results were adjusted for multiple comparisons using the Benjamini-Hochberg method [30]. All MRI brain volume analyses were conducted in *R* (version 4.2.1; R Core Team). For a detailed workflow of validation using MRI, see Figure S1 in Multimedia Appendix 4.

Results

Study Data

The study data consisted of visit notes from the latest encounters of 1712 patients (Figure 2). The visit notes were from 866 (50.6%) male and 846 (49.4%) female patients, with an average age at visit of 77.5 (SD 8.3) years. All patients had 1 of the following ADRD diagnoses: AD, DLB, FTD, PD, PPA, and VCI. The patient demographics are described in Table 1.

From these 1712 visit notes, we compiled 2 gold standard datasets. Gold standard dataset I included 10,089 sentences or phrases labeled as *symptom* (n=5468, 54.2%) or *no symptom* (n=4621, 45.8%). Gold standard dataset II included 6784 sentences or phrases labeled as *intact*, *impaired*, or *no information* across the 7 symptom domains. The ADRD diagnoses in dataset II predominantly included AD (2862/6784, 42.2%) and DLB (1866/6784, 27.5%), followed by FTD (879/6784, 13.0%), PD (628/6784, 9.3%), VCI (479/6784, 7.1%), and PPA (70/6784, 1.0%). Specifically, AD had the highest counts for *memory* and *visuospatial* symptoms; DLB led in *executive function* symptoms; PD was predominant in *motor* symptoms; PPA led in *language* symptoms; and FTD was notable for *neuropsychiatric* and *sleep* symptoms, with high counts also noted in *visuospatial* and *sleep* symptoms for VCI and DLB, respectively (refer to Table 2 for detailed distributions). A standardized mean difference (SMD) threshold of 0.1 was employed to assess the equilibrium of each metric, with measurements exceeding 0.1 indicating a comparative lack of balance. The MRI validation dataset included 582 visit notes from 528 unique patients and had clinical MRI performed within 1 year (Figure S2 in Multimedia Appendix 4). For demographic distribution related to these visit notes, refer to the last column of Table 1.

Symptom Recognition Using a Transformer-Based Language Model

We trained, validated, and tested a transformer-based LLM to identify symptoms related to ADRD diagnoses. The symptom extraction process was executed through a 2-stage framework. The stage I binary symptom classification model categorized sentences as either *symptom* or *no symptom*. The model attained a micro-averaged AUROC of 1.00 (95% CI 0.99-1.00), along with a micro-averaged F_1-score of 0.98 (95% CI 0.97-0.98), micro-averaged precision of 0.98 (95% CI 0.97-0.98), and micro-averaged recall of 0.98 (95% CI 0.97-0.98), highlighting its ability to accurately detect symptom presence. The 95% CIs for each metric reflect the reliability of these estimates, confirming the model's overall efficacy in symptom classification across diverse clinical features.

This initial classification is followed by the use of the stage II multi-label symptom classification models, which further classify each detected symptom into *impaired*, *intact*, and *no information*. The 7 stage II models are tailored to each specific domain (*memory*, *executive function*, *motor*, *language*, *visuospatial*, *neuropsychiatric*, and *sleep*). All symptom domains showed robust model performance, with micro-averaged AUROC values of 0.97-0.99, micro-averaged F_1-score values of 0.89-0.96, micro-averaged precision values of 0.87-0.96, and micro-averaged recall values of 0.91-0.96 across all symptoms. Among these, we observed slightly lower metrics in the visuospatial domain (micro-averaged AUROC: 0.97, 95% CI 0.95-0.99; micro-averaged F_1-score: 0.89, 95% CI 0.85-0.93; micro-averaged precision: 0.87, 95% CI 0.83-0.91; micro-averaged recall: 0.91, 95% CI 0.87-0.94). Table 3 provides a comprehensive evaluation of the performance metrics for both models.

Table 3. Performance of the 2-tier hierarchical symptom classification model.

Model	F_1-score[a], value (95% CI)	AUPRC[a,b], value (95% CI)	Precision[a], value (95% CI)	Recall[a], value (95% CI)	AUROC[a,c], value (95% CI)	Accuracy[a], value (95% CI)
Stage I binary symptom classification model	0.98 (0.97-0.98)	1.00 (0.99-1.00)	0.98 (0.97-0.98)	0.98 (0.97-0.98)	1.00 (0.99-1.00)	0.98 (0.97-0.98)
Stage II multi-label symptom classification model						
Memory	0.96 (0.94-0.98)	0.94 (0.91-0.96)	0.96 (0.95-0.98)	0.95 (0.94-0.97)	0.99 (0.98-1.00)	0.94 (0.92-0.96)

Model Validation With ADRD Differential Diagnosis

To validate the accuracy of our 2-tier hierarchical symptom classification model, we used a machine learning model to classify ADRD diagnoses with the counts of identified symptoms as model features. We compared 2 L1-regularized logistic regression models: one based on regex-derived symptom counts and another using counts derived from the 2-tier hierarchical LLM. This method allowed us to assess the efficacy of traditional regex techniques against more advanced LLM approaches in the context of ADRD diagnostic accuracy.

First, we predicted ADRD diagnoses using L1 logistic regression based on regex-derived symptom counts. Using regex patterns, we extracted symptom counts from the latest visit notes of 1712 patients diagnosed with ADRD, spanning 7 domains: memory, executive function, motor, language, visuospatial, neuropsychiatric, and sleep. These counts were used to build an L1-regularized multinomial logistic regression model, which predicted the type of ADRD diagnosis using symptom counts as features. The model's average AUROC was 0.59 (95% CI 0.51-0.66). Detailed AUROC values for each ADRD diagnosis relative to the rest are displayed in Figure 3A.

Figure 3. Performance of Alzheimer disease and related dementias (ADRD) differential diagnosis. (A) Receiver operating characteristic (ROC) curves for predicting 6 ADRD diagnoses (Alzheimer disease [AD], dementia with Lewy bodies [DLB], frontotemporal dementia [FTD], Parkinson disease [PD], primary progressive aphasia [PPA], and vascular cognitive impairment [VCI]) using an L1-regularized logistic regression model based on regex-derived symptom counts. The area under the receiver operating characteristic curve (AUROC) is 0.59 (95% CI 0.51-0.66). (B) ROC curves for an L1-regularized logistic regression model using 2-tier hierarchical large language model (LLM)-derived symptom counts. The AUROC is 0.83 (95% CI 0.77-0.89). (C) Feature importance ranking for the model using LLM-derived symptom counts, with an average across the coefficients of symptoms in all ADRD diagnoses. Executive function is the most important feature, followed by language, motor, memory, neuropsychiatric, visuospatial, and sleep. AUC: area under the curve.

XSL•FO
RenderX

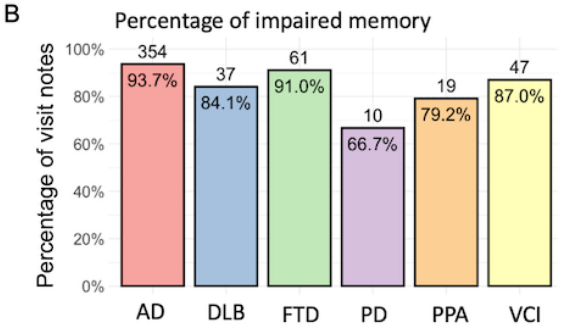
Second, we predicted ADRD diagnoses using L1 logistic regression based on LLM symptom counts. The second model, leveraging symptom counts extracted from patient visit notes via the 2-tier hierarchical LLM, aimed to predict specific ADRD diagnoses using L1-regularized logistic regression. This model demonstrated a substantial enhancement in diagnostic accuracy, achieving an AUROC of 0.83 (95% CI 0.77-0.89) compared to the AUROC of 0.59 (95% CI 0.51-0.66) obtained with the regex-based model. This marked improvement highlights the model's efficacy in accurately classifying ADRD categories, underscoring the potential of transformer-based BioBERT models in capturing the context of clinical symptoms from notes. The detailed AUROC for each diagnosis compared to the rest is displayed in Figure 3B.

Further, analysis using feature importance derived from the LLM-based logistic regression model showed that *executive function* had the greatest predictive power on average, followed by *language*, *motor*, *memory*, *neuropsychiatric*, *visuospatial*, and *sleep*. This ranking, illustrated in Figure 3C, emphasizes the critical roles of *executive function*, *language*, *memory*, and *motor* symptoms in predicting ADRD diagnoses. Feature importance rankings for each ADRD diagnosis are illustrated in Figure S3 in Multimedia Appendix 4.

Model Validation With Brain MRI

We used MRI brain volume data to assess our model's ability to identify symptoms from clinical notes. We hypothesized that the volumes of selected brain regions associated with each domain would be smaller in patients with impaired symptoms predicted from the notes compared to those without. The model analyzed 582 sentences or phrases, identifying memory impairment in 90.7% (528/582) and motor impairment in 80.6% (469/582) of cases. In particular, we observed that memory-impaired individuals showed smaller hippocampal and prefrontal cortex volumes (SMDs >0.1), while motor-impaired individuals had reduced volumes in subcortical regions, including the thalamus, putamen, pallidum, and accumbens area (SMDs >0.1). For brain volume summary statistics from *memory* and *motor* BioBERT model predictions, see Figure 4A.

The *memory* model predicted that visit notes of patients with AD had the highest proportion (93.7%) of *memory* symptoms relative to the other ADRD diagnoses, which is consistent with our understanding that memory impairment is the initial and primary symptom for most patients with AD [2] (Figure 4B). The MRI analysis of *memory* symptoms revealed that a smaller hippocampal volume was associated with an increased likelihood of memory impairment (odds ratio [OR] 0.62, 95% CI 0.46-0.84; P=.006) (Figure 4C). Power analysis for the logistic regression, using 1000 simulations, yielded an 89.7% chance of detecting a significant impact of hippocampal volume on *memory* symptoms, thereby confirming the reliability of these findings. Nonetheless, the volumes of the entorhinal cortex and prefrontal cortex did not show a significant relationship with *memory* symptoms (P>.05), but the prefrontal cortex had high SMDs (Figure 4A).



In terms of *motor* symptoms, the *motor* model predicted that visit notes with DLB (95.5%) and PD (100%) diagnoses had the highest proportion of *motor* symptoms across visit notes of ADRD diagnoses, which is consistent with our understanding that motor impairment is the primary symptom for patients with DLB and PD [3,5] (Figure 4D). The MRI analysis of *motor* symptoms revealed that a smaller pallidum size was significantly associated with the presence of motor impairments (OR 0.73, 95% CI 0.58-0.9; P=.04) (Figure 4E). Power analysis for the logistic regression, conducted with 1000 simulations, revealed an 84.7% probability of accurately detecting a significant influence of pallidum volume on motor symptoms, which substantiates the robustness of our results. Other regions related to motor function did not exhibit significant volumetric differences (P>.05). Age and sex were accounted for in all analyses. All results were corrected for multiple comparisons [30]. Thus, the MRI findings corroborated both *memory* and *motor* symptom predictions made by our 2-tier hierarchical LLM.

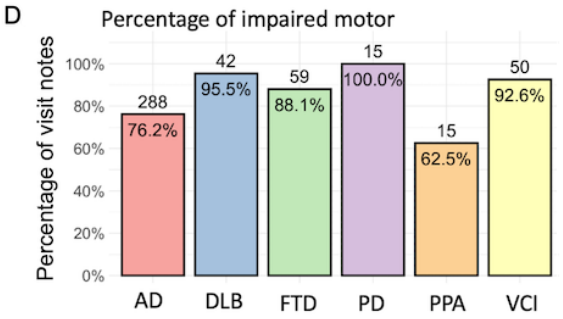

Figure 4. Evaluation of model performance with magnetic resonance imaging brain volume. (A) Summary statistics of the volumes of brain regions associated with memory or motor functions. A standardized mean difference (SMD) threshold of 0.1 has been employed to assess the equilibrium of each metric. Measurements with an SMD exceeding 0.1 (highlighted in bold) signify a comparative lack of balance. (B) Percentage of visit notes with at least one impaired memory symptom predicted by the memory model across visit notes with Alzheimer disease and related dementias (ADRD) diagnosis. The number above each bar represents the number of visit notes in each ADRD diagnosis where impaired memory symptoms were detected. As expected, visit notes with Alzheimer disease (AD) diagnosis had the highest proportion of memory symptoms across all ADRD diagnoses. (C) Coronal view of the brain area associated with memory impairment. Patients with a smaller hippocampus had a higher likelihood of memory impairment (odds ratio [OR] 0.62; *P*=.006). (D) Percentage of visit notes with at least one impaired motor symptom predicted by the motor model across visit notes with ADRD diagnosis. The number above each bar represents the number of visit notes in each ADRD diagnosis where impaired motor symptoms were detected. As expected, visit notes with dementia with Lewy bodies (DLB) and Parkinson disease (PD) diagnoses had the highest proportion of motor symptoms across all ADRD diagnoses. (E) Coronal view of the brain area associated with motor impairment. Patients with a smaller pallidum had a higher likelihood of motor impairment (OR 0.73; *P*=.04). All *P* values have been adjusted for multiple comparisons. FTD: frontotemporal dementia; PPA: primary progressive aphasia; VCI: vascular cognitive impairment. **P*<.05, ***P*<.01.

Error Analysis

We performed an error analysis to gain insights into the misclassifications made by the 2-tier hierarchical LLM, particularly in its ability to classify symptoms as intact or impaired across the 7 domains. We included both the held-out test set and the MRI validation dataset in our analysis to ensure thoroughness. It is worth mentioning that since the MRI validation dataset does not include true labels, we relied on chart reviews to validate predictions (Figure S1 in Multimedia Appendix 4).

Our error analysis began by examining instances where the models' predictions of symptoms across ADRD types did not align with known disease profiles. For example, in AD cases, where memory impairment is a prominent symptom [2], the model did not predict *memory* symptoms in 6.1% (23/378) of cases. These instances were notable for their focus on broader cognitive decline or general test scores rather than explicit mentions of *memory* symptoms. In FTD, 93% (62/67) of visit notes referenced *memory* symptoms, which is intriguing since memory impairment is not typical in FTD, particularly in its behavioral variant [31]. Manual review confirmed that these symptoms were indeed documented. In VCI, 87% (47/54) of visit notes mentioned *memory* symptoms, with a consistent recognition of memory issues as a feature of VCI [32]. The model detected *memory* symptoms in 84% (37/44) of DLB visit notes and 79% (19/24) of PPA cases, which often concerned semantic memory challenges. Another example involves *motor* symptoms. The model showed a small margin of error in DLB cases, failing to detect *motor* symptoms in just 2 cases (2/44, 5%). In AD visit notes, *motor* symptoms were predicted accurately in 76.2% (288/378) of notes. FTD cases showed an 88% (59/67) occurrence of *motor* symptoms, and VCI notes included *motor* symptom references in 92.6% (50/54) of cases, often related to lower body motor challenges. PPA patients were identified with *motor* symptoms in 63% (15/24) of notes, with manual verification confirming the presence of true *motor* symptoms in majority (11/15, 73%) of these cases.

The second part of the error analysis investigated visit notes by random sampling, with a focus on notes with high symptom counts (more than 10 symptom predictions). This examination uncovered several types of errors affecting prediction accuracy across all symptoms, including six types of false positives: (1) generalizing cognitive function as a symptom, (2) confusing one symptom with another symptom, (3) identifying evaluation or test statements as impairment, (4) misrecognizing intact as impaired, (5) misleading by ambiguous or complex sentences, and (6) confusing medical history as present symptoms. Four types of false negatives were also identified, including (1) overlooking particular expressions, (2) overlooking particular test scores, (3) misrecognizing impaired as intact, and (4) overlooking sentences or phrases that require contextual information. Table 4 provides a detailed breakdown of these error types and examples from visit notes. Additionally, to understand the distribution of false positives and false negatives across the model's predictions at the sentence level, we calculated confusion matrices based on the held-out test set for each symptom, and the data are presented in Figure S4 in Multimedia Appendix 4.

XSL•FO
RenderX

Table 4. Types of errors in model prediction.

Types of errors	Example (mislabeled category; correct category)
False positive	
Generalizing cognitive function as a symptom	• "problem in cognitive functioning" (mislabeled: impaired memory; correct: no information)
Confusing one symptom with another symptom	• "she began to have trouble sorting items" (mislabeled: impaired memory; correct: impaired executive function) • "cannot remember a word" (mislabeled: impaired motor; correct: impaired memory)
Identifying evaluation or test statements as impairment	• "patient visit for evaluation of memory impairment" (mislabeled: impaired memory; correct: no information)
Misrecognizing intact as impaired	• "Mild wordfinding difficulty has resolved" (mislabeled: impaired language; correct: intact language) • "No disorientation in time" (mislabeled: impaired memory; correct: intact memory) • "Plantar response is flexor bilaterally" (mislabeled: impaired motor; correct: intact motor)
Misleading by ambiguous or complex sentences	• "Speech is fluent but some dysnomia is noted" (mislabeled: intact language; correct: impaired language) • "Long term memory is fine but short term memory is not great" (mislabeled: intact memory; correct: impaired memory) • "Impairment of short-term memory has declined" (mislabeled: intact memory; correct: impaired memory)
Confusing medical history as present symptoms	• "ask about his past falls" (mislabeled: impaired motor; correct: no information)
False negative	
Overlooking particular expressions	• "repeat the same question over and over again" (mislabeled: no information; correct: impaired memory) • "he puts things away in the wrong place" (mislabeled: no information; correct: impaired memory)
Overlooking particular test scores	• "CDR-SOB memory is 1" (mislabeled: no information; correct: impaired memory)
Misrecognizing impaired as intact	• "oriented partially in time" (mislabeled: intact memory; correct: impaired memory) • "oriented to his wife but has visual agnosia" (mislabeled: intact visuospatial; correct: impaired visuospatial) • "He requires help to dress only for adult undergarments but not for clothes" (mislabeled: intact motor; correct: impaired motor)
Overlooking sentences or phrases that require contextual information	• "memory has been stable for 2 years. He has worsened in the past 5 months" (mislabeled: intact memory; correct: impaired memory) • "Gait: … slow to initiate." (mislabeled: no information; correct: impaired motor)

Discussion

In this study, we developed and evaluated an LLM-based 2-tier hierarchical model for automated symptom extraction, which was trained on expert-labeled visit notes from patients with ADRD at the MGH memory clinic. The model classified sentences or phrases into categories of *impaired*, *intact*, or *no information* for 7 ADRD symptoms: *memory*, *executive function*, *motor*, *language*, *visuospatial*, *neuropsychiatric*, and *sleep*. Our method demonstrated superiority over rule-based and keyword-dependent methods [7-11], which often miss nuanced contextual and semantic relationships. The model achieved robust performance in detecting each symptom from clinical notes, with a micro-averaged AUROC ranging from 0.97 to 0.99. Furthermore, with the implementation of our LLM-based symptom extraction, the AUROC for ADRD differential diagnosis improved substantially (AUROC=0.83) compared to regex-based extraction (AUROC=0.59). Moreover, our model's predictions aligned with clinical evidence, with most clinical notes correctly matching their respective symptoms. Further, the associations of symptoms with different affected brain regions were substantiated through brain MRI findings. Thus, our model holds potential as a screening tool to streamline diagnosis, improve precision in clinical trials and treatment

XSL•FO
RenderX

planning, and enhance our understanding of ADRD subtype heterogeneity.

Traditional approaches, such as regex-based methods, are highly dependent on predefined sets of keywords or rules. They struggle with variations in how symptoms are expressed. For instance, the phrase "difficulty swallowing" could be documented in various ways, such as "unable to swallow" and "has trouble swallowing," or with more context-specific expressions like "takes 60 minutes to feed the patient a meal." It is difficult to build a one-size-fits-all rule for captioning every symptom in each domain. To illustrate these challenges, we created a list of regex patterns for ADRD symptoms (Multimedia Appendix 3) and compared the performance of our LLM-based model with traditional regex techniques. We evaluated both methods using 2 L1-regularized logistic regression models: one based on symptom counts derived from regex patterns, and another using counts from our 2-tier hierarchical LLM. Our results showed that the LLM-based model significantly outperformed the regex-based model, achieving an AUROC of 0.83, compared to an AUROC of 0.59 obtained with the regex-based model. This improvement demonstrates the LLM's ability to better capture the context of clinical symptoms in ADRD, highlighting the superiority of transformer-based models, like BioBERT, in overcoming the limitations of traditional rule-based approaches. Other researchers have used NLP approaches to determine or extract information from clinical notes as well. For example, Prakash et al [33] achieved strong accuracy and F_1-scores (83%-92%) for determining the presence of ADRD severity information in clinical notes using rule-based methods. Similarly, Chen et al [34] developed a rule-based NLP pipeline to extract cognitive test scores and biomarkers from clinical narratives, achieving an F_1-score of 0.9059 across 7 different measures. Their focus was on identifying and harmonizing cognitive test scores in severity categories for patients with ADRD. However, these approaches primarily focus on specific cognitive tests and biomarkers, which are typically more straightforward to identify. In contrast, our method focuses on symptom extraction of sentences across 7 distinct domains. Symptoms are more complex and less structured, requiring a deep understanding of contextual relationships to accurately identify and classify them. Our study verified that the transformer-based BERT model can address this challenge to handle complex medical terminologies and capture the meanings of terms within their context.

As expected, in ADRD differential diagnosis, *memory* emerged as the most crucial symptom for predicting AD (Figure S3A in Multimedia Appendix 4), *motor* was the most significant symptom for predicting DLB (Figure S3B in Multimedia Appendix 4), and *language* was the most important symptom for predicting PPA (Figure S3E in Multimedia Appendix 4). These findings are consistent with our understanding of the clinical manifestations of these diseases [2-4].

While no single disease required all 7 symptoms for prediction (Figure S3 in Multimedia Appendix 4), *executive function* stood out as the most important (for AD, PD, and VCI; see Figures S3A, D, and F in Multimedia Appendix 4) or moderately important (for DLB, FTD, and PPA; see Figures S3B, C, and E in Multimedia Appendix 4) feature across all predictions. Notably, the importance of *executive function* in predicting AD was comparable to that of *memory*. This may be due to the broad range of behaviors associated with *executive function*, such as planning, time management, and working memory, which are intricately woven into the complexity of daily life. Additionally, the frontal lobe, a key hub for *executive function* [35], is extensively connected with other brain regions involved in various functions [36]. For example, *memory* impairment may impact the hippocampal-prefrontal pathway [37], thereby affecting tasks that require both *memory* and *executive function*, such as remembering to take medications at specific times. This pattern also helps explain why, in the case of FTD, a disease characterized by severe behavioral manifestations [4] and frontal or temporal lobe degeneration [38], *executive function* provides only moderate predictive power. Although this might seem counterintuitive given the role of *executive function* in FTD, it may be because the behavioral symptoms in FTD are more prominent, and *executive function* may not have sufficient discriminatory power for a differential diagnosis. Moreover, frontal lobe atrophy in FTD may affect behavior in a manner similar to how disruption in the connection between the frontal lobe and other functional areas impacts executive tasks, thereby influencing the overall predictive value of *executive function* in this context.

In the context of ADRD differential diagnosis, our model identified *memory* as a moderately important symptom on average for diagnosing ADRD (Figure 3C). When evaluating prediction performance by specific ADRD diagnoses, *memory* was ranked as the most crucial symptom for predicting AD (Figure S3A in Multimedia Appendix 4); moderately important for FTD (Figure S3C in Multimedia Appendix 4) and VCI (Figure S3F in Multimedia Appendix 4); and least important for DLB (Figure S3B in Multimedia Appendix 4), PD (Figure S3D in Multimedia Appendix 4), and PPA (Figure S3E in Multimedia Appendix 4). This importance ranking for *memory* aligns with existing knowledge about the prevalence of memory impairment across different ADRD diagnoses [2-5,32]. The model generally performed well in identifying *memory* symptoms. However, in some patients with AD, *memory* symptoms were not predicted. Further analysis revealed that this was likely due to follow-up notes simply stating "no change" in the patient's condition, which did not trigger the model's detection mechanisms. This suggests a need for improvement in detecting implied or static memory impairments. Additionally, some notes detailed atypical AD presentations, emphasizing language or motor difficulties rather than memory loss, which can indicate variations in clinical presentation among patients with the same underlying etiology. Further, an unexpectedly high prevalence of *memory* symptoms in FTD underscores the complexity of symptomatology. While aging has been suggested as a confounding factor for *memory* symptoms in FTD [4], our data indicated no significant age difference in patients with and without *memory* symptoms. Meanwhile, some studies have suggested that *memory* symptoms can emerge in patients with progressive FTD, akin to AD presentations [39], which may explain our observation. In DLB cases, our model detected *memory* symptoms in many visit notes, with only 1 case later reclassified as AD. Although DLB

XSL•FO
RenderX

typically lacks early memory impairment, such symptoms can develop as the condition advances [3]. Most evaluated visit notes were from initial visits, suggesting that DLB diagnoses might already be at more advanced stages by then. Further analysis showed that AD cases had more frequent memory-related references than DLB (Wilcoxon rank sum test W=105474; $P<.001$), demonstrating our model's ability to distinguish patterns of the same symptom across different diagnoses.

Motor symptoms were the most prevalent impairments among patients with ADRD in our dataset (Table 2) and showed moderate importance on average in predicting ADRD diagnoses (Figure 3C). When evaluating prediction performance by specific ADRD diagnoses, *motor* was ranked as the most crucial symptom for predicting DLB (Figure S3B in Multimedia Appendix 4); moderately important for AD (Figure S3A in Multimedia Appendix 4), PD (Figure S3D in Multimedia Appendix 4), PPA (Figure S3E in Multimedia Appendix 4), and VCI (Figure S3F in Multimedia Appendix 4); and least important for FTD (Figure S3C in Multimedia Appendix 4). This importance ranking for *motor* aligns with existing knowledge about the prevalence of motor impairment in AD, DLB, PPA, and VCI diagnoses [2-4,32]. The low ranking of *motor* in predicting FTD and its moderate ranking for PD was unexpected, considering that these 2 diseases have more behavioral symptoms closely associated with motor function [4,5]. This discrepancy might be due to the broad range of *motor* functions involved, making it harder to distinguish nuances between these diseases and others, similar to the case where *executive function* had a moderate contribution in predicting FTD. As expected, patients with DLB or PD had the highest occurrences of *motor* symptoms. Notably, 1 patient initially diagnosed with mild cognitive impairment was later found to have DLB, which the model had correctly predicted, underscoring the model's robustness. FTD cases often exhibited *motor* symptoms, even though their diagnoses did not change to DLB or PD in later visits. This was observed despite excluding *motor* symptom subtypes like corticobasal syndrome or progressive supranuclear palsy [4], and no motor neuron diseases were noted. This underscores that motor symptoms can develop in patients with FTD over time, even when they are not diagnosed with conditions typically associated with these symptoms. Moreover, patients with FTD having *motor* symptoms were generally older, aligning with symptom progression, although the age difference was not statistically significant. In patients with AD, the model's prediction of frequent *motor* symptoms, such as "unsteady stance" and "perseveration of movement" (largely confirmed upon chart review), aligns with literature indicating that late-stage AD can manifest motor impairments [2], similar to those seen in DLB or PD [3,5]. This suggests that these patients with AD may be at more advanced stages of the disease. Patients with AD having *motor* symptoms were generally older, which is consistent with the progression hypothesis, though this relationship was not statistically significant. The high occurrence of *motor* symptoms in VCI cases (confirmed through manual review), which emphasized sentences or phrases that particularly mention the lower body being affected, such as "gait instability" and "frequent falls," aligns with clinical knowledge [32]. Only 1 predicted VCI case was later diagnosed with DLB, highlighting the model's specificity for differential diagnosis.

Among all symptom predictions, *visuospatial* symptoms had the lowest performance (Table 3). Further review revealed that certain behaviors might reflect mixed symptoms in patients' clinical presentations. For example, "unable to drive" in clinical notes could be due to impaired navigation ability [40-42], typically categorized as a *visuospatial* symptom, but driving is a complex behavior that also involves *executive function* for planning the route [43], *memory* for remembering place names [43], and *motor* skills for physical control [43]. Therefore, developing more refined models that can better distinguish and specifically target *visuospatial* symptoms will be essential for improving the accuracy of symptom extraction.

This study has several limitations. While our current NLP techniques proved to be effective in symptom extraction, the model performance is still susceptible to diverse clinical narratives and abbreviations. For example, we tailored data preprocessing templates for each provider, which makes it challenging to generalize the model to different health care settings. Additionally, our study focused on patients with a single ADRD diagnosis, yet many patients fall into the dementia unspecified category due to mixed dementia. For instance, autopsy studies revealed that patients with pure VCI were less common than those with mixed dementia [44], which often co-occurred with AD pathology [45] and complicated the diagnostic process. Finally, our method is primarily intended for research use, and several challenges, such as data privacy, clinician–artificial intelligence interaction, and model performance, need to be overcome before it is ready for clinical decision-making.

Future studies should include patients with multiple ADRD diagnoses and at different disease stages to better reflect real-world complexities. Enhancements might include more sophisticated language parsing and the integration of clinical criteria for improved specificity. Moreover, integrating structured patient data, such as demographics and neurological tests, could enhance the model's precision and generalizability. Recent studies, such as the study by Xue et al [46], have shown the potential of transformer-based models for multi-modal differential diagnosis of dementia, suggesting avenues for further refinement of our approach. Furthermore, the dataset generated through our efforts provides a foundation for successive cycles of the active learning loop, having the potential to continually refine and elevate the model's performance over time. Future research should leverage this dataset to further improve model performance and explore avenues for expanding the scope of symptom extraction in diverse clinical scenarios.

Abstract

Background: Pharmacoepidemiologic studies, which promote rational drug use and improve health outcomes, often require Anatomical Therapeutic Chemical Classification System (ATC) drug classification within real-world data (RWD) sources. Existing classification tools are expensive, brittle, or have restrictive terms of service, and lack context that may inform classification itself.

Objective: This study sought to establish large language models (LLMs) as an assisting technology in the drug classification task. This included developing artificial intelligence prompts that reason about drugs using RWD and showing that the resulting accuracy, efficiency, and effectiveness are favorable to alternative methods.

Methods: A prompt was constructed to classify aspirin as either an analgesic or antithrombotic and evaluated within 12,294 anonymized daily dose strings from a polychronic population residing in the United States and Canada. The patients used a smart medication dispenser called “spencer” and consented to the use of their data for research. The LLM prompt requested that the best and next-best second-level ATC code be returned, and grading was performed on a 3-point scale. After success in a pilot sample of 20, an inference sample of 200 was taken without replacement. Finite population inference was carried out on the proportion of outputs receiving 1 of the top 2 grades. As a benchmark, Google’s Programmable Search Engine was used to query the drug name plus “ATC code” followed by regex-based extraction of ATC codes. All imperfect results were reviewed.

Results: The population consisted of 12,294 daily dose strings from 86.26% (2908/3371) patients residing in Canada and 13.73% (463/3371) residing in the United States. A prompt using the chain-of-thought reasoning was able to distinguish between aspirin’s analgesic versus antithrombotic therapeutic uses and performed well in the pilot sample. In the inferential sample, 87.5% (175/200) were graded as perfect, 5% (10/200) had a minor issue, and 7.5% (15/200) had a major issue. The estimate of the proportion of at least mostly correct classification was 92.5% (185/200, 80% CI 90.1%-94.9%). For the search-based algorithm, 82.5% (165/200) were deemed acceptable. The chain-of-thought reasoning was most helpful with supplements (eg, folic acid) when high doses indicated antianemic preparations. The problem formulation of daily dose inputs and multiple ATC outputs was sometimes incompatible with the drug (eg, pregabalin, calcitriol, and methotrexate).

Conclusions: GPT-4o offers cost-effective drug classification from RWD without violating any terms of service. Using a chain-of-thought prompting technique, GPT-4o can reason about drug dosages that affect the class. The wide accessibility of LLMs gives every research team the ability to classify drugs at scale, a key prerequisite of pharmacoepidemiologic research.

Introduction

Background

Pharmacoepidemiology is a "bridge science" between epidemiology and clinical pharmacology that has, since its formative years, encompassed wide-ranging fields such as epidemiology, pharmacology, medicine, biostatistics, and social sciences [1]. It is positioned to benefit from advances in an even wider array of disciplines, including bioinformatics, data science, machine learning, artificial intelligence (AI), natural language processing, large language models (LLMs), systems pharmacology, pharmacogenomics, pharmacometabolomics, and health informatics [2-7]. These advances are integrated into pharmacoepidemiologic research to discover ineffective or unsafe drugs, encourage better prescription decisions, and reduce unnecessary health care costs [8].

LLMs are assistive tools that process broad ranges of factual knowledge, opening new avenues for synthesizing information across diverse fields. Their incorporation into pharmacoepidemiology holds great potential for redefining how we can understand the safety, efficacy, and use patterns of prescribed medications in large patient populations and reduce unnecessary costs.

Pharmacoepidemiology and the Anatomical Therapeutic Chemical Classification System

Pharmacoepidemiologic research depends on a concept of *drug class*, a classification of drugs regarding mechanism of action, therapeutic intent, or chemical structure, with the Anatomical Therapeutic Chemical Classification System (ATC) classification system considered mandatory [8-11]. Applications of the ATC methodology according to the World Health Organization are included in Table 1.

Table 1. Applications of the Anatomical Therapeutic Chemical Classification System (ATC) methodology according to the World Health Organization.

Application	How ATC codes are used
National standard for medicinal products	Used as a national standard for the classification of medicinal products for various countries
International classification	Provides a common language for describing drugs
Health policy	Drug use statistics using ATC codes are used to improve the quality of drug use in a population
Pharmacoepidemiology or drug use research	To study trends and patterns in drug use
Pharmacovigilance	For linking adverse drug reactions to ATC classes
Assisting procurement agencies and payer organizations	To gain an overview of the availability of drugs and reduce the risk of drug shortages

The ATC system classifies active substances (ie, drugs), including combinations of active ingredients, into groups at 5 different levels. This 5-level structure of the ATC system enables a hierarchical classification, which supplies broad and specific categorization of drugs, and helps in different levels of analysis in pharmacoepidemiologic studies. Using the example of lisinopril and hydrochlorothiazide, the first level ATC code is "C" for cardiovascular, the organ or system acted upon, the second-level ATC code is "C09" for agents acting on the renin–angiotensin system, and the fifth-level ATC code is "C09BA03": lisinopril and diuretics [12,13]. While there is the basic principle of 1 ATC code for each drug [12], here the fifth-level ATC code is still ambiguous due to the presence of an unspecified diuretic.

The ATC system is not suitable for guiding decisions about reimbursement, pricing, and therapeutic substitution [14], and thus, real-world data (RWD) typically lack ATC codes, rather using drug codes that support day-to-day operation and logistical functions within health care and pharmaceutical systems. This discrepancy between research needs and RWD structures presents a significant challenge for pharmacoepidemiologists.

In the United States, most pharmacy management systems and electronic health record systems use National Drug Codes (NDCs), which were designed for inventory management and reimbursement and do not directly identify a drug class [9,15]. In Canada, the analogous system is the Drug Identification Number (DIN) [16]. In the Netherlands, it is the Z-Index [17]. To conduct pharmacoepidemiologic research with these data sources, accurate ATC classification of drugs becomes an essential task to the research process. This necessity for accurate drug classification underscores the potential value of advanced computational methods, such as machine learning and natural language processing, in bridging the gap between diverse drug coding systems and the standardized ATC classification required for robust pharmacoepidemiologic analysis.

Tools to Map Prescribed Drugs to ATC Classes

The Center's ATC/defined daily dose Index web utility includes a query engine for drug name strings [13]. While there is no published application programming interface (API) for the search tool, adding /?name=<drug> to the end of the URL will execute the search and could set up a web scraping task. Fuzzy matching is limited to the options of "containing query" and "starting with query," which is restrictive in practice. For example, in either case, the drug string "apo-domperidone" returns no results while "domperidone" returns 3.

XSL•FO
RenderX

ATC codes appear in Wikipedia infoboxes which suggest the use of DBpedia [18]. Querying DBpedia, however, requires exact resource names, for instance, “dbr:Metformin.” The DBpedia organization does provide a lookup service [19] for text queries, like the ATC/defined daily dose Index, but it is also thrown off by variations in the drug’s name.

When operational drug codes (eg, NDC or DIN) are in the database, a different suite of tools becomes available. In the United States, the National Library of Medicine offers a service around RxNorm, a standardized nomenclature for clinical drugs [20], which links NDC to fourth-level ATC code [21]. Health Canada’s Drug Product Database [22] allows joining on the DIN directly. For countries with languages spoken by fewer people, the task is more difficult. Researchers in the Netherlands, for instance, had to resort to multiple data sources and extensive data cleaning to build their Dutch ATC ontology, and it still requires manual tasks [23].

DrugBank offers a full-text search built on top of Amazon Web Services Elasticsearch that can map drug names in various forms to standard terminology [24,25]. A DrugBank search result includes the full list of appropriate ATC codes, synonyms, indications, and more. While DrugBank is offered to the public and academia for free, commercial use requires a paid license [26]. The reliance on such commercial products can limit the accessibility of crucial drug classification tools, potentially creating disparities in research capabilities between well-funded and resource-limited institutions.

A commercial option that is inexpensive, yet controversial, is the use of Google’s Programmable Search Engine via the Custom Search JavaScript Object Notation (JSON) API [27]. The results contain the data essential to displaying search results on a website, and while they do not include the entire content of each site, they contain a “snippet” which often includes key information of interest. While recent US court decisions indicate a trend toward more leniency in web scraping of publicly accessible data, such as hiQ Labs versus LinkedIn [28], Google’s terms of service explicitly prohibit storing information obtained from the service in “any nontransitory manner” [29]. This, in principle, makes possible a claim against the user for breach of contract, but the actual enforceability of these terms is questionable [30].

ATC Drug Classification Challenges in a Multiregional Smart Medication Adherence System

Integration into the medication database of the ATC classification is critical to ensuring robust pharmacoepidemiologic research across a wide array of health care systems. This section demonstrates the challenges and limitations of the implementation of the ATC classification in the context of a real-world smart medication dispenser.

Spencer Health Solutions (SHS) is a health technology startup that manufactures “spencer” [31], a smart medication dispenser that dispenses strip-packaged oral solid tablets (Figure 1). At the time of drug refill creation, records are inserted into a database (maintained by SHS), which includes the scheduled time of each pouch and information on the drugs it contains. A separate set of drug records contains drug name, drug code (NDC for US drugs, DIN for Canadian drugs, and Z-Index for Dutch drugs), and strength description.

Figure 1. Key components of the spencer smart medication dispenser.

The spencer device shows the potential of smart medication dispensers to generate RWD that are useful in pharmacoepidemiologic studies, but there have been difficulties with relying on operational drug codes to obtain second-level

XSL•FO
RenderX

ATC codes. First, many of the drugs in the SHS drug database do not contain valid NDC or DIN codes, especially supplements such as *advanced 4-strain probiotic* or *webber naturals womens 50 plus most* (as they are abbreviated in the database). In addition, when the daily dose informs the therapeutic subgroup, NDC and DIN codes are insufficient, since patients often take multiple pills per day. For example, aspirin at low daily doses (75-100 mg) is a match to second-level ATC code B01 (antithrombotic agents), whereas aspirin, whereas aspirin at doses >325 mg maps to N02 (analgesics, a second-level ATC code), that is, analgesics. Finally, since the original drug classification exercise, patients began using spencer in the Netherlands, with Z-index values populating the drug code field in the European database. Although out of the scope of this paper, the existing classification pipeline based on 2 region-specific methodologies is unhelpful for this new drug source. These challenges indicate both the complexity of drug classification in multiregional systems, and that more sophisticated, context-aware approaches would be required, accounting for differences in dosage, formulation, and regional coding systems.

The limitations seen in the real-world application set a clear case for the need for a more flexible, comprehensive, and automated approach to drug classification. Advanced computational methods, such as machine learning, natural language processing, and AI, can help address these challenges by providing more accurate, adaptable classification systems dealing with diversified drug information across different regions and contexts of health care.

Drug Classification Using GPT-4o

In recent years, LLMs have shown the ability to perform a broad array of tasks with minimal task-specific training using textual prompts with "few-shot" and "chain-of-thought" prompting techniques [7], enabling the automation of tasks that are currently difficult and manual. GPT-4o [32], OpenAI's most advanced model at the time of writing the initial manuscript, contains a wealth of information about pharmaceutical drugs as well as the ATC classification system. In interactive exploration, GPT-4o was good at reasoning about second-level ATC level codes from drug inputs that had a variety of input formats. This feature of flexibility in handling various formats of input is valuable as sources of drug information are heterogeneous among different health care systems and across countries. In addition, a GPT-4o prompt can include additional information in an efficient and optimized manner about the daily dose that a patient is taking, which is useful when the dose may influence the final ATC classification.

The application of LLMs to drug classification presents a novel approach that could potentially address many of the limitations of traditional methods of drug classification. In this context, a large pharmacoepidemiologic knowledge base that uses LLMs (eg, GPT-4o) is robust in its handling of regional variations, dose-dependent classification, and data harmonization across different health care systems. Therefore, LLMs may improve multiregional pharmacoepidemiologic research capabilities related to drug classification challenges.

Objectives

This paper sought to establish LLMs as assisting technology in the drug classification task. This includes developing AI prompts that reason about drugs using RWD and showing that the resulting accuracy, efficiency, and effectiveness are comparable to alternative methods. The developed prompts should be available immediately to classify drugs under a wide range of research budgets.

Methods

Patient Population

Drug records of patients were included in this study if they met the criteria described in Textbox 1.

No raw drug record was sent outside the corporate network as part of this research. As will be described in the next section, the data submitted to GPT-4o was an irreversibly anonymized set of daily drug dose strings.

Textbox 1. Inclusion criteria for drug records in the study.

Inclusion criteria
1. The patient resided in the United States and Canada and belonged to a value-based care management organization.
2. The patient signed the care organization's consent form and agreed to the Spencer Health Solutions' end-user license agreement, permitting their deidentified data to be used for research purposes.
3. A refill was created with a pouch scheduled to be dispensed on or after January 1, 2024, as queried on June 1, 2024.

Anonymization Procedure for Daily Drug Doses

This section describes the anonymized extraction of drug dosing data from the database. A drug table in the application database included the drug name, the strength as a text string, and the quantity of pills (including fractions). The drug names were sometimes combinations of a manufacturer and a generic name (eg, "apo-rosuvastatin") and other times a brand name (eg, "prolopa 50-12.5"). Other times, the drug name would be as generic as "acetaminophen." Dosage strengths were unstandardized strings such as "50 mg" or "50 MG" and could include multiple active ingredients ("50/200MG" for carbidopa levodopa), a unit of time ("300.0 MG/24HR"), and other variations (while lower case "mg" is more appropriate than upper case "MG" to represent milligrams, the two are used interchangeably in this paper).

To construct a set of inputs suitable for OpenAI's chat completion API, a string was constructed for each unique drug and daily dose combination, without any other patient information. The drug name was processed by only a lower-case transformation. Drug strength was processed by imputing

XSL•FO
RenderX

missing strengths as "UNK" and otherwise left unchanged (strengths of "0" were allowed to pass through). The daily dose processing was described in Textbox 2.

For example, consider a patient prescribed the drug with the name "pms-quetiapine" (generic quetiapine fumarate from manufacturer Pharmascience, Inc) twice per day at 8 AM and 7 PM. At each dispense, 1 pill of strength 200 mg and 2 pills of strength 25 mg are scheduled. Following the steps described in Textbox 2, "pms-quetiapine|2 pills of 200 mg, 4 pills of 25 mg" would be the resulting string input. An example with combination ingredients is 1 pill of "carbidopa/levodopa er" of strength "25/100 MG" scheduled twice daily, or "carbidopa/levodopa er|2 pills of 25/100 MG." These are anonymized records that cannot be linked back to an individual.

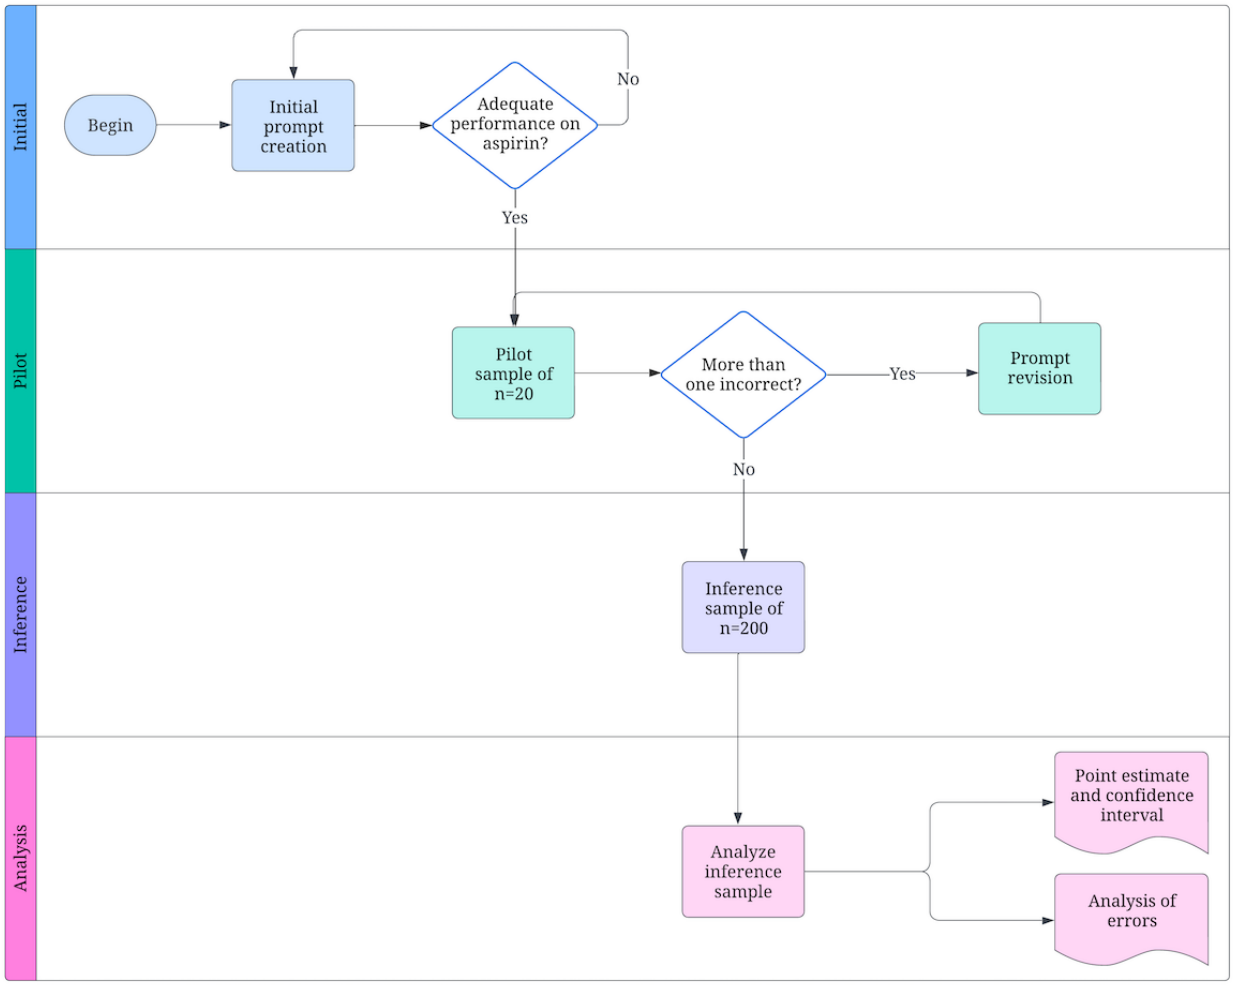
Textbox 2. The processing of the daily dose.

- Pill quantity was summed by patient ID, date, drug name, and drug strength.
- A pill quantity string was defined within the previous dataset using the formula:
  - "{quantity} pill" if quantity=1,
  - "{quantity} pills" otherwise
- The previous dataset was aggregated over drug strength within patient, date, and drug name by creating a comma-delimited list of multiple strengths for each drug, taking the form

  "{pill quantity string} of {drug strength}."
- The patient identifier was discarded, and a distinct operation was performed on the drug name and drug strength string.

Developing the Classification AI Prompt

The iterative development of the AI classification prompt used a single motivating example, the case of aspirin, and the goal of iterative prompt development was to guide the LLM to classify low doses as ATC code B01 for antithrombotic use and higher doses as ATC code N02 for pain relief. Aspirin is a well-known example of a drug where context matters, and any bias from this specific motivating example will be apparent in the results. The creation of the prompt was an iterative exercise that existed in 2 phases: the initial prompt creation and revision using the pilot sample. In the inference stage, the prompt was fixed, and no further changes were made.



During the initial prompt creation phase, 2 techniques that were available to be used were few-shot learning and chain-of-thought prompting. After achieving a prompt that worked as desired for aspirin at different daily dosing levels, 20 drug names and drug strength strings were randomly sampled from all possibilities observed in the dataset and served as a pilot sample for the initial prompt. These were evaluated by expert review by coauthor IRR-C, with expertise in clinical research, digital medicine, and regulatory affairs.

The pilot sample was sent to GPT-4o via the OpenAI Batch API [33] with all parameters set at their defaults except for the following. Temperature is a parameter that can vary between 0 and 2, where low values (eg, 0.2) result in more consistent outputs, whereas higher values result in "more creative" results (eg, 1) [34]. This research used a temperature of 0, as consistency was a priority. The other nondefault parameter was "max_tokens," set to 1000, which represents the maximum number of tokens that can be generated in the chat completion [35]. A token is on average three-fourth of a word (100 tokens is about 75 words) [36], and max_tokens was set below the highest allowed value of 4096 to avoid the longest explanations but to still allow for long responses if necessary.

If more than 1 classification was deemed incorrect, the prompt would be revised before proceeding. The development and validation of this AI-driven classification system were thus optimized through an iterative refinement process guided by expert feedback (Figure 2).

Figure 2. The methodology used to develop and test Anatomical Therapeutic Chemical Classification System (ATC) classification artificial intelligence (AI) prompt.

Finite Population Inference

This section details the statistical methodology that was used in estimating the performance of the GPT-4o model and custom prompt in second-level ATC classification. The methodology focused on the finite population of daily dose strings in the SHS database. Finite population formulas, while not materially different in this case from their infinite population counterparts, were used to emphasize that the inference is made to the specific set of SHS drug prescriptions and not to any larger population. This approach emphasizes the study's focus on the internal validity of the findings. The finite population sampling approach is model free and has well-understood properties in repeated sampling [37].

The values that were sampled were numerical grades of 1, 2, and 3, generated in the following manner. The output from GPT-4o was graded collaboratively among the authors on a 3-point scale, where a grade of 1 is flawless, a grade of 2 is more correct than incorrect, and 3 is more incorrect than correct. While the counts of each grade will be provided, formal inference to the full population of 12,294 daily dose strings focused on *p*, the proportion of at least mostly correct grades (ie, grades of 1 or 2) in this population. This focused the presentation of performance on a meaningful criterion while reducing inferential complexity.

The finite population sampling estimate of *p* is the sample proportion of outputs that are at least mostly correct in the chosen sample of *n*. The finite population CI is:

Where N is the number of daily drug dose strings in the full population, n is the sample size, and a is the proportion corresponding to the approximate (1–*a*) 100% CI for population parameter *p*. This formula accounts for the finiteness of the population, giving a better estimate of the CI compared with formulas for infinite populations.

The CI formula was also used to arrive at the sample size. A margin of 0.02 combined with a population proportion of 0.95 and an 80% confidence leads to a sample size of 189, which was rounded up to n=200. The lower level of confidence than the typical 95% was chosen here to lead to a somewhat smaller sample, and there is precedent in making this trade-off in medical research contexts where "reasonable certainty" is acceptable [38].

XSL•FO
RenderX

Each imperfect output (grades of 2 or 3) was examined qualitatively and presented to the reader in tabular form. The errors were then coded into categories, and the frequencies were displayed visually. For mistakes that were difficult to explain, the OpenAI interactive "playground" was consulted for reproducibility.

The Benchmark of Google's Programmable Search Engine

When researching a single drug, it is generally easy to find ATC codes by searching for the drug name in Google Search followed by "ATC code." Despite the issues with the automation of this approach at scale, the drugs from the 200 daily dose strings were sent to Google's Custom Search JSON API in the form "<drug name>ATC Code." For each drug, a Python program looped through the top 10 results (the default number of items returned) and searched for strings matching the regular expression "[A-Z]\d{2}[A-Z]{2}\d{2}." The first 3 characters of these strings were added to a list, and the highest frequency second-level ATC code was the choice made by the search-based algorithm.

The grading of the search-based algorithm was simplified. While the LLM-based algorithm had to find the best and next-best second-level ATC codes, the search-based algorithm only had to find the single best ATC code. There were only 2 grades applied: "appropriate" and "not appropriate," where appropriateness is for a database of oral solids. If there is a tie between 2 second-level ATC codes and both are appropriate, then the output is appropriate. If there is a tie and at least 1 code is inappropriate, then that output is not accepted. This sets up the fraction of appropriate grades as a benchmark, acknowledging that the search-based algorithm is not encouraged to pick ATC codes relating to oral solids.

The results of the search-based algorithm are adjunctive to the results of the LLM, and the decision was made not to pursue formal inference. Comparing the success rates was inevitable, but not the goal of the paper. However, it was informative to see cases where the search-based algorithm failed and the LLM succeeded, and vice versa. A table of cross frequencies was thus compiled, and all cases where the search-based algorithm's output was graded "not appropriate" were added to the table of errors.

Ethical Considerations

This study used operational data collected from a commercial medication dispensing system used in routine patient care and was not subject to institutional review board review requirements, so approval was not obtained. Users of the spencer device provided consent for data collection through the End User License Agreement, which covers the collection of medication adherence data and responses to quality of life and patient-reported outcome surveys as part of the system's standard operation. No additional compensation was provided to users beyond the normal terms of their device use agreement. All data analyzed in this study were deidentified before the analysis. SHS has achieved both ISO 27001 and Data Privacy Framework certifications, and the system uses industry-standard encryption and security measures.

This research analyzed data collected during standard clinical care and device use. All results are presented as anonymous aggregate statistics. The original data collection occurred as part of routine clinical practice, with patients providing consent for research use through the device's terms of service and care management agreement. Under the Tri-Council Policy Statement: Ethical Conduct for Research Involving Humans, Article 2.4, research ethics board review is not required for research that relies exclusively on the secondary use of anonymous information, where the process does not generate identifiable information [39]. Under US regulation 45 CFR 46 104(d)(4)(ii), institutional review board review is not required when information is recorded by the investigator in such a manner that participants cannot be identified, directly or through identifiers linked to the participants; the investigator does not contact the participants; and the investigator will not reidentify participants [40].

Results

The Initial AI Prompt

The initial prompt constructed is provided in Textbox 3 and made available as a plain text file in Multimedia Appendix 1. With a goal of classifying aspirin in a dose-dependent manner with instructions and examples, this prompt requested output consisting of only ATC codes in a pipe-delimited list.

When tested interactively, the initial prompt repeatedly failed to classify high doses of aspirin with N02 as the most likely second-level ATC code. The following inputs all consistently produced the response "B01|N02": "aspirin|1 pill of 81mg," "aspirin|2 pills of 325mg," "aspirin|12 pills of 325mg," and "aspirin|3 pills of 1000mg." Sentences were added, such as "Prioritize the dose" and "Think about what conditions the total daily dose would be most likely to treat," but these were not effective. Results from testing this first AI prompt, with a focus on aspirin classification performance, emphasized challenges faced in the development of a robust classification system that may deal with dose-dependent categorizations. This motivated the creation of a second prompt with chain-of-thought reasoning techniques.

XSL•FO
RenderX

Textbox 3. The initial artificial intelligence (AI) prompt: few-shot learning with concise output.

Instructions

You are a classifier of drug prescriptions into Anatomical Therapeutic Chemical (ATC) second level subgroups. As a drug and dose combination may contain multiple ATC second level subgroups, your job is to return to the closest ATC second level category, followed by the next closest. If there is one and only one category, then return "NA" for the second category. If the drug cannot be classified or is ambiguous, return "UNKNOWN" for both ATC fields. Return exactly two fields are separated by a pipe ("|").

Input and Output format

- Input: <drug name>|<daily drug dose>

- Output: <Best level 2 ATC Code>|<Next Best level 2 ATC Code (if applicable)>

Additional Information

All drugs are oral solids. The drug name as a string. Handle different capitalizations, common misspellings, and concatenations with manufacturer names. If the daily drug dose is missing or unintelligible, then do your best with the drug name alone.

Examples

* Input: metformin|2 pills of 500MG

* Output: A10|NA

* Input: apo-dexamethasone|0.5 pills of 4.0 MG

* Output: H02|S01

* Input: XYZ−1234|1 pill of 1 g

* Output: UNKNOWN|UNKNOWN

* Input: webber naturals womens 50 plus most

* Output: A11|NA

The Revised AI Prompt Using Chain-of-Thought Reasoning

On the basis the results of the initial AI prompt, the preference for concise output was dropped in favor of a chain-of-thought prompting technique. The hypothesis was that prompting the LLM to reason about drugs before reporting second-level ATC codes would lead to higher quality classifications as, at the time of making the classification, the LLM would have access to its own reasoning before outputting the ATC classes so that the LLM can use the text generated by the reasoning. Few-shot learning examples were used here as well, and the entire revised AI prompt is shown in Textbox 4 and made available as a plain text file in Multimedia Appendix 2.

As a side note, dexamethasone from the initial prompt examples was omitted from the revised prompt. It is a secondary classification of S01, an ophthalmological drug, would not be dispensed through spencer as it is a liquid eye drop.

The revised prompt was able to classify aspirin in the desired manner. For instance, in the OpenAI playground, the assistant responded to the input "aspirin|1 pill of 81mg" with the output presented in Textbox 5.

Despite the carriage returns, the output was pipe-delimited as requested, and the reasoning correctly specifies that aspirin that this dose is used for its antiplatelet effects rather than its pain relief effects. It did not include N02 as the next most likely drug classification, and this was deemed acceptable since a patient is unlikely to be taking 81 mg of aspirin daily for pain. An input of "aspirin|2 pills of 325mg" led to the output in Textbox 6.

Thus, the revised prompt with chain-of-thought reasoning returned N02 as the best ATC code for high-dose aspirin and B01 as the next-best second-level ATC. This was deemed acceptable as aspirin could conceivably be taken for a dual purpose, and the revised prompt was promoted to the pilot sample phase.

XSL•FO
RenderX

Textbox 4. Revised artificial intelligence prompt with chain-of-thought prompting techniques.

#Instructions

You are a classifier of oral drug prescriptions into Anatomical Therapeutic Chemical (ATC) level 2 therapeutic subgroups. Handle different capitalizations, common misspellings, and concatenations with manufacturer names. As a drug and dose combination may be linked to several ATC level 2 subgroups, your job is to return the most likely and next most likely level 2 subgroups. The user's input should take the from <Oral solid drug name>|<Daily drug dose>, whereby you should output a 3-column, pipe-delimited message taking the form: <Reasoning>|<Most likely level 2 ATC Code>|<Next most likely level 2 ATC Code (or "NA")>. Reason step by step as demonstrated in the examples, taking into consideration the most likely indication given the daily dose.

#Examples

*Input: metformin|2 pills of 500MG

*Output: 2 pills of 500MG is 1000MG per day. The typical effective dose range for metformin in managing type 2 diabetes is between 500mg to 2000mg per d., and 1000MG is right within this range. The code A10 refers to "Drugs used in diabetes."|A10|NA

*Input: apo-dexmethasone|0.5 pills of 4.0MG

*Output: 0.5 pills of 4.0 MG is 2.0 MG per day. Dexamethasone at this dose is typically used for mild to moderate inflammatory and autoimmune conditions. The primary code H02 refers to "Corticosteroids for systemic use, plain."|H02|NA

*Input: XYZ-1234|1 pill of 1g

*Output: XYZ-1234 is not an oral solid drug I am familiar with.|NA|NA

*Input: webber naturals womens 50 plus most|1 pill of UNK

*Output: The dose is unintelligible, but this is a multivitamin and is classified by ATC Code A11: Vitamins.|A11|NA

Textbox 5. The output for aspirin at 81 mg per day.

1 pill of 81mg is 81mg per day. Aspirin at this low dose is typically used for its antiplatelet effects to prevent cardiovascular events such as heart attacks and strokes. The primary ATC code for antithrombotic agents is B01.

Reasoning: Aspirin at 81mg is commonly used for cardiovascular protection rather than for pain relief or anti-inflammatory purposes, which would require higher doses.

|B01|NA

Textbox 6. The output of aspirin at 650mg per day.

2 pills of 325mg is 650mg per day. Aspirin at this dose is typically used for pain relief, anti-inflammatory purposes, and sometimes for cardiovascular protection. The primary ATC code for aspirin when used for pain and inflammation is N02: "Analgesics." When used for cardiovascular protection, the ATC code is B01: "Antithrombotic agents." Given the dosage, it is more likely to be used for pain relief.

Reasoning: 2 pills of 325mg is 650mg per day. Aspirin at this dose is typically used for pain relief and anti-inflammatory purposes. The primary code N02 refers to "Analgesics."

|N02|B01

A Finite Population of Daily Drug Doses

To this point, all AI prompt testing was done via hypothetical examples. For testing on prescription drugs in a real population, 3371 deidentified patients met the inclusion criteria described in Textbox 1, of which 2908 (86.26%) resided in Canada and 463 (13.73%) resided in the United States. These patients collectively had 4.76 million doses scheduled after January 1, 2024, according to the database query date of June 1, 2024. Within these doses, there were 2077 distinct drug names, 517 (24.89%) of which were prescribed to patients residing in Canada, and 646 (31.1%) were prescribed to patients residing in the United States. Only 86 (4.14%) out of 2077 drug names were prescribed to patients residing in both regions. When combined with daily pill quantity and strength information, there were 12,294 daily drug prescription strings (eg, "pms-quetiapine|1 pill of 100.0 MG, 1 pill of 200.0 MG"), the finite population of interest.

The Pilot Sample for Testing the AI Prompt

The random sample of 20 daily dosage strings was used to determine if the revised prompt would continue to be studied. The 20 daily dose strings appear in Table 2 alongside the output from the OpenAI Batch API.

This result was deemed adequate for proceeding, despite 2 issues. The string "apo-lamotrigine|0.5 pills of 25.0 MG" returned a correct best second-level ATC code of N03 but an incorrect next-best second-level ATC code of N05. For the string "apo-pregabalin|4 pills of 75.0 MG," the first of several pregabalin doses to come, the antiepileptic nature is emphasized at the expense of the neuropathic pain aspect that the drug has come to be most associated with. The N02 best second-level ATC code would have arguably been superior.

XSL•FO
RenderX

Table 2. The pilot sample for testing the revised artificial intelligence (AI) prompt.

Input string for user role	Best second-level ATC[a]	Next-best second-level ATC
carbamazepin tab|2 pills of 200MG	N03	N/A[b]
calcium-ng-vitd - jam|1 pill of UNK	A12	N/A
teva-entacapone|7 pills of 200.0 MG	N04	N/A
apo-midodrine|8 pills of 2.5 MG	C01	N/A
hydroxyzine hydrochloride|4 pills of 10.0 MG	N05	R06
apo-domperidone|2 pills of 10.0 MG	A03	N/A
aventyl|4 pills of 25.0 MG	N06	N/A

The Inference Sample for Estimating Accuracy of AI Drug Classification

With the 20 records from the pilot sample excluded, a final sample of 200 daily drug dose strings were taken without replacement. These strings were sent to the OpenAI Batch API using GPT-4o with the settings previously described on July 10, 2024, for a total cost of US $0.33. Of the 200 daily dose string inputs, 175 (87.5%) were graded as perfect, 10 (5%) had a minor issue, and 15 (7.5%) had a major issue. For inference to our population of 12,294 daily drug prescription strings, the estimate of mostly correct outputs was 92.5% (185/200, 80% CI 90.1%-94.9%).

Despite not being tuned for an oral solid database, the pipeline based on Google's Programmable Search Engine did well. Out of the 200 drug names submitted to the algorithm, 82.5% (165/200) were deemed acceptable for use in the oral solid database, while 17.5% (35/200) were not. Table 3 shows the breakout of grades from both algorithms.

Table 3. GPT-4o with prompt versus a pipeline using Google's Programmable Search Engine and regular expressions.

Large language models score	Search-based algorithm score		Margin
	Acceptable	Not acceptable	
1 (perfect)	148	27	175
2 (minor issue)	8	2	10
3 (major issue)	9	6	15
Margin	165	35	200

All imperfect gradings from either algorithm are presented in Multimedia Appendix 3.

When discussing the imperfect grades from the LLM algorithm, pregabalin was the most frequent culprit, appearing total 7 times in the inference sample under different brand names and different dosing configurations. In each case, the LLM's output returned N03 as the best second-level ATC code followed by N06. The search-based algorithm consistently returned N02, which aligns with pregabalin's most well-recognized role of treating neuropathic pain. However, pregabalin, developed as an antiepileptic, is still used in that capacity and also for generalized anxiety disorder. Thus, the LLM's outputs were considered more correct than incorrect.

XSL•FO
RenderX

The largest category of serious errors is where the LLM either did not recognize a real drug or reasoned about the wrong drug. An example of the former was MYA, a Canadian birth control oral solid [41] that GPT-4o was unable to retrieve information about. Interactive prompt modifications in the OpenAI playground could not overcome this. In a second case, the Canadian morphine drug STATEX [42] was reasoned about as a statin, presumably due to the lexical similarity. However, this mistake could not be replicated within the OpenAI playground.

Reasoning about vitamins that might be anemia treatments caused two grade 3 errors relating to the best second-level ATC. The decision was made to require B03 (Antianemic preparations, a second-level ATC code) as the best second-level ATC code for Vitamin B12 supplements if the dose was high or if the dose was unknown, and in these 2 cases Vitamin B12 supplements were classified primarily as A11 (vitamins, a second-level ATC code). A11 was allowed as a next-best code if it was provided but was not required.

The vitamin D analog calcitriol proved to be another noteworthy case in the domain of vitamins. While Vitamin D analogs explicitly fall under A11, calcitriol is no ordinary vitamin, and its therapeutic use case falls better under H05 (calcium homeostasis). The decision was made to require both A11 and H05 for full credit, but to give mostly correct status if either one was present. In the 2 times that calcitriol appeared, only A11 was present in one case and only H05 in the other, so these were graded as more correct than incorrect.

The reasoning in the chain-of-thought responses was not without cost. The extra output costs money, and there's additional likelihood of a delimiter error because the algorithm needs to stop reasoning and add the pipe delimiters and ATC codes. In total, 2 (1%) times out of the 200, delimiter errors were a primary cause of a mostly incorrect grade.

The LLM respected the oral solid criteria, sometimes to a fault. In a favorable case, azithromycin was classified as J01 when it would have been classified as S01 if packaged in liquid form as eye drops. However, the search-based algorithm also returned J01, without any oral solid prompting. For the case of a reminder pouch for Repatha, an injectable, the LLM was a reminder pouch for Repatha, an injectable, where the LLM only returned missing data points even though Repatha itself is easily classified as C10. This was not considered incorrect because the prompt was specifically asked to return NAs when drugs could not be classified as oral solids.

During the grading process, difficulties with the problem formulation of best versus next-best ATC code became apparent in ways that were not obvious from the motivating example of aspirin. Terazosin, which can be used as an antihypertensive or a urological in oral solid form and where doses overlap, was well served by a C02|G04 output. Calcium, magnesium, zinc, and Vitamin D3 were well served by an A12|A11 output. However, in other cases, things were less clear. Pregabalin could have at least 3 ATC codes. For the case of calcitriol, there are only 2 relevant ATC codes, but the order of best versus next best is not obvious.

The drug methotrexate illuminated a limitation of the daily dose formulation of the prompt. The string input was "pms-methotrexate|5 pills of 2.5 MG" which suggests a 12.5-mg daily dose; however, this medication is often dosed once per week. This output was graded as mostly incorrect as it returned L01 instead of L04, whereas the former would more typically be associated with high-dose infusions for cancer treatment.

After focusing the first part of this research on chain-of-thought reasoning about drug dose, it is natural to question whether this was worth the additional prompt complexity and number of prompts. While the reasoning would often mention "at this dose," or mention that the dose fell within a common range of prescriptions, in the end, the results mostly aligned with the search-based algorithm. The cases where the dose mattered were antianemic preparations such as high-dose folic acid (a case that the search-based algorithm missed) and high-dose folate. It also helped to give prednisone an H02 systemic use classification as opposed to a higher dosage A07 classification for inflammatory bowel disease. Notably, low-dose aspirin did show up in the inferential sample, but the drug name was "aspirin low dose" and the search-based algorithm was easily able to reach a majority vote of B01.

Discussion

Principal Findings

LLMs such as GPT-4o perform well in the drug classification task. In the handpicked example of aspirin, GPT-4o was able to distinguish between 2 therapeutic uses based on the dose, which happened only after incorporating a chain-of-thought prompting technique. This prompt, when applied to a larger sample, was deemed mostly correct a vast majority of the time (n=200, 92.5%).

Google's Programmable Search Engine via the Custom Search JSON API also does well with extracting ATC codes when combined with a simple pipeline using regular expressions and voting. While the proportion of appropriate search-algorithm responses (n=200, 82.5%) was somewhat lower than the mostly correct proportion mostly correct proportion from the LLM, the algorithm was not specifically tuned to the task of coding oral solids. Different search terms could be tried or more pages could be returned.

However, the question is not whether Google's Programmable Search Engine could be tuned to outperform an LLM, because with enough time and effort, the answer can likely be found online. One place where such answers show up is a publicly accessible version of DrugBank, a proprietary source of drug information, that is indexed by Google's Programmable Search Engine and often shows up in the summary snippets returned by the Custom Search JSON API. Along with Google's restriction on persistent storage of results, automatic scraping of such data represents multiple terms-of-service violations. While the enforceability is questionable, why incur the risk when LLMs perform as well as they do and are meant to extract information for the user to keep for as long as is necessary?

In addition, Google Search, while quite reproducible in the short term due to caching, has faced allegations of declining quality

XSL•FO
RenderX

[43] and its long-term reproducibility is uncertain. Prediction algorithms built upon Google's Search infrastructure have failed when the infrastructure changed, as in the case of Google flu [44].

Reproducibility for versioned LLMs with temperature parameters like GPT-4o should, in principle, be perfect, as setting the temperature parameter to 0 should lead to deterministic output (at least when there are no probability ties between tokens). However, this is not true in practice [45]. Differences between the Batch API and OpenAI playground were sometimes material, and this has been experienced by other users. One user of the OpenAI Batch API commented that batching changed the behavior of an OpenAI LLM, making the results "too similar" [46]. At the time of writing, an experimental feature from OpenAI is available that includes a seed parameter and system fingerprint, which may be helpful in achieving perfect reproducibility.

Despite concerns with reliability in this research, GPT-4o's reliability has been praised in medical contexts as higher than alternatives. In a study on extraction and summarization of Japanese-language clinical research protocols, GPT-4o was said to exhibit "high reproducibility," with 80% and 100% accuracy for research objectives and research designs [47]. In an information extraction task on veterinary electronic health records, GPT-4o demonstrated greater reproducibility than human pairs, with an average Cohen κ of 0.98 versus 0.8 for humans [48].

For US $0.33, 200 daily drug prescription strings were classified into best and next-best second-level ATC codes with the reasoning provided. That would correspond to spending approximately US $20 to classify all 12,294 daily drug prescription strings in the SHS drug database. The affordability of GPT-4o as a drug categorization tool signifies a democratization of research instruments in pharmacoepidemiology, as the inexpensive use of GPT-4o, especially via the OpenAI Batch API, means that drug classification can be accommodated on virtually any research budget. Prompts can be shared within the research community, and the richness of drug datasets will be enhanced for teams worldwide. Furthermore, as competition increases, capabilities are likely to improve while prices fall. An example of this is GPT-4o itself, which at the time of release was twice as fast and half the price of GPT-4 Turbo [49]. This cost-effectiveness democratizes access to advanced drug classification tools and, as such, promotes equitable research opportunities.

Limitations and Future Work

This study involved a specific population of daily drug prescriptions from polychronic patients in a value-based care organization residing in the United States and Canada. Geographically, the patients were biased toward Canada, with some US representation. Future work is needed to replicate drug classification in other settings. In addition, one of the motivations for One motivation for adopting LLMs was their ability to accommodate drugs in non-English speaking countries that use operational codes other than DIN and NDC. While GPT-4o boasts of "significant improvement on text in non-English languages" [49], such classification was out of scope for this research. Future studies are needed to test the global generalizability of this approach.

The manual grading used in this paper has the potential for bias and errors. The grading process was tedious and represented 220 separate research investigations. It is likely that contradictions remain; however, all imperfect grades were documented in the Results section. In the future, more formal methods, such as the Delphi method [50], could add additional rigor.

The problem formulation of best and next-best second-level ATC codes, based on daily dosage strings, was occasionally not ideal for the drugs and doses encountered. Examples include cases where more than 2 ATC codes were necessary, times where ordering was not clear, questionable relevance of a next-best code, and weekly dosing schedules. Other formulations could be considered, such as those that return true or false for a set of codes, potentially not based on dose at all. Ignoring the dose would greatly simplify the problem formulation. In addition to alleviating the daily versus weekly frequency complexity, the multiplicity of inputs is cut down to a fraction of what was encountered in this research, as only the drug name is the input.

Complete and total reproducibility of GPT-4o outputs was not possible at the time of writing. New features such as system fingerprints and seeds may address this and are an important topic for future research. One prompting technique to deal with a multiplicity of possible outputs is to sample them from the LLM with temperature set above 0 and use a voting process. This is the essence of the "self-consistency" prompting approach [46]. In addition, with powerful open-source LLMs becoming available, such as the Llama family of models [51], there is the question of whether full reproducibility is achievable when the researcher is running the model locally. If so, is there a reduction in the quality of the drug classification when using an open-source model that may pose a trade-off to reproducibility?

Outside of reproducibility, more research on the benefits of open-source LLMs for drug classification and related tasks is needed. For instance, open-source models run locally have the privacy advantage of not needing to have data leave any internal network but could open up other privacy risks. The economics of using an open-source LLM vs proprietary LLMs via APIs is also unclear. This research was limited to one LLM, the proprietary GPT-4o (specifically the version "gpt-4o-2024-05-13").

New LLMs are arriving regularly, with new capabilities. Future research will be needed to evaluate the drug classification capabilities of the next generation of the next generation of models. Continuing assessment of the emergence of new AI models will enable the use of the most-effective and updated tools for pharmacoepidemiologic research.

Conclusions

This research demonstrated that GPT-4o is a powerful and accessible tool for enhancing pharmacoepidemiologic research by automating drug classification. GPT-4o and LLMs in general represent an inexpensive and straightforward method for augmenting real-world drug databases with Anatomical Therapeutic Chemical drug classes. This gives nearly all

XSL•FO
RenderX

research teams access to a powerful tool to satisfy a key prerequisite of pharmacoepidemiological analysis using data from electronic health records, pharmacy management systems, and claims records. It is not just a matter of increased efficiency but also democratizing access to high-quality pharmacoepidemiologic drug classification instruments. Better, more accessible drug information is a precursor to higher quality and greater quantity of pharmacoepidemiologic datasets and a path toward better drug prescription policy and clinical outcomes for patients across the world.

Acknowledgments

This work was funded by Spencer Health Solutions, Inc, a private corporation headquartered in Morrisville, North Carolina.

Data Availability

A subset of the data generated during this study—specifically, examples of large language model–generated errors and corresponding processed drug and dose strings—is included in the supplementary information files. The complete set of processed drug strings and evaluation outcomes is available from the corresponding author on reasonable request. The raw data containing numerical identifiers are not publicly available due to privacy and confidentiality restrictions.

Authors' Contributions

All authors participated in the conceptualization, review, and revision of the final manuscript draft for submission. IRR-C provided expert guidance on the performance grading. BO and IRR-C proposed the methodology, assessed the performance of the algorithms, and wrote the original draft. BO performed the statistical analyses. EF and TR supervised the research through all stages and performed validation activities.

Conflicts of Interest

The authors are all current or former employees or contractors of Spencer Health Solutions, Inc, the developer of the spencer platform.

Abstract

Background: Artificial intelligence (AI) is transforming medical imaging, with large language models such as ChatGPT-4 emerging as potential tools for automated image interpretation. While AI-driven radiomics has shown promise in diagnostic imaging, the efficacy of ChatGPT-4 in liver ultrasound analysis remains largely unexamined.

Objective: This study aimed to evaluate the capability of ChatGPT-4 in liver ultrasound radiomics, specifically its ability to differentiate fibrosis, steatosis, and normal liver tissue, compared with conventional image analysis software.

Methods: Seventy grayscale ultrasound images from a preclinical liver disease model, including fibrosis (n=31), fatty liver (n=18), and normal liver (n=21), were analyzed. ChatGPT-4 extracted texture features, which were compared with those obtained using interactive data language (IDL), a traditional image analysis software. One-way ANOVA was used to identify statistically significant features differentiating liver conditions, and logistic regression models were used to assess diagnostic performance.

Results: ChatGPT-4 extracted 9 key textural features—echo intensity, heterogeneity, skewness, kurtosis, contrast, homogeneity, dissimilarity, angular second momentum, and entropy—all of which significantly differed across liver conditions (P<.05). Among individual features, echo intensity achieved the highest F_1-score (0.85). When combined, ChatGPT-4 attained 76% accuracy and 83% sensitivity in classifying liver disease. Receiver operating characteristic analysis demonstrated strong discriminatory performance, with area under the curve values of 0.75 for fibrosis, 0.87 for normal liver, and 0.97 for steatosis. Compared with IDL image analysis software, ChatGPT-4 exhibited slightly lower sensitivity (0.83 vs 0.89) but showed moderate correlation (r=0.68, P<.001) with IDL-derived features. However, it significantly outperformed IDL in processing efficiency, reducing analysis time by 40%, and highlighting its potential for high throughput radiomic analysis.

Conclusions: Despite slightly lower sensitivity than IDL, ChatGPT-4 demonstrated high feasibility for ultrasound radiomics, offering faster processing, high-throughput analysis, and automated multi-image evaluation. These findings support its potential integration into AI-driven imaging workflows, with further refinements needed to enhance feature reproducibility and diagnostic accuracy.

Introduction

In recent years, advancements in artificial intelligence (AI) have transformed various fields, and one notable application is in the realm of medical imaging [1-6]. AI holds significant potential in revolutionizing the field of medical imaging, as it can automate numerous tasks and even surpass human abilities in specific areas, whether it be in diagnostic or interventional applications [7]. Integrating AI with ultrasound imaging is particularly compelling. Unlike other imaging modalities, ultrasound relies heavily on human operators [8,9]. This dependence on human expertise presents unique challenges, especially with the growing use of portable ultrasound devices. These devices are increasingly used by a diverse range of health care providers, including nonradiologists, who may have varying levels of training and experience [10]. AI algorithms offer a powerful solution to mitigate the challenges associated with operator dependency in ultrasound imaging. These algorithms can play a crucial role in the automated detection of anomalies and significant findings, providing not only descriptive analysis but also valuable diagnostic guidance [11-13]. This capability is particularly beneficial for less experienced operators or in situations where expert radiologists are not readily available in regions with limited medical resources. The integration of AI in ultrasound imaging can lead to more accurate and efficient diagnostic processes, reducing the likelihood of human error and improving patient outcomes [12-17].

ChatGPT is an advanced and powerful AI natural language processing model developed by OpenAI and was designed to comprehend and generate human-like text responses [18]. Having been extensively trained on a diverse corpus of data, ChatGPT has cultivated the capacity to grasp context, acquire knowledge from examples, and produce cohesive responses [19]. Consequently, it has evolved into a versatile tool applicable to a wide array of uses, including health care and medical imaging [20-26]. In health care, its capacity to process and interpret vast amounts of information can support medical diagnostics, patient communication, and research. The latest version, ChatGPT-4, expands its ability to multimodal interactions, including image processing and potential capabilities in audio and video formats [27-29]. This enhancement is especially beneficial in health care, where it can analyze medical imagery, assist in creating educational materials, and offer visually descriptive assistance in patient care. By integrating advanced image analysis and generation, ChatGPT-4 stands poised to transform how AI supports health care professionals, offering tools for more accurate diagnoses, treatment planning, and patient engagement through rich, interactive media.

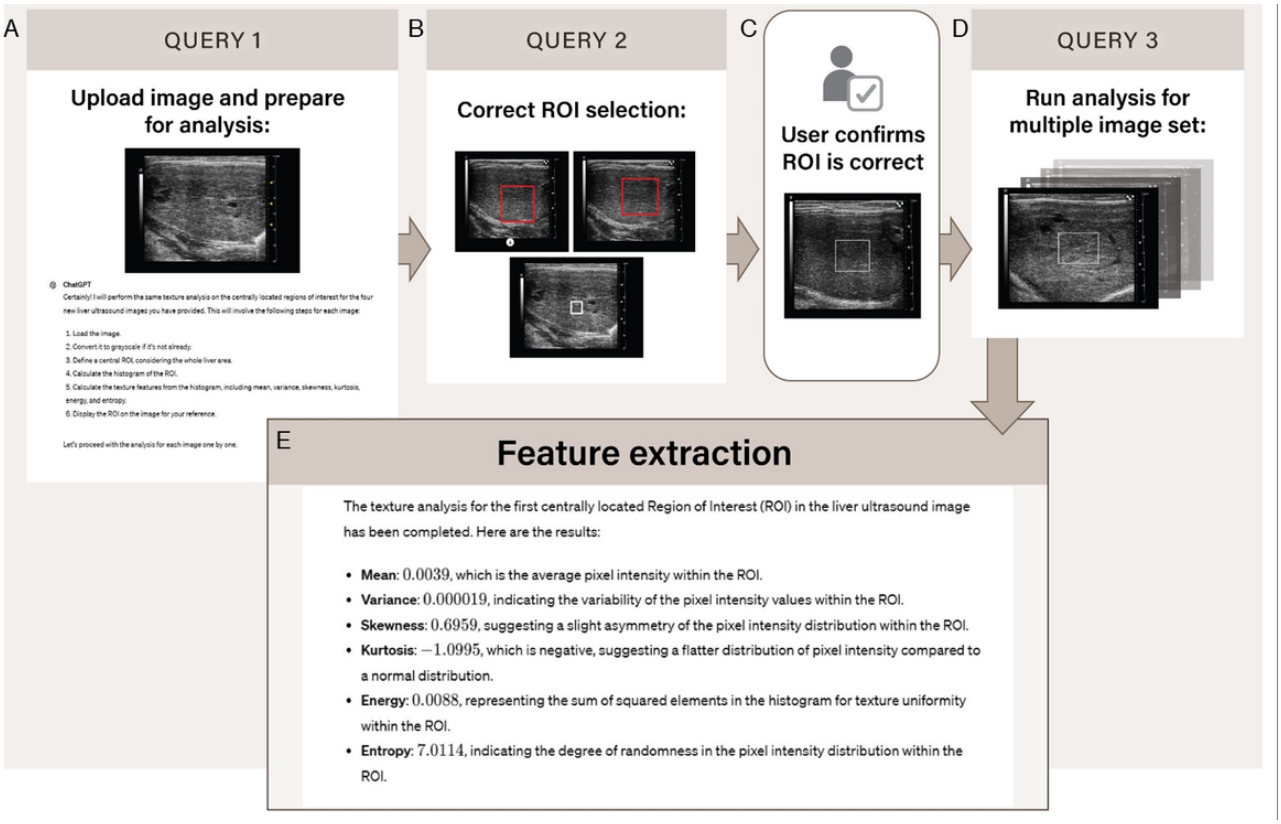
In this study, we explore the potential of ChatGPT-4 in ultrasound imaging, particularly its capabilities in radiomics analysis for detailed tissue texture characterization. We focus on using ChatGPT-4–based radiomics to detect 3 distinct liver tissue types—normal, fibrotic, and fatty liver—using ultrasound images. To address challenges related to clinical data security, patient privacy, and ethical compliance, the liver ultrasound images in our study were sourced from an animal model. We then compared the findings generated by ChatGPT-4 with those obtained from conventional image analysis software. Our exploration highlights the potential of ChatGPT-4 to enhance research efforts and future clinical applications by improving the accuracy of quantitative image analysis.

Beyond radiomics analysis, we evaluated ChatGPT-4 as a tool for distinguishing normal from abnormal cases based on imaging findings. We aimed to demonstrate its capability as a supportive tool in clinical settings. Such a tool could significantly reduce the workload of radiologists by efficiently filtering out normal cases, allowing them to focus their expertise on more complex and abnormal cases. This expanded exploration highlights the promising role of ChatGPT-4 in enhancing diagnostic accuracy and supporting clinical decision-making in liver disease detection.

Methods

Image Data Acquisition

Seventy B-mode grayscale ultrasound images acquired from validated rat liver disease models [30-32] were used for analysis. The images were distributed across 3 categories of liver health: fibrosis (n=31), steatosis (fatty liver) (n=18), and normal (n=21). To maintain consistency and reliability in the analysis, the imaging parameters were standardized, including transducer frequency, gain settings, imaging depth, focus, and dynamic range. These standardizations ensured that the liver tissue's echogenicity and overall image quality were consistent across all samples, allowing for accurate comparisons between the different health states. Additionally, each analysis focused on a single image depicting a section of the right lobe of the liver. The right lobe was chosen due to its larger size and easier accessibility, which provided a more representative and consistent area for imaging and subsequent histopathological validation. The liver pathology in these images was validated with histopathology, further ensuring the accuracy of the ultrasound-based categorization.



Ultrasound Image Analysis by ChatGPT-4

Overview

We leveraged the advanced capabilities of ChatGPT-4 for radiomics analysis of ultrasound images. ChatGPT-4 was used to select regions of interest (ROIs), extract radiomic features, and classify liver disease conditions. These critical steps are depicted in Figure 1.

XSL•FO
RenderX

Figure 1. ChatGPT-4–assisted liver ultrasound image radiomics analysis workflow. The image illustrates the stepwise process of liver ultrasound texture analysis using ChatGPT-4. The process begins with uploading the image and preparation for analysis (query 1), where ChatGPT-4 performs texture analysis based on a selected ROI. In query 2, the user verifies and corrects the ROI selection. The ChatGPT-4 interface allows the user to refine the ROI to ensure accurate analysis. Once confirmed, the system proceeds to apply the same process to a series of images (query 3). Feature extraction details the analysis outputs, including texture metrics such as mean, variance, skewness, kurtosis, energy, and entropy, which provide insights into pixel intensity distribution and texture uniformity within the selected ROI. Figure prepared by Brittany Bennett, CMI. ROI: region of interest.

Region of Interest Delineation

The first critical step involved selecting a region of interest (ROI) within the liver tissue depicted in each ultrasound image (Figures 1B and 1C). ROIs were automatically defined using ChatGPT-4's advanced algorithms. Upon receiving the query, ChatGPT-4 initially proposed an ROI based on its automated analysis of the image, highlighting a region that it determined to be representative of the liver parenchyma. Users then refined these suggestions to ensure alignment with clinical standards, making adjustments as necessary to ensure that the selected area was optimal for analysis meticulously excluding artifacts such as vascular structures, acoustic shadows, and reverberation. This interactive process allowed for fine-tuning of the ROI, combining the computational efficiency of ChatGPT-4 with the expert judgment of the user. Once the ROIs were verified for accuracy in an analyzed image, they were replicated across 10 subsequent ultrasound images, which were then uploaded for subsequent radiomics analysis using a batch processing approach (Figure 1). Having liver images captured consistently in the same plane and region facilitated the reproducibility of ROI placement across the images. This method significantly enhanced the efficiency of our analysis, allowing for a more comprehensive assessment of liver tissue samples

Feature Extraction

Feature extraction was conducted in batches of 10 ultrasound images, the maximum allowed by ChatGPT-4, requiring multiple sessions to analyze all 70 cases. However, conducting analyses across different sessions introduced variability—some features were occasionally omitted, while others appeared inconsistently across sessions. To mitigate this session-dependent variability and ensure consistency in feature extraction, we implemented a standardized approach. At the beginning of each session, we carefully refined the prompts provided to ChatGPT-4 to align with previously extracted features (Table S1 in Multimedia Appendix 1). Missing features were explicitly requested, and any inconsistently appearing features were excluded. If ChatGPT-4 returned incomplete or inconsistent features, prompts were reissued or clarified until the correct output was obtained. Our final analysis included only features that were consistently and reliably extracted across all sessions. This approach minimizes session-to-session variation while maintaining reproducibility across users.

ChatGPT-4 extracted a comprehensive set of radiomic features to characterize liver tissue texture [33-35]. These included first-order statistics and second-order texture features. First-order statistics are quantitative measures such as mean intensity, variance (heterogeneity), skewness, and kurtosis, reflecting pixel intensity distribution. Second-order texture features are derived from the gray-level co-occurrence matrix (GLCM), and these features include contrast, homogeneity, entropy, and angular second momentum (ASM), providing deep insights into spatial relationships and textural heterogeneity within the ROI.

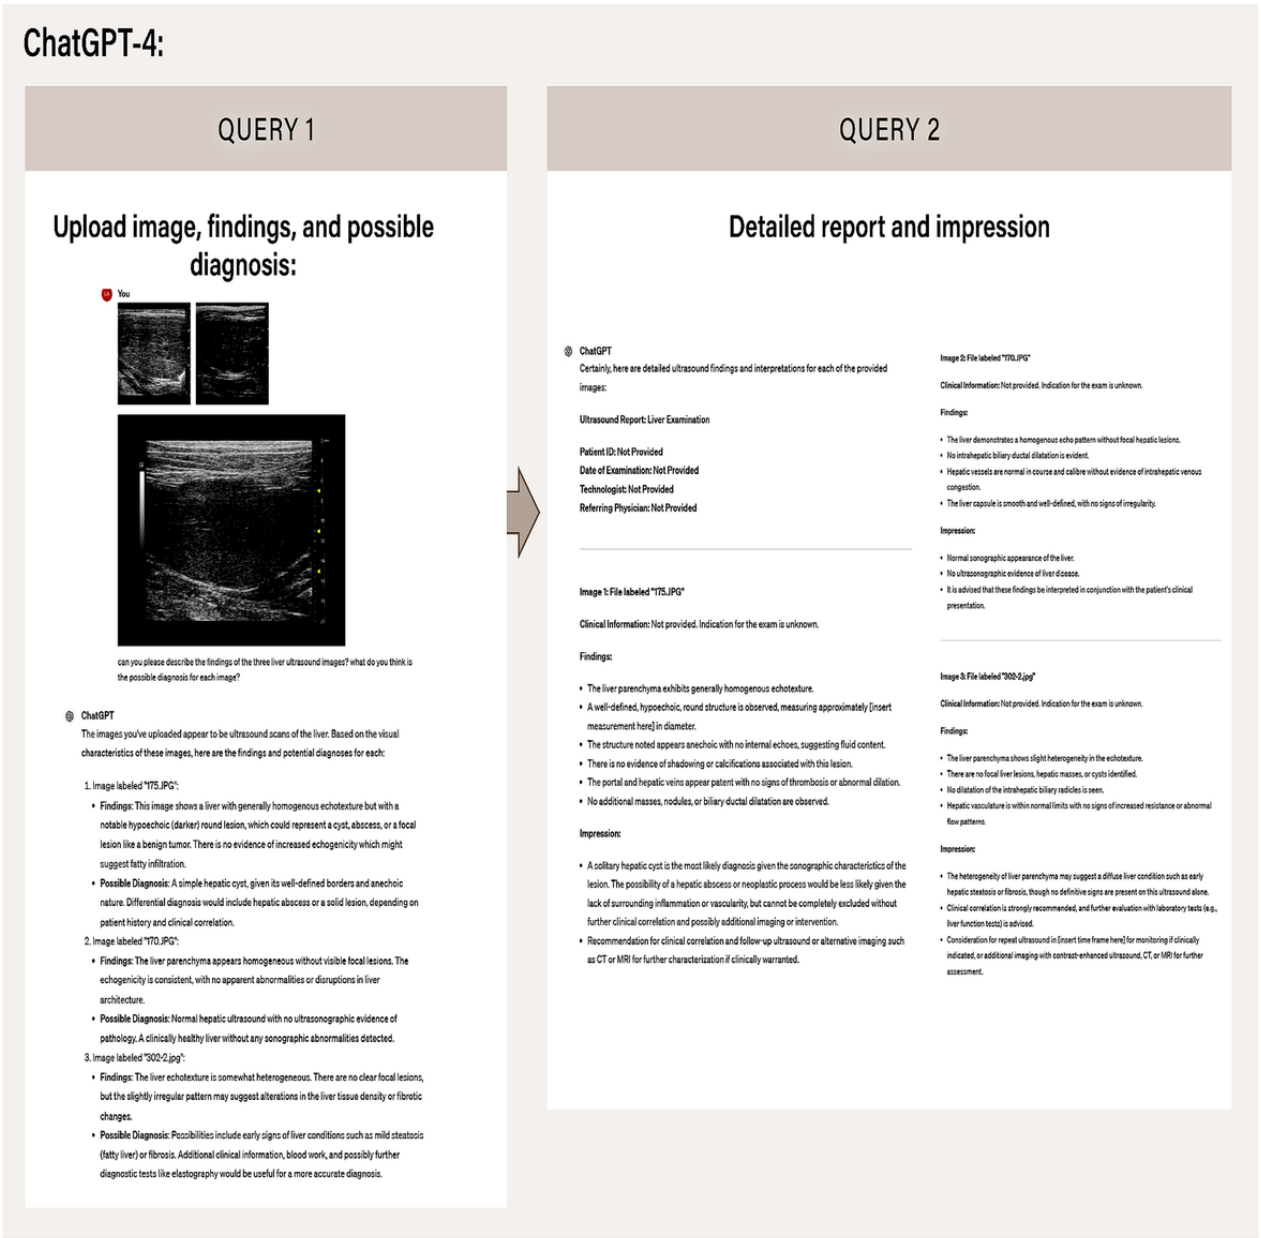
XSL•FO
RenderX

Machine Learning for Feature Model Assessment

The extracted radiomic features were used to develop a diagnostic model based on logistic regression, a method selected for its interpretability and clinical relevance. The model was configured with L2 regularization, and the regularization strength parameter (C) was optimized through grid search over a predefined range [36,37]. The liblinear solver was used for its suitability with small datasets, and the maximum number of iterations was set to 1000 to ensure model convergence. The dataset was divided into training (60%), testing (20%), and validation (20%) subsets using stratified random sampling to maintain a balanced representation across liver disease categories (Table S2 in Multimedia Appendix 1). Hyperparameter tuning was performed using a grid search to optimize model performance. Specifically, the regularization strength parameter (C) in the logistic regression model was adjusted to balance model fit and prevent overfitting [37]. A range of C values (eg, 0.001 to 100) was evaluated, and the optimal configuration was selected based on performance on the test set. To maintain methodological rigor, the test set was used exclusively during hyperparameter tuning, while the validation set was reserved for final model evaluation. The 3-way split ensured an unbiased assessment of model generalizability. Key metrics, including accuracy, sensitivity, specificity, and the area under the receiver operating characteristic (ROC) curve (AUC), were used to quantify diagnostic precision.

Ultrasound Image Analysis by Interactive Data Language–Based Software

Concurrently, the same ultrasound images were analyzed using an established interactive data language (IDL)–based tool designed for image analysis [33,38]. For this analysis, ROIs within the liver were manually defined using a specialized tool, which ensured the precise selection of the target areas based on the same selection criteria mentioned earlier. ROI delineation was performed manually by expert users, ensuring the precise inclusion of clinically relevant areas and the exclusion of artifacts. The ROIs were selected to resemble the same areas selected using ChatGPT-4. Following that, texture features describing the first-order and second-order histograms were extracted from ROIs. The same feature extraction and logistic regression methodology described above was applied, allowing for a direct comparison of the 2 approaches.



Evaluating ChatGPT-4 for Imaging Findings–Based Diagnosis

To explore the potential of ChatGPT-4 as a tool for distinguishing normal from abnormal liver cases, we conducted an experiment involving liver ultrasound images representing various conditions. We uploaded these images to ChatGPT-4 and tasked it with providing detailed descriptions of the findings and possible diagnoses for each image (Figure 2). ChatGPT-4's output included comprehensive imaging findings that described the characteristics of the liver tissue and suggested potential diagnoses based on these observations.

Following this, we compared the diagnoses provided by ChatGPT-4 with the actual diagnoses to assess its diagnostic performance in identifying liver pathology. This involved calculating metrics such as sensitivity, specificity, and overall accuracy to determine how well ChatGPT-4 could identify normal and abnormal cases.

XSL•FO
RenderX

Figure 2. ChatGPT-4–assisted liver ultrasound image diagnosis and report generation workflow. The figure depicts the workflow of using ChatGPT-4 for generating liver ultrasound image findings, possible diagnoses, and detailed reports. In query 1, images are uploaded for analysis, and ChatGPT-4 provides initial findings and potential diagnoses based on visual characteristics, such as liver parenchyma echotexture and the presence of lesions. In query 2, ChatGPT-4 generates a detailed report and impression, summarizing the clinical interpretation of the ultrasound images. Each image is examined for hepatic abnormalities, including potential cysts, signs of fibrosis, or normal liver architecture, with impressions supporting clinical correlation or further diagnostic imaging recommendations. This stepwise approach demonstrates ChatGPT-4's ability to assist in diagnostic interpretations and report generation for liver ultrasound studies, streamlining clinical workflows and enhancing diagnostic accuracy.

Statistical Analysis

To interpret the differences in ultrasound texture features among the 3 liver health categories, we calculated the mean values and SEs. A 1-way ANOVA was conducted to identify any statistical differences across the study groups.

When comparing 2 groups, the Shapiro-Wilk test was used to assess normality. If the data did not meet the normality assumption, the Mann-Whitney test was applied to determine significance, otherwise, statistical significance was evaluated using 2-tailed paired Student *t* tests, with a threshold of $P<.05$. Diagnostic performance of individual features, and combined, including sensitivity, specificity, accuracy, and F_1-score were calculated. To support the visualization of multiclass separability, an additional exploratory analysis was performed using a decision tree classifier. A one-vs-rest classification scheme was used to generate ROC curves and compute AUC values for each class: fibrosis, normal, and steatosis. In addition, the intraclass correlation coefficient (ICC) analysis was performed between 2 observers to assess the reproducibility of ChatGPT-derived features. All analyses were performed using MedCalc software (version 19.0.5; MedCalc Software Ltd).

Results

Multiclass Liver Disease Classification by ChatGPT-4–Based Ultrasound Radiomics

Identification of Key Features

The ultrasound radiomics data processed by ChatGPT-4 has provided significant insights into the textural characteristics associated with various liver diseases (Figure 3). An ANOVA analysis identified 9 key textural features (from 10 features studied)—echo intensity, heterogeneity, skewness, kurtosis, contrast, homogeneity, dissimilarity, ASM, and entropy—as significantly varying among different liver conditions.

Figure 3. This figure presents the distribution of normalized texture features extracted from liver ultrasound images using ChatGPT-4, comparing 3 diagnostic groups: fibrosis, normal liver, and steatosis. (A) Plot 1 displays first-order histogram features, including echointensity, heterogeneity, kurtosis, and skewness. Fibrotic livers exhibit the highest echogenicity, followed by steatotic livers, both exceeding normal liver levels. Additionally, fibrosis is characterized by increased heterogeneity, whereas steatosis appears more homogeneous. (B) Plot 2 illustrates higher-order texture features, including entropy, contrast, dissimilarity, homogeneity, and ASM. Fibrosis is associated with greater contrast and dissimilarity, alongside reduced ASM, reflecting increased microstructural irregularity. Conversely, normal liver tissue demonstrates higher ASM and homogeneity, indicating a more uniform texture. ASM: angular second moment.

Predictive Performance of Individual Features

Further analysis revealed varying degrees of accuracy, sensitivity, and specificity for the identified imaging features across different metrics (Table 1). The accuracy of these features ranged from 0.48 to 0.62, with echointensity and entropy exhibiting the highest accuracy at 0.62. Specificity and sensitivity also varied, with echointensity showing a high specificity of 0.62 and entropy demonstrating a lower specificity at 0.42. Heterogeneity and skewness presented moderate

XSL•FO
RenderX

accuracy levels at 0.57, with heterogeneity having slightly higher sensitivity. Energy stood out for its specificity at 0.66, while ASM, despite having the lowest sensitivity at 0.33, exhibited the highest specificity at 0.67. When these features were combined, the overall accuracy improved to 0.76, with a sensitivity of 0.83. An analysis of feature-wise F_1-scores revealed also variability in their predictive contributions (Table 1). Echo intensity also exhibited the strongest performance (F_1-score=0.85), while heterogeneity followed with F_1-score of 0.67. Notably, the combined feature approach achieved F_1-score (0.77), emphasizing the advantage of integrating multiple features, particularly weak ones.

Table 1. Performance metrics for key radiomic features in multiclass liver disease classification. Results are derived from logistic regression models configured as described above.

Feature	Accuracy	Sensitivity	Specificity	F_1-score
Echo-intensity	0.62	0.56	0.62	0.85
Heterogeneity	0.57	0.50	0.55	0.67
Skewness	0.57	0.47	0.62	0.63
Kurtosis	0.48	0.36	0.64	0.63
ASM	0.48	0.33	0.67	0.42
Energy	0.57	0.47	0.66	0.42
Contrast	0.52	0.41	0.55	0.58
Dissimilarity	0.52	0.41	0.55	0.58
Entropy	0.62	0.60	0.42	0.56
Homogeneity	0.52	0.41	0.60	0.54

ROC curve analysis for features combined using a decision tree classifier showed the following AUC values: 0.75 for fibrosis, 0.87 for normal, and 0.97 for steatosis (Figure 4). ROC comparison for individual features is shown in Table 2 (Figure S1 in Multimedia Appendix 1). The comparison showed that echo intensity and heterogeneity were highest in fibrosis (0.91 and 0.86, respectively), suggesting increased structural disruption compared with steatosis and normal liver. ASM was highest in steatosis (0.88), reflecting greater textural uniformity, while fibrosis had the lowest value, indicative of higher heterogeneity. Contrast and dissimilarity, measures of local intensity variation, were most pronounced in fibrosis (0.79 and 0.73, respectively) and lowest in normal liver, reinforcing fibrosis's greater textural complexity. Homogeneity and energy, which indicate texture smoothness and uniformity, were highest in normal liver (0.87 and 0.58, respectively), reflecting well-organized tissue architecture, and lowest in fibrosis, further supporting its structural disorganization.

XSL•FO
RenderX

Figure 4. This ROC curve illustrates the diagnostic performance of ChatGPT-4 in classifying liver conditions using a decision tree model based on combined features. The model's performance is evaluated across 3 classes: Fibrosis (the ROC curve for fibrosis shows an AUC [area under the ROC curve] of 0.75, indicating moderate diagnostic accuracy), Normal (the ROC curve for the normal class shows an AUC of 0.87, suggesting high diagnostic accuracy), and Steatosis (the ROC curve for steatosis shows an AUC of 0.97, indicating excellent diagnostic accuracy). The black dashed line represents a random guess with an AUC of 0.50. This figure demonstrates the capability of ChatGPT-4 to distinguish between different liver conditions with varying degrees of accuracy. ROC: receiver operating characteristic.

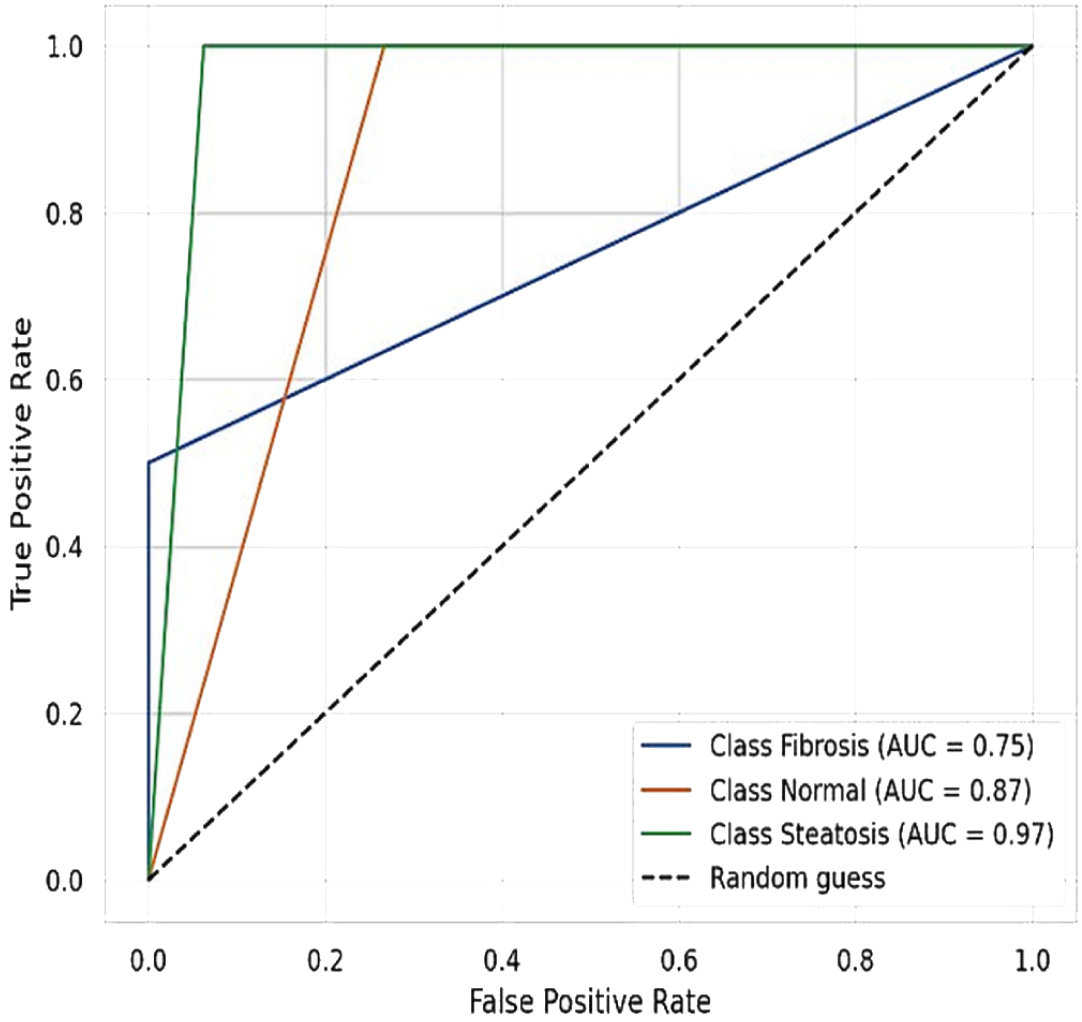

Table 2. This table presents the area under the receiver operating characteristic (ROC) curve (AUC) values for radiomic features extracted from liver ultrasound images using ChatGPT-4, assessing their ability to differentiate fibrosis, steatosis, and normal liver tissue. These findings demonstrate the feasibility of ChatGPT-4–assisted ultrasound radiomics for noninvasive liver disease characterization.

	Fibrosis	Steatosis	Normal
Echo intensity	0.91	0.39	0.12
Heterogeneity	0.86	0.33	0.23
Kurtosis	0.22	0.51	0.82
Skewness	0.22	0.45	0.87
Angular second momentum	0.11	0.88	0.59
Correlation	0.53	0.33	0.61
Dissimilarity	0.73	0.39	0.33
Contrast	0.79	0.42	0.22
Entropy	0.44	0.90	0.21
Energy	0.49	0.43	0.58
Homogeneity	0.20	0.49	0.87

XSL•FO
RenderX

Reproducibility and Reliability

To assess the reproducibility of ChatGPT-4 outputs across users, 2 independent observers used the same ChatGPT-4–assisted workflow to select ROIs and extract radiomic features from the same ultrasound images. Both were trained physicians with clinical and research expertise in liver ultrasound. The ICC was calculated across the extracted radiomic features to quantify consistency. The results demonstrated high reproducibility for most features exceeding ICC of 0.8, with energy (ICC=0.96), correlation (ICC=0.92), and echo intensity (ICC=0.88) showing excellent agreement between observers (Table 3). Entropy (ICC=0.81) and homogeneity (ICC=0.81) also indicated strong reliability, suggesting consistent feature extraction across different evaluators. Skewness (ICC=0.6) exhibited moderate agreement, while ASM showed the lowest ICC (ICC=0.25), indicating poor reproducibility for this metric.

Table 3. This table presents the intraclass correlation coefficients (ICC) assessing interobserver agreement for key radiomic features extracted from liver ultrasound images using ChatGPT-4. These results indicate strong to excellent reliability for most features, supporting the robustness of ChatGPT-4–assisted radiomic analysis in liver ultrasound imaging.

Feature	ICC
Echo-intensity	0.88
Heterogeneity	0.90
Kurtosis	0.39
Skewness	0.60
Angular second momentum	0.25
Correlation	0.92
Dissimilarity	0.78
Contrast	0.89
Entropy	0.81
Energy	0.96
Homogeneity	0.81

Binary Classification of Healthy Liver Versus Steatosis and Fibrosis Using ChatGPT-4 Ultrasound Radiomics

Significant distinctions were observed between normal liver and diseased conditions, particularly in 8 out of 10 analyzed features. For the binary comparison between normal and liver diseases (steatosis and fibrosis), 8 features showed significant differences (<0.05): echo-intensity (27.47 vs 50.47), heterogeneity (423.96 vs 687.17), skewness (0.95 vs 1.86), kurtosis (1.34 vs 5.24), energy (0.18 vs 0.22), contrast (30.65 vs 57.37), ASM (0.003 vs 0.001), and homogeneity (0.20 vs 0.38), for normal versus liver disease, respectively.

Comparing normal to fibrosis revealed significant differences in 8 features (<0.05): echo-intensity, heterogeneity, skewness, kurtosis, entropy, contrast, homogeneity, and correlation. For normal versus steatosis, 6 features showed significant differences: echo-intensity, entropy, skewness, kurtosis, Homogeneity, ASM, and energy. These mean values for the features are summarized in Table 4.

Table 4. This table illustrates the differences between liver disease groups (normal, steatosis, and fibrosis) by showing the mean values of features extracted through ChatGPT-4–based radiomics analysis. The features include echo intensity, heterogeneity, skewness, kurtosis, contrast, homogeneity, dissimilarity, angular second momentum (ASM), and entropy. The mean values for these features provide insights into the distinct textural characteristics associated with each liver disease group.

	Echo-intensity, mean (SD)	Heterogeneity, mean (SD)	Entropy, mean (SD)	Skewness, mean (SD)	Kurtosis, mean (SD)	Energy, mean (SD)	Contrast, mean (SD)	Dissimilarity, mean (SD)	Homogeneity, mean (SD)	ASM, mean (SD)
Liver disease (fibrosis and steatosis)	50.47 (2.34)	687.17 (57.19)	8.91 (0.28)	0.95 (0.05)	1.34 0.20	0.18 (0.03)	57.37 (4.31)	5.73 (0.26)	0.20 (0.01)	0.001 (0.00)
Liver fibrosis	56.67 (2.56)	857.07 (65.62)	7.99 (0.34)	0.93 (0.07)	1.18 (0.27)	0.18 (0.03)	64.65 (5.04)	6.21 (0.29)	0.19 (0.02)	0.001 (0.00)
Liver steatosis	39.10 (2.88)	366.24 (46.85)	10.66 (0.06)	0.97 (0.06)	1.64 (0.29)	0.19 (0.05)	43.62 (6.71)	4.81 (0.43)	0.22 (0.02)	0.001 (0.00)
Normal	27.44 (2.32)	423.96 (57.93)	8.15 (0.46)	1.86 (0.15)	5.24 (0.97)	0.22 (0.03)	30.65 (5.22)	4.88 (0.77)	0.38 (0.03)	0.003 (0.00)

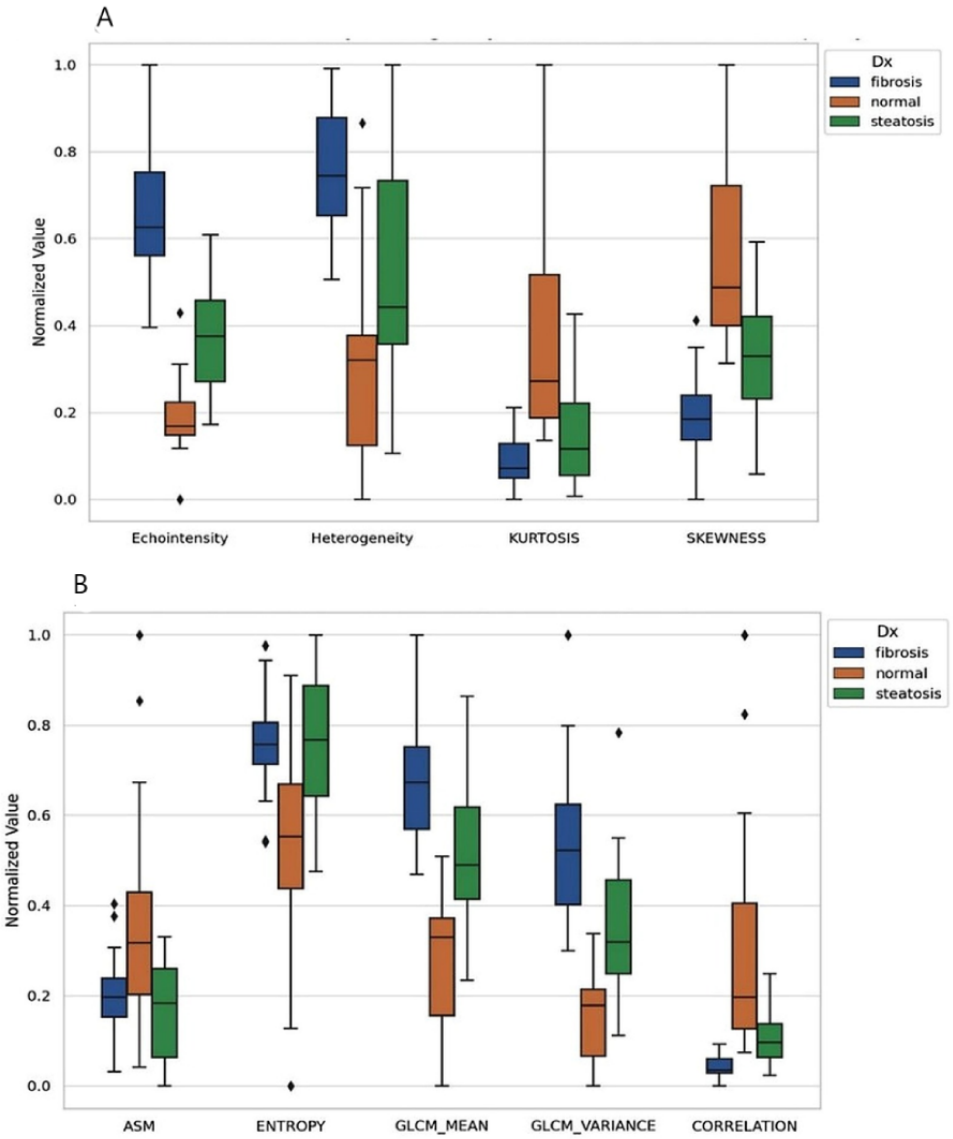
Distinguishing Liver Disease by ChatGPT-4–Based Ultrasound Image Findings

The classification tool for liver ultrasound images exhibited strong diagnostic performance across 3 categories: normal liver, fibrosis, and steatosis. Achieving an overall accuracy of 77%, the tool demonstrated its potential in aiding radiological assessments. For normal liver conditions, the tool achieved a precision, recall, and F_1-score of 0.75, indicating reliable detection accuracy. In the case of fibrosis, the tool excelled with a perfect recall of 1.00, meaning it successfully identified all fibrosis cases, and an F_1-score of 0.86, with a precision of 0.75. This highlights its robustness in diagnosing fibrotic conditions without missing any positive cases. However, for steatosis, while the tool showed a high precision of 0.80, the recall was slightly lower at 0.67, leading to an F_1-score of 0.73. This indicates a strong ability to correctly identify steatosis when predicted, though there is room for improvement in sensitivity. The macroaveraged metrics (precision=0.77, recall=0.81, and F_1-score=0.78) and weighted averages (precision=0.77, recall=0.77, and F_1-score=0.76) further underscore the tool's balanced performance across different liver conditions. These results suggest that while the tool is already valuable for distinguishing normal and abnormal liver conditions, further refinements could enhance its sensitivity, particularly for steatosis.



Evaluation of IDL-Based Ultrasound Radiomics for Liver Disease Classification

Identification of Key Textural Features

The radiomics analysis of liver ultrasound images conducted using IDL has provided significant insights into the textural characteristics associated with various liver diseases. Through ANOVA analysis, 9 textural features were identified as significantly varying among groups with different liver conditions (Figure 5).

XSL•FO
RenderX

Figure 5. Interactive data language (IDL)–based radiomics analysis in liver ultrasound images: This figure presents the distribution of texture parameters extracted using IDL from liver ultrasound images, comparing 3 diagnostic groups: fibrosis (blue), normal liver (orange), and steatosis (green). (A) Plot displays first-order texture features, including echointensity, heterogeneity, kurtosis, and skewness. Fibrotic livers exhibit increased echogenicity and heterogeneity compared with both normal and steatotic livers, reflecting structural alterations associated with fibrosis. (B) Plot illustrates higher-order texture features, including ASM, entropy, GLCM mean, GLCM variance, and correlation. Fibrotic livers demonstrate higher GLCM mean and variance, indicating greater textural complexity, whereas normal liver tissue exhibits lower values for these parameters but higher ASM and correlation, suggesting a more homogeneous texture. These findings highlight the capability of IDL-based radiomics in quantifying microstructural liver alterations across different pathological states, reinforcing its potential as an advanced imaging biomarker for disease characterization. ASM: angular second moment; GLCM: gray-level co-occurrence matrix.

Predictive Performance of Features

The predictive performance of features of these ultrasound imaging features varied, with accuracy ranging from 0.47 to 0.76 sensitivity, from 0.33 to 0.73, and specificity from 0.43 to 0.70 (Table 5). The feature “echo-intensity” demonstrated the highest performance with an accuracy of 0.76, sensitivity of 0.73, and specificity of 0.53, indicating balanced performance. Similarly, “Heterogeneity” also showed an accuracy of 0.76, with a sensitivity of 0.68 and a specificity of 0.51. On the other hand, “Kurtosis” had lower accuracy at 0.48 and sensitivity at 0.38, but a higher specificity of 0.64, highlighting its strength in correctly identifying true negative cases. Integrating multiple textural features enhances diagnostic performance. By combining the features, the overall accuracy improved to 0.77, with a notable accuracy of 0.89. Similarly, F_1-score performance varied across features, with echo intensity achieving the highest F_1-score (0.84), indicating its superior predictive power. Heterogeneity also performed well, with an F_1-score of 0.56. In contrast, kurtosis, ASM, entropy, and correlation had the lowest F_1-scores (ranging from 0.26), reflecting weaker predictive contributions. Notably, the combined feature approach achieved the highest F_1-score (0.81), emphasizing the advantage of integrating multiple features to enhance predictive accuracy.

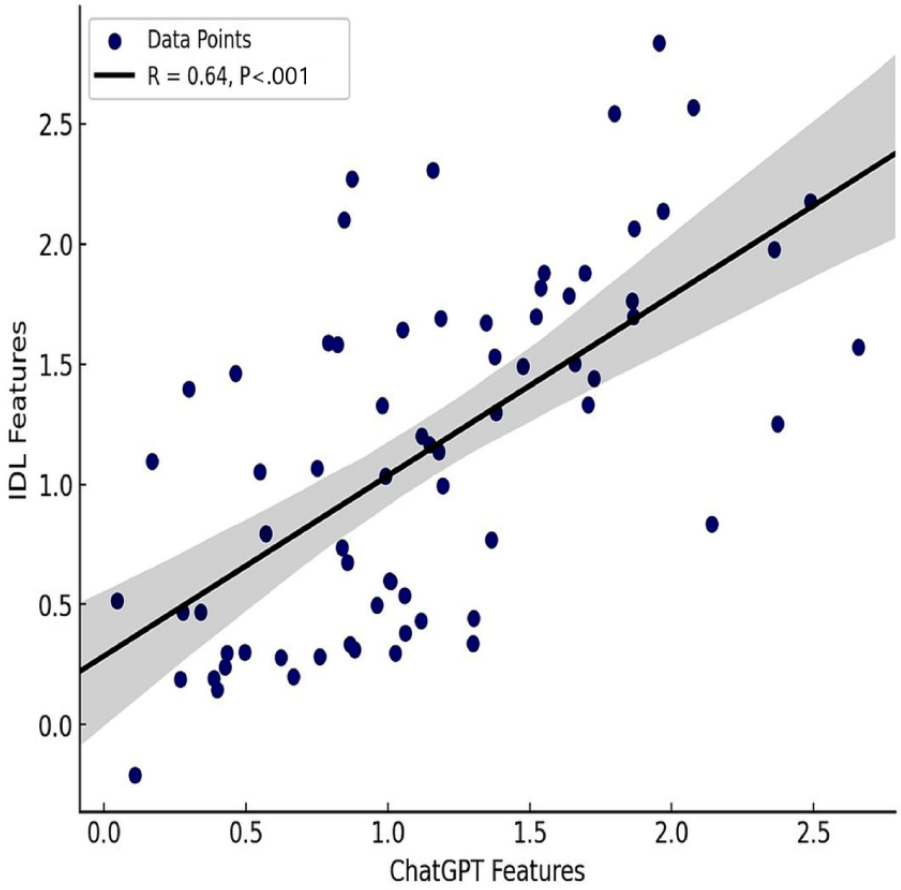
RenderX

Table 5. Diagnostic accuracy and performance of radiomic features extracted using interactive data language software. This table displays the diagnostic accuracy and performance metrics for various textural features extracted from the liver ultrasound images using interactive data language software as part of liver texture analysis. These metrics provide insights into the effectiveness of each feature in distinguishing between different liver conditions, contributing to the overall assessment of liver disease.

Feature	Accuracy	Sensitivity	Specificity	F_1-score
Echo-intensity	0.76	0.73	0.53	0.84
Heterogeneity	0.76	0.68	0.51	0.56
Kurtosis	0.47	0. 38	0.64	0.38
Skewness	0.67	0.58	0.55	0.48
ASM[a]	0.48	0.33	0.56	0.26
Entropy	0.48	0.33	0.43	0.26
GLCM[b]_mean	0.67	0.56	0.51	0.48
GLCM_variance	0.62	0.59	0.53	0.57
Correlation	0.48	0.33	0.7	0.26

[a]ASM: angular second momentum.

[b]GLCM: gray-level co-occurrence matrix.



Comparison Between ChatGPT and IDL Features

Correlation and Agreement Analysis Between Feature Sets

To assess the relationship between ChatGPT-4-derived features and IDL-based features, we performed correlation and agreement analyses. Each feature set was consolidated into a single value using multiple regression, allowing for a direct, one-to-one comparison between the 2 methods. The multiple linear regression model using ordinary least squares was applied to combine all extracted radiomic features into a single predicted value per image, with the liver disease category as the dependent variable. This was done separately for ChatGPT-4 and IDL outputs to generate comparable summary values. The results showed a moderate positive correlation (r=0.64) across all extracted features, which was statistically significant (P<.001; Figure 6). In other words, increases in ChatGPT-4 feature values tended to coincide with increases in IDL feature values, albeit with some variability. While this correlation is not perfect, it demonstrates that ChatGPT-4–derived features are reasonably well aligned with IDL features, supporting the feasibility of ChatGPT-4 for ultrasound radiomics analysis.

XSL•FO
RenderX

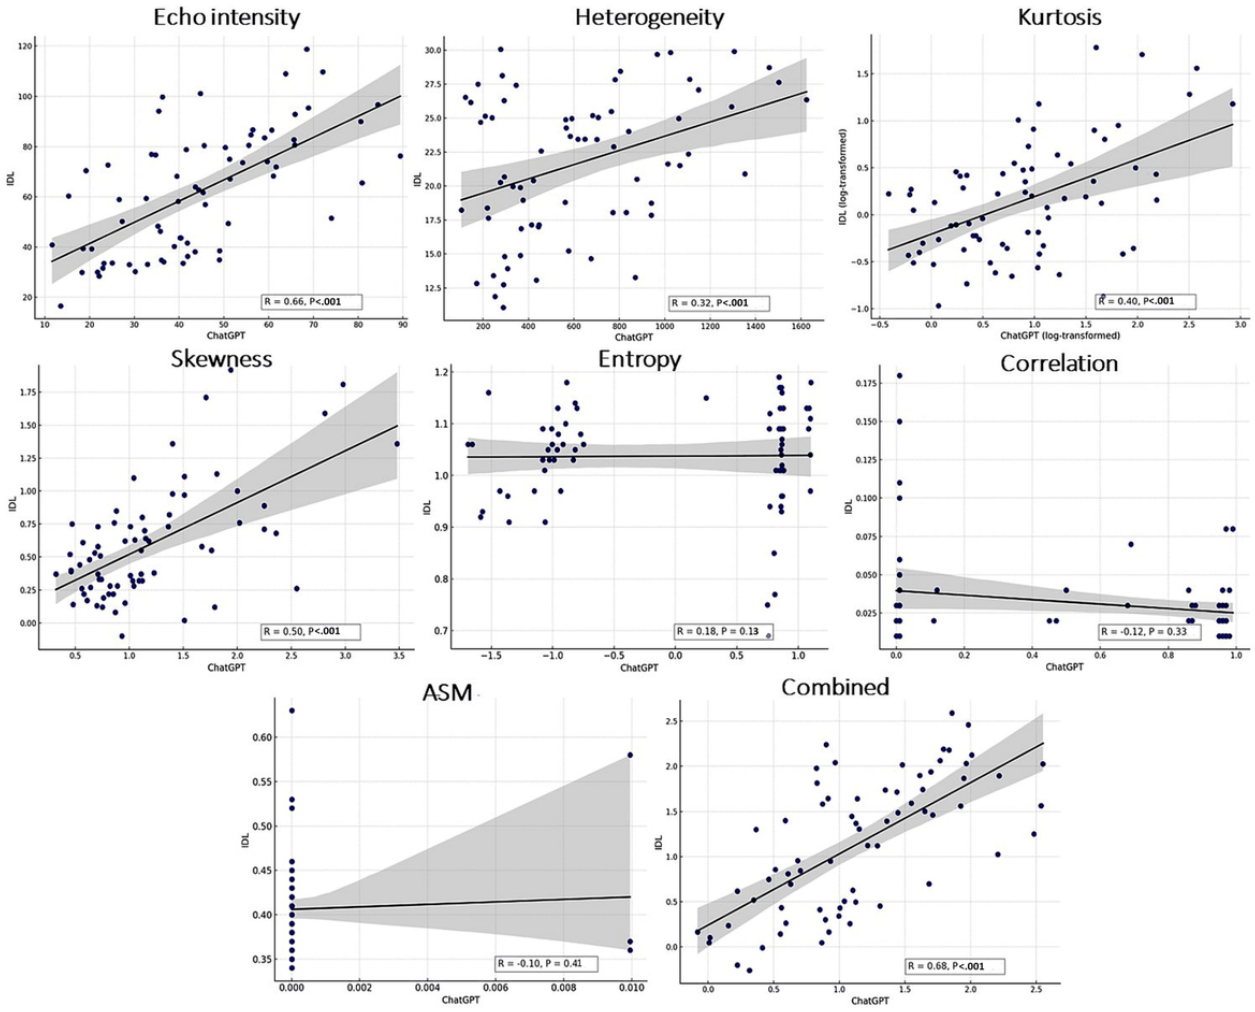


Figure 6. Correlation between ChatGPT Features and IDL Features. The scatter plot illustrates the relationship between ChatGPT features and IDL features, with a Pearson correlation coefficient (r) of 0.64 and a significant *P* value (*P*<.001). Each blue circle represents an individual data point, while the solid black line shows the fitted linear regression model. The shaded region surrounding the regression line represents the 95% CI. The moderate positive correlation suggests that as ChatGPT features increase, IDL features tend to increase as well, indicating a consistent, albeit not perfect, relationship between the 2 feature sets. IDL: interactive data language.

We further examined the correlation between the 2 software packages by focusing on 7 common features extracted by ChatGPT-4 and IDL showing a correlation (*r*) of 0.68 (Figure 7). The degree of correlation varied among the individual features, with the strongest correlation observed for combined features (*r*=0.68, *P*<.001). Notably, first-order histogram measures such as echo-intensity (*r*=0.60) and kurtosis (*r*=0.52) showed stronger correlations, whereas GLCM-based features exhibited weaker alignment. In particular, measures like correlation and kurtosis derived from GLCM demonstrated lower correlations.

XSL•FO
RenderX

Figure 7. This figure presents scatter plots illustrating the correlation between radiomic features extracted using ChatGPT-4 and the corresponding common features derived from the reference software, IDL. Each subplot represents a specific feature, with ChatGPT-4 values on the x-axis and IDL values on the y-axis. Linear regression lines with shaded 95% CIs are shown to illustrate the strength and direction of the associations. Pearson correlation coefficients (r) and *P* values (P) are reported for each feature. Strong correlations were observed for echo intensity (r=0.66, *P*<.001) and skewness (r=0.50, *P*<.001), while entropy (r=0.18, *P*=.13), correlation (r=–0.12, *P*=.33), and ASM (r=–0.10, *P*=.41) showed weaker or nonsignificant associations. The final plot displays a combined score derived from the 7 shared features, generated using multiple regression. This aggregated output demonstrated a moderate correlation (r=0.68) between ChatGPT-4 and IDL, supporting overall agreement across platforms. These findings highlight both the variability in feature-level agreement and the potential value of composite feature models in radiomics analysis. ASM: angular second momentum; IDL: interactive data language.

To further assess agreement between features extracted by the 2 software, a Bland-Altman analysis was performed (Figure S2 in Multimedia Appendix 1). The results demonstrated that combined features exhibited the best agreement, with narrow agreement limits and minimal bias, reinforcing their robustness. Skewness showed particularly strong agreement, indicating interchangeability between ChatGPT-4 and IDL for this feature. Minimal proportional bias was observed for well-correlated features, supporting the feasibility of using ChatGPT-4 for radiomics analysis in this context. Based on these results, the agreement between ChatGPT-4 and IDL-derived features can be categorized into three levels: (1) strong agreement (reliable and interchangeable): skewness and correlation; (2) moderate agreement (requires minor adjustments): ASM, entropy, and echo-intensity; and (3) weak agreement (fundamental differences requiring major corrections): kurtosis and heterogeneity.

Processing Time Comparison

In addition to feature correlation, we also compared batch processing efficiency between ChatGPT-4 and IDL-based tools. The results demonstrated that ChatGPT-4 outperformed IDL in processing speed. ChatGPT-4 completed the entire analysis process—including ROI selection, refinement, and texture analysis—in 4 minutes and 12 seconds for a batch of 10 images (the maximum batch size). In contrast, IDL required approximately 50 seconds per case, totaling over 8 minutes for the same batch. ChatGPT, therefore, showed more than a 40% reduction in processing time, highlighting ChatGPT-4's efficiency in automated batch processing. These findings suggest that ChatGPT-4 provides a viable alternative for high-throughput ultrasound radiomics analysis, offering both speed and reasonable alignment with IDL-based feature extraction.

Discussion

Expanding ChatGPT-4's Role in Radiology

AI and natural language processing tools, such as ChatGPT, have been increasingly explored for their role in enhancing radiology workflows [39]. Recent studies demonstrated how ChatGPT can be integrated into radiology workflows to improve efficiency in patient registration, scheduling, image acquisition, interpretation, and reporting [40,41]. The findings of these studies highlight ChatGPT's potential to streamline repetitive tasks, reduce radiologist workload, and enhance communication in diagnostic imaging. Our study builds upon this foundation by extending the role of ChatGPT-4 beyond workflow optimization into advanced radiomics analysis. Specifically, we evaluate ChatGPT-4's ability to extract quantitative ultrasound texture features, distinguish between different liver disease states, and compare its performance against conventional radiomics software. By bridging workflow optimization with diagnostic analysis, our findings contribute to the ongoing evolution of AI-assisted radiology, reinforcing ChatGPT's potential as a tool for both administrative and analytical applications in medical imaging.

ChatGPT-4's Diagnostic Performance and Reproducibility

Our study results show that ChatGPT-4's radiomic analysis exhibited robust performance in distinguishing among the 3 liver pathology groups, achieving a sensitivity of 0.83 and AUC exceeding 0.75, when all radiomic features were combined. While the diagnostic utility of individual features varied, the aggregated analysis compensated for weaker predictors, thereby enhancing overall classification accuracy. Moreover, the high ICC values observed between independent observers (reaching 0.92) suggest excellent reproducibility, reinforcing the robustness of ChatGPT-4–derived texture parameters in ultrasound imaging. However, not all features demonstrated high reliability; for instance, ASM yielded an ICC of 0.25, indicating poor reproducibility. Such discrepancies in intraclass agreement for extracted ultrasound features can arise from small differences in ROI placement, even if they are close. Ultrasound images are highly sensitive to pixel-level changes, which can affect texture-based features. Additionally, interpolation effects, quantization errors, and software implementation variability can contribute to differences. These findings underscore the need for further refinement in feature extraction methodologies, particularly for features with lower reproducibility. Future research should prioritize the standardization of algorithms to enhance observer consistency, ensuring that AI-generated radiomic features are both reliable and clinically actionable.

Interpretation of the Radiomic Biomarkers in Liver Disease

The radiomic biomarkers identified in this study align with established pathophysiological changes in liver disease. Increased heterogeneity and entropy, for instance, reflect greater structural disorder where excessive collagen deposition disrupts tissue uniformity, consistent with fibrosis [42,43]. GLCM-based texture features provide additional microstructural insights, for example, ASM (or energy) serving as an index of texture uniformity—higher values indicate preserved architecture, while lower values suggest structural disruption, such as that seen in fibrosis [44]. These features may serve as robust, noninvasive biomarkers for disease detection and monitoring. Our results showed that distinct textural patterns can be related to different liver conditions. Fibrosis presents with increased echogenicity, heterogeneity, and contrast, indicating architectural disruption. While steatosis also exhibits high echogenicity, it is associated with a smoother, more homogeneous texture, suggesting uniform yet structurally altered tissue. In contrast, normal liver maintains the most uniform texture, with high homogeneity and low contrast, reflecting preserved tissue organization.

Comparison of ChatGPT-4 With Traditional Image Analysis Software

Direct comparison between features extracted by ChatGPT-4 and IDL revealed a moderate correlation (r=0.68), when features are combined with notable variations between specific features on an individual basis. First-order features, which primarily assess pixel intensity distributions, exhibited strong agreement between the 2 platforms, whereas GLCM-based features showed greater discrepancies. This discrepancy is likely attributable to differences in pixel adjacency definitions, quantization methods, and sampling protocols across the 2 analytical frameworks. These results highlight a persistent challenge in radiomics: reproducibility across different software implementations. Variability in image acquisition parameters, preprocessing steps, and computational feature extraction methodologies can significantly impact radiomic feature consistency. Prior studies have underscored the necessity of harmonized radiomic pipelines to enhance cross-platform reproducibility [45,46]. Establishing standardized radiomic workflows will be critical for ensuring the clinical applicability of AI-driven ultrasound analysis.

A key advantage of ChatGPT-4 in this study was its ability to process multiple images in parallel, demonstrating significant efficiency gains over conventional software. Notably, processing time was reduced by more than 40% compared with IDL, suggesting that AI-driven tools can significantly enhance radiological workflow efficiency. This capability is particularly valuable in research settings requiring high-throughput image analysis, as well as in clinical environments where real-time assessment is essential for guiding interventional procedures. Moreover, ChatGPT-4's scalability supports its application in large-scale imaging studies, enabling rapid dataset processing while minimizing manual input. This efficiency could facilitate applications in population-based screening programs, multicenter trials, and AI-assisted educational platforms. While compute capacity was controlled for in this study, we acknowledge that hardware variability can influence software performance. Future work should evaluate AI efficiency across diverse computing environments to better account for system-dependent constraints. Despite its slightly lower diagnostic performance compared with IDL, the results are encouraging given that ChatGPT-4 was not originally designed for medical image analysis. With additional domain-specific training and fine-tuning using large-scale ultrasound datasets, its performance is expected to improve. Future research should explore ChatGPT-4's integration into routine radiology

XSL•FO
RenderX

workflows, particularly in triage settings, where automated interpretation of liver ultrasound images could expedite clinical decision-making and optimize resource allocation.

Limitations and Challenges

Session Variability and Model Robustness

Despite its promising performance, ChatGPT-4 exhibited session-dependent variability in feature extraction. This phenomenon, which possibly arises from differences in how the model processes context and maintains internal states across separate analyses, introduces potential inconsistencies in feature reproducibility. While batch analyses remained stable, independent session resets occasionally yielded variations in extracted parameters. Session-dependent variability is a recognized limitation of large language models [47-49] and warrants further investigation in the context of medical imaging. To mitigate this challenge, we refined our prompting strategies, ensuring that feature extraction parameters were explicitly aligned across sessions. While steps were taken to standardize ChatGPT-4 prompts and maintain session continuity, variability in output due to the model's inherent stochastic nature remains a limitation. Although incomplete feature sets were addressed through repeated prompting and prompt refinement, future studies may also benefit from averaging outputs across multiple runs or sessions to account for variability and enhance consistency. Additionally, future research should prioritize the development of standardized initialization protocols and structured prompt engineering strategies to improve the reproducibility of AI-driven radiomic analyses.

Automated ROI Selection

A key limitation of ChatGPT-4 is its fully automated ROI selection, which lacks the flexibility and precision needed for clinical applications. This may affect diagnostic accuracy, especially when critical pathological features fall outside the AI-defined ROI. While ChatGPT-4 does not allow direct manual ROI adjustments, we used a hybrid approach [50], iteratively refining prompts to guide the model until the desired ROI was accurately identified. This method combined AI-driven automation with user oversight, improving ROI placement and reducing errors. Future iterations of ChatGPT-4 could enhance clinical applicability by incorporating interactive manual ROI modifications [51]. Additionally, integrating advanced machine learning algorithms could refine automated ROI selection, allowing AI to prioritize clinically relevant areas [52]. A promising direction is the development of hybrid models that preselect an ROI while allowing clinician refinement, balancing automation with expert oversight [53].

Preclinical Model and Clinical Translatability

Our preclinical liver disease model closely mirrors human pathology, with histological findings aligning well with clinical presentations of fibrosis and steatosis. This translatability strengthens the relevance of our results; the model has undergone extensive validation to ensure robustness and suitability for studying liver disease [30-32]. Nonetheless, this study serves as an initial assessment of ChatGPT-4 in a preclinical setting. Future work will extend to human liver ultrasound datasets, potentially involving diverse populations and multiple medical centers to enhance generalizability. Importantly, moving to clinical datasets raises privacy and ethical concerns, requiring strict compliance with HIPAA (Health Insurance Portability and Accountability Act), GDPR (General Data Protection Regulation), and other data security frameworks. Additionally, AI bias—stemming from skewed or nonrepresentative training data—remains a critical challenge, necessitating multicenter validation to ensure fairness and accuracy across varied clinical settings.

Uncertainty in AI-Generated Diagnoses

Reliable AI outputs are critical in medical imaging. Currently, ChatGPT-4 lacks inherent uncertainty quantification. Integrating probabilistic methods could improve reliability by assigning confidence levels based on prior data distributions, similar to deep learning–based radiomics [54]. Monte Carlo dropout modeling could provide uncertainty intervals, flagging cases needing further review [55]. Ensemble modeling could further enhance reliability through consensus-based confidence scores [56]. Explainability improvements, such as structured reasoning frameworks, would support informed decision-making [57]. Implementing these methods would ensure ChatGPT-4 functions as a decision-support tool rather than an autonomous diagnostic system.

Clinical Applications and Future Directions

This study highlights ChatGPT-4's potential in medical imaging, particularly in image interpretation. While CNNs have achieved over 90% accuracy in tasks like liver fibrosis staging [44,58], ChatGPT-4 offers distinct advantages by integrating image analysis with narrative generation and enabling interactive ROI refinement [19]. Unlike traditional deep learning models requiring extensive training, ChatGPT-4's adaptability supports multimodal integration, making it a promising tool for clinical applications. Fine-tuning on specialized datasets could enhance its diagnostic accuracy, bridging the gap between specialized AI models and broader usability. Enhancing ChatGPT-4's clinical utility involves several advancements. Transfer learning can improve domain-specific accuracy by incorporating structured radiology reports and labeled diagnostic cases [59]. Multimodal training could allow it to analyze medical images alongside textual and radiomic data, improving correlation with clinical insights [60]. Real-time clinical decision support through interactive learning could refine outputs, while integrating longitudinal patient data could enhance disease monitoring, particularly for chronic conditions [61]. Future research should compare ChatGPT-4 with leading deep learning models to evaluate its role in multimodal medical imaging.

Integrating ChatGPT-4 into clinical workflows has the potential to enhance diagnostic efficiency by streamlining triage, anomaly detection, and preliminary report generation. AI-driven tools have demonstrated the ability to expedite time-to-diagnosis by prioritizing critical imaging findings [1,19]. In liver ultrasound, ChatGPT-4 could assist by distinguishing normal scans or minor abnormalities, allowing radiologists to focus on complex cases. Its radiomic analysis capabilities may facilitate early disease detection, akin to AI models that have identified microvascular changes in brain imaging and tumor margins in mammography [5,7]. Automated report generation is another promising

XSL•FO
RenderX

application, as AI-generated reports have been shown to match human interpretation in accuracy [20,21]. Additionally, real-time feedback during ultrasound-guided procedures and batch-processing for large-scale imaging analysis could support multicenter studies and population-based disease screening [11,26]. Despite its potential, key challenges include validation across diverse populations, regulatory approval, and clinician training. Prospective studies are needed to assess ChatGPT-4's impact on diagnostic accuracy, workflow efficiency, and patient outcomes. Addressing these challenges could establish ChatGPT-4 as a transformative tool in radiology, optimizing early disease detection and clinical workflows.

Conclusions

In conclusion, our study confirms the feasibility of using ChatGPT-4 for liver disease diagnosis through ultrasound image analysis, emphasizing its potential to assist radiologists in making more accurate diagnoses. Despite some limitations, ChatGPT-4's ability to efficiently handle large-scale image datasets and its robust feature extraction capabilities make it a valuable tool for enhancing diagnostic accuracy and supporting radiological decision-making. By integrating ChatGPT-4 into radiological workflows, radiologists can leverage its capabilities to improve the precision and efficiency of liver ultrasound image analysis. This tool's potential to manage vast amounts of data with high efficiency is particularly appealing in modern medical research and clinical practice.

Abstract

Background: Intensive care units (ICUs) treat patients with life-threatening illnesses. Worldwide, intensive care demand is massive. Predicting patient outcomes in ICUs holds significant importance for health care operation management. Nevertheless, it remains a challenging problem that researchers and health care practitioners have yet to overcome. While the newly emerging health digital trace data offer new possibilities, such data contain complex time series and patterns. Although researchers have devised severity score systems, traditional machine learning models with feature engineering, and deep learning models that use raw clinical data to predict ICU outcomes, existing methods have limitations.

Objective: This study aimed to develop a novel feature extraction and machine learning framework to repurpose and extract features with strong predictive power from patients' health digital traces for ICU outcome prediction.

Methods: Guided by signal processing techniques and medical domain knowledge, the proposed framework introduces a novel, signal processing–based feature engineering method to extract highly predictive features from ICU digital trace data. We rigorously evaluated this method on a real-world ICU dataset, demonstrating significant improvements over both traditional and deep learning baseline methods. The method was then evaluated using a real-world database to assess prediction accuracy and feature representativeness.

Results: The prediction results obtained by the proposed framework significantly outperformed state-of-the-art benchmarks. This demonstrated the framework's effectiveness in capturing key patterns from complex health digital traces for improving ICU outcome prediction.

Conclusions: Our study contributes to health care operation management by leveraging digital traces from health care information systems to address challenges with significant implications for health care.

Introduction

Background

As the Fourth Industrial Revolution unfolds, health care organizations worldwide are implementing an increasing number of digital artifacts capable of producing or collecting data to modernize services, scale business, and improve the efficiency of information exchange. These digital artifacts generate and record vast quantities of data regarding the conditions and outcomes of patients, enabling the digital tracing of these individuals [1]. These digital traces offer a rich collection of novel and valuable sociotechnical empirical data. This abundance of new information can greatly enhance decision-making processes in health care applications. As part of this tendency, the implementation of electronic intensive care unit (eICU) technology over the last decade has allowed large amounts of intensive care unit (ICU) patients' vital sign data (ie, a group of medical signs that indicate the status of the body's life-sustaining functions, such as blood pressure, heart rate, and respiratory rate) to be collected and streamed [2]. These real-time time-series data, originally used to monitor patients' real-time conditions, coupled with other patient information recorded in health IT systems (eg, demographics), constitute ICU patients' health digital traces.

ICUs are hospital departments dedicated to providing critical care medicine to patients who are at risk of, currently experiencing, or recovering from life-threatening illnesses or injuries. ICU patients are extremely vulnerable to adverse outcomes due to their rapid disease progression and have the highest mortality rate of all patients across different health care departments [3]. Worldwide, intensive care demand is massive. Researchers and health care practitioners have long recognized the significance of ICU outcome prediction, which is generally defined as predicting patient outcomes resulting from medical treatment in the ICU, including but not limited to patient mortality, length of stay, readmission, morbidity, disability, and quality of life [4]. It has significant implications on health care operation management, such as laying the scientific foundation for assessing the severity of illness, providing a standard for adjudicating new treatments and policies, providing a way for comparing cohorts of ICU patients treated across different hospitals and countries, allocating resources and determining levels of care, and discussing expected outcomes with ICU patients and families [5,6].

However, predicting ICU outcomes is a complex problem that practitioners and researchers have yet to overcome. ICU patients have diverse and dynamic characteristics; they come from various diagnosis cohorts, have unique demographics and disease progressions, and may receive different levels of medical interventions [7,8]. Effectively identifying patterns and predicting patients' ICU outcomes poses great challenges in health care analytics. The emergence of eICUs during the Fourth Industrial Revolution, along with the availability of patients' digital health data from eICUs, has created new opportunities for developing more sophisticated methods for predicting ICU outcomes. Researchers have demonstrated that, in addition to being used for monitoring purposes, ICU patients' health digital traces contain rich dynamic patterns that can be repurposed to inform prognosis, provide early forecasts of life-threatening conditions, and predict patient outcomes [9]. Many researchers who work on ICU outcome predictions have explored the value of patients' health digital traces by incorporating real-time vital sign data as the input of traditional machine learning models with feature engineering or deep learning models using raw clinical data. However, both types of methods have limitations. This is because ICU patients' health digital traces include complex time-series data and patterns [8]. Current feature engineering–based traditional machine learning models rely largely on simple summary statistics of vital signs and are incapable of capturing heterogeneous and dynamic patterns from patients' health digital traces, resulting in unsatisfying performance. On the other hand, deep learning models rely heavily on computational power and large amounts of training data, which are normally not available for health care predictive tasks [10]. This is because the integration of patient data for a prediction task in health care analytics must be executed with great care (eg, considering different patient cohorts and different periods), making it impractical to acquire a sufficient amount of training data for complex deep learning models. Researchers and practitioners urge the next generation of ICU outcome prediction models to be more accurate (predict with better performance), autonomous (execute without time-consuming or manual data entry), and dynamic (capture temporal changes in physiological signals and clinical events) [4,11]. Using mortality prediction as a research case, the objective of this study was to develop a new method that aims to extract meaningful patterns from readily available health digital traces to facilitate accurate ICU outcome predictions.

To achieve this goal, we repurposed and used ICU patients' health digital trace data from the eICU systems as input. To effectively extract patterns from the complex time series of vital signs in patients' health digital traces, we then used signal processing techniques to decompose the time-series data, enhance useful signals, and reduce noise in complex time series. Next, guided by medical domain knowledge and feature selection techniques, we identified the most representative features from the decomposed health digital trace data for ICU mortality prediction. Finally, using a state-of-the-art machine learning technique, the proposed framework accurately predicted the mortality rate for ICU patients. To demonstrate the effectiveness of the proposed framework, we evaluated it on a large real-world ICU database. The proposed method outperformed strong baseline methods, including the Acute Physiology and Chronic Health Evaluation (APACHE) IV model (ie, the best-performing scoring system in ICU outcome prediction that is already used in hospitals), time-series forecasting methods (ie, autoregressive moving average [ARMA] and autoregressive integrated moving average [ARIMA]), other traditional machine learning models with statistical features, and deep learning models (ie, convolutional neural networks [CNNs], long short-term memory [LSTM], and gated recurrent unit [GRU]), by a large margin.

Our main contributions are as follows: (1) we propose a new feature engineering framework that leverages stochastic signal processing and medical domain knowledge to extract predictive

XSL•FO
RenderX

features from ICU digital traces; (2) we designed a structured feature selection process to enhance model interpretability and prediction accuracy; (3) through extensive experiments, we demonstrated that our method significantly outperforms traditional statistical and deep learning models on ICU mortality prediction tasks; and (4) we showed that the features extracted by our framework generalize across patient cohorts and can be integrated into existing clinical decision systems. Moreover, our work has practical implications for ICU outcome prediction and health care operation management: (1) it requires only readily available digital health trace data from ICU bedside monitors rather than laboratory results and intensivists' assessments, (2) it significantly improves the performance of ICU mortality predictions, and (3) the extracted features can effectively represent heterogeneous ICU patient cohorts.

Related Work

ICU Outcome Prediction and Limitations of Extant Studies

The existing methods for predicting ICU outcomes can be classified into 3 main types (Table 1): severity scoring systems, traditional machine learning models with feature engineering, and deep learning models with raw clinical data. For severity scoring systems, the most reputable ones (including major revisions of these models) are the APACHE [12], Simplified Acute Physiology Score [13], and Mortality Probability Model [14]. Among the existing severity scoring systems, APACHE IV demonstrates the highest performance in terms of area under the curve (AUC) [15]. Despite their widespread use, the reliability of the severity scoring systems, including APACHE IV, has been questioned by practitioners [4]. More importantly, there are ongoing concerns about the prolonged waiting time of laboratory data collection and the assessments needed from subject matter experts for calculating the severity scores [11]. For instance, APACHE IV requires 24 hours to gather all the necessary information for prediction. The predicting variables include laboratory test results and Glasgow Coma Scale (GCS) measures—the laboratory test results can take hours to days to obtain depending on the complexity of the tests [16], the GCS scores necessitate expert medical evaluation, and their reproducibility has raised concerns among researchers [11]. Researchers argue that the next generation of ICU mortality predictive models should use an automated electronic system for data gathering and prediction generating [4,11].

With the emergence of health digital trace data, researchers have recognized the potential of such data in enhancing ICU outcome prediction [9]. This is because these data reveal patients' pathological conditions and their response to treatments, making them valuable for improving prediction performance. Traditional machine learning models have been adopted for ICU outcome predictions using patients' digital trace data, which have included demographic information and summary statistics of vital measurements (Table 1). Despite researchers continuously introducing various prediction models, the features extracted from the health digital traces remain relatively simple—basic statistics of vital sign time series, such as the minimum and maximum respiration rates or blood pressure. However, there is increasing evidence suggesting that

XSL•FO
RenderX

superior accuracy in ICU outcome prediction requires more effective feature extraction methods [4]. The complexity of patient cohorts' heterogeneity and the complexity of the time series of health digital traces pose significant challenges in extracting meaningful dynamic patterns and uncovering the relationships among these patterns.

Deep learning models with strong pattern recognition capabilities are also used in ICU outcome prediction. CNNs, which can summarize patterns from patients' health digital traces, have been implemented first [22,23]. Researchers also input patients' vital sign data into recurrent neural networks (RNNs) to infer ICU outcomes, which takes advantage of the temporal information of vital signs [24]. However, these models take the entire time series of vital signs as input, and their performance greatly depends on computer power and massive amounts of training data, which is challenging in health care practice [10]. In health care predictive analyses, the integration of patient data must be executed with great care, making it impractical to acquire sufficient training data for complex deep learning models. The integration of health care data from different patient cohorts (eg, various diseases, distinct ICU admission types, different races, and diverse age groups) must be undertaken with meticulous care. For example, patients with different genetic backgrounds (ethnicities) are sometimes susceptible to certain diseases; patient cohorts comprising geriatric, neonatal, and general patients show notable variations in disease risks and prognosis. These differences significantly influence health care prediction results. In ICU outcome prediction, it is often necessary to separate the different patient cohorts instead of integrating their data. There is also an inherent temporal aspect to patient data, and it is not appropriate to integrate patient data from vastly different periods. Societal development changes patients' physical fitness, underlying health conditions, and health care providers' treatments, leading to significant variations in patient data distribution. Overall, acquiring sufficient training data for complex deep learning models is usually impractical for health care predictive analytics. Consequently, the performance of complex deep learning models is constrained by the limitations of available training data (experiments are provided in Postanalysis: The Impact of Limited Patient Data on Deep Learning Model Performance section).

As ICU patients' health digital traces contain complex time-series data, statistical forecasting models such as ARMA and ARIMA may also be used to analyze the time-series data. However, these time-series models are developed to predict the value of the time series at the next time step and are not created for prediction or classification tasks or probability estimations. To make predictions using time-series data, researchers regard the coefficients of the time-series models as input features and train machine learning classifiers [25]. Nevertheless, these methods are not ideal for the time series of patients' health digital traces from ICUs. The order of a time-series model has to be determined by the statistical characteristics of a specific time series (eg, one time series of vital signs from a specific patient). Researchers usually treat model orders as hyperparameters and determine them through experiments and the Akaike information criterion; a fixed order of time-series models is required for all patients to ensure that the input features have the same dimension for the classification task, which limits the predictive power of the time-series forecasting models in ICU outcome prediction.

ICU Patients' Health Digital Traces and Stochastic Signal Analysis Techniques

The health digital traces of ICU patients have been originally used for monitoring and assessing patients' immediate well-being. A growing body of literature has shown that many shared dynamic patterns can be identified across heterogeneous patient cohorts that may be repurposed to evaluate illness severity, identify future clinical abnormalities, predict adverse events, or distinguish heterogeneous patient cohorts [9]. However, identifying and extracting meaningful features from health digital traces remains a challenging task given that the range of a digital trace varies with a patient's age, gender, weight, environment, medical condition and intervention, and many other factors [9]. As a result, the health digital traces contain complex time series and exhibit diverse and dynamic patterns. As we later demonstrate (refer to the Results section), extant feature extraction and ICU outcome prediction methods are inadequate.

Stochastic signal processing, a field of science concerned with processing and analyzing time-series data, is a well-suited tool to extract complicated patterns of time-series digital traces. Stochastic signal processing techniques are particularly useful for extracting patterns from time-series signals, which are normally described as aperiodic, noisy, intermittent, and transient [26]. They differ from other time-series analysis tools for 2 reasons. First, they examine the signal in both the time domain (ie, the time series of patients' health digital traces) and the frequency domain (ie, the magnitude of change within each frequency band of the time series) simultaneously. Therefore, they have powerful capabilities for enhancing the useful signals in complex time series and increasing the signal-to-noise ratio, which facilitates feature extraction from patients' digital traces. Second, they have computational algorithms that reduce the computing time and complexity of large transformations, so the time-series data can be processed almost instantaneously.

Although complex time series in patients' health digital traces can be decomposed using signal processing techniques for noise reduction and signal enhancement, specific domain knowledge is required to determine how to extract meaningful patterns from the decomposed representations of health digital traces. In health care research, medical diagnosis signals, including signals from electrocardiograms (ECGs), electroencephalograms, and photoplethysmogram, are analyzed using signal processing techniques based on researchers' and practitioners' medical knowledge in beat-to-beat heart rate patterns, electrical activity in the brain, and optical signals in blood volume changes [26]. These studies show the potential of adapting stochastic signal processing techniques in health care analytics research. However, in these existing studies, signal processing has been used for specific diagnostic purposes, with an emphasis on explanation rather than prediction. In this study, we sought to combine medical knowledge regarding the patterns and variability of ICU patients' vital signs to extract

XSL•FO
RenderX

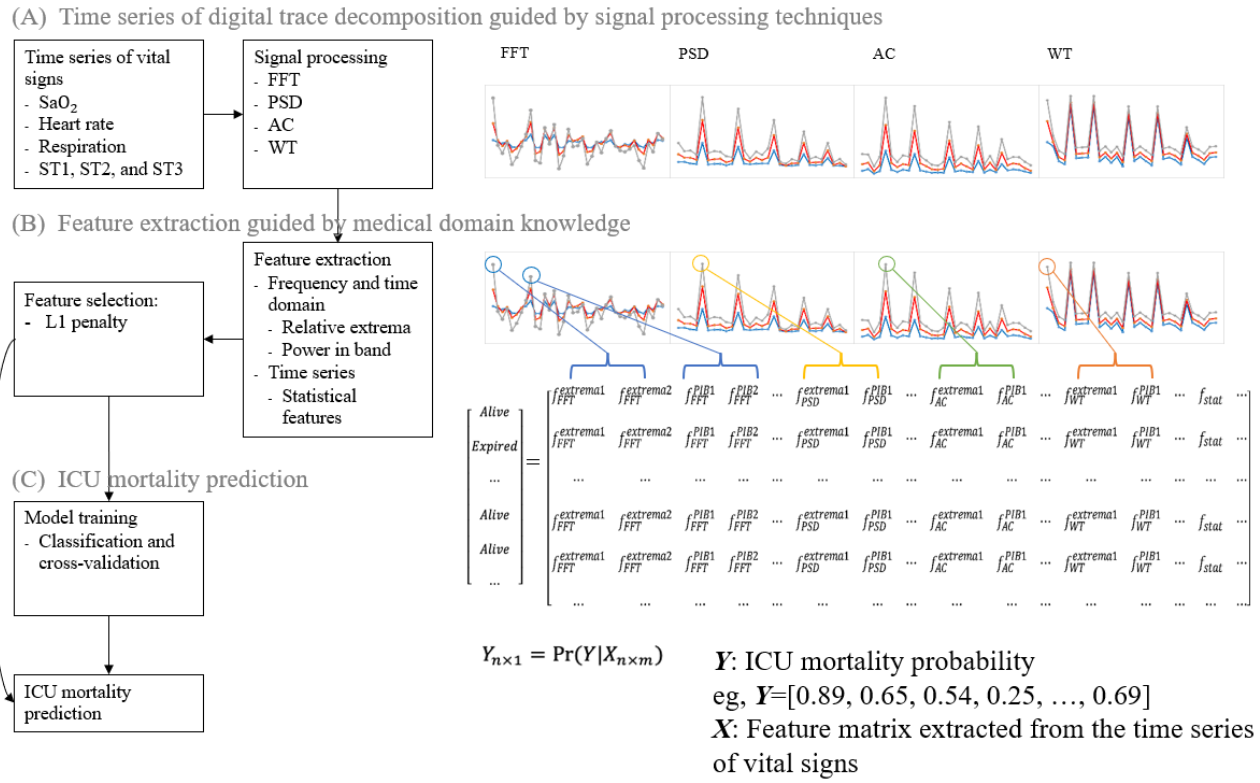
meaningful features for predicting ICU outcomes. To our knowledge, the complicated time series of vital signs in patients' digital traces have never been systematically analyzed using signal processing techniques. Combining medical domain knowledge, the proposed method provides a novel strategy to extract predictive features for improved ICU outcome prediction results.

To summarize, the deficiencies of existing ICU mortality prediction methods, coupled with the challenges associated with leveraging patients' health digital traces contained in complex time series, motivate us to propose a new method that can be used to (1) effectively extract representative features from ICU patients' digital trace data and (2) accurately predict ICU mortality using readily available data.

Feature Engineering in ICU Outcome Prediction

In previous ICU prediction literature, feature engineering has predominantly focused on extracting basic statistical descriptors from vital signs, such as minimum, maximum, mean, and SD [18-21]. These summary statistics provide coarse information about the central tendency and spread of physiological signals but often overlook dynamic temporal and spectral patterns.

Meanwhile, signal processing techniques such as wavelet transforms (WTs), spectral analysis, and autocorrelation have been explored in predictive modeling for specific signals (eg, most notably from ECGs) for tasks such as arrhythmia classification, early warning score prediction, and ICU mortality estimation [26-29]. However, these studies generally target a narrow range of signals and transformations. Our work expanded on this by applying a broader set of signal decomposition methods (fast Fourier transform [FFT], power spectral density [PSD], autocorrelation, and WT) across multiple ICU vital signs (eg, arterial oxygen saturation [SaO_2], heart rate, and respiration) and by combining the results with clinical insights to guide feature design. Moreover, we introduced new composite features, such as power in band and relative extrema, that more precisely quantify signal variability and instability, both of which are clinically meaningful. This approach results in a diverse and interpretable feature set that enhances the model's ability to predict ICU outcomes across heterogeneous patient cohorts.



To ensure that these engineered features are clinically relevant, we grounded our signal processing techniques in established medical knowledge. First, for heart rate variability, we computed power within the low-frequency and high-frequency bands using PSD analysis. These frequency bands are associated with sympathetic and parasympathetic nervous system activities, respectively, and are critical in assessing autonomic function in patients who are critically ill [30]. Second, given the nonstationary nature of physiological signals such as ECG and respiratory patterns, we used WT to capture transient features and localized frequency components. This approach facilitates the detection of clinically significant events such as arrhythmias and respiratory irregularities. Notably, unstable respiration can lead to respiratory muscle fatigue, cardiovascular collapse, and impaired oxygen delivery [31]. Third, features such as relative extrema were designed to identify sudden changes in vital signs, such as abrupt drops in peripheral oxygen saturation or spikes in heart rate, which may indicate acute clinical events. Similarly, power-in-band features help in quantifying the energy within specific frequency bands associated with pathological conditions [32]. Fourth, by aligning our signal processing techniques with established medical knowledge, we aimed to extract features that are not only statistically robust but also clinically interpretable, thereby enhancing the utility of our predictive models in real-world ICU settings.

Methods

We propose a novel method to effectively extract features with strong predictive power from the complex time series of health digital traces for ICU mortality prediction. As shown in Figure 1, the proposed model includes three steps: (1) time series of digital trace decomposition guided by signal processing techniques, (2) feature extraction guided by medical domain knowledge, and (3) ICU mortality prediction using ν–support vector classification (SVC).

Time Series of Health Digital Trace Decomposition Guided by Signal Processing Techniques

Overview

ICU patients' health digital traces contain multiple complex time series; each time series is denoted by v_t (t is the time index and $t \leq N$). To enhance useful signals and reduce noise in v_t, in the first step, guided by signal processing techniques (Table 2), we decomposed v_t using FFT, PSD, autocorrelation, and WT.

Table 2. Signal processing techniques and relations to health digital traces.

Technique	Signal processing guidelines[a]	Motivation and relation to health digital traces
FFT[b]	Using FFT, any time series can be decomposed into a series of simple sinusoids of different frequencies. The FFT estimates the coefficients of each sinusoid for a given time series.	To decompose complex health digital traces into several relatively milder, more regular, and stable subsequences
PSD[c]	The PSD describes the distribution of the power of a time series over frequency. FFT is great at analyzing vibration when there are a finite number of dominant frequency components, but PSDs can be used to characterize random vibration signals.	To analyze the random vibration signals, which are common in patients' health digital traces.
AC[d]	AC is the correlation of a time series with the lagged version of itself over successive time intervals, which is usually used to detect repeating patterns, such as periodic signals hidden in noisy data.	To detect and enhance repeating patterns in patients' health digital traces and reduce noise.
WT[e]	The WT decomposes a time series into a series of wavelets with different scales at different time points. Thus, the outputs of WT present both the strength and location of frequencies (ie, patterns from both the frequency and time domains) in the time series.	To include the information of the frequencies' time location (time domain) as the outputs of the aforementioned 3 techniques (FFT, PSD, and AC) mainly provide information about the frequencies (frequency domain) in time-series data. Time domain information reveals patients' disease or condition progression.

XSL•FO
RenderX

The decomposed v_t is denoted as $F(\omega)$ (ie, frequency spectrum), where ω is the parameter of the signal processing. Specifically, ω indicates frequency in FFT and PSD, scale and shift parameters in WT, and time difference in autocorrelation. For FFT, PSD, and autocorrelation, the frequency spectrum of a time series v_t is a vector, $[F(\omega_1), F(\omega_2),..., F(\omega_t)]$; for WT, the frequency spectrum is a matrix ($[F(\omega_{1,1}), F(\omega_{1,2}),..., F(\omega_{1,t})]$, $[F(\omega_{2,1}), F(\omega_{2,2}),..., F(\omega_{2,t})]$,..., $[F(\omega_{s,1}), F(\omega_{s,2}),..., F(\omega_{s,t})]$) where s is the number of rows decided by the scale of the WT. All frequency spectrums converted from time series of patients' health digital traces form a space $X_{n\times w}$ (n=number of patients; w=the number of frequency spectrums). The following paragraphs introduce the signal processing transfer processes in our research setting.

FFT Process

The Fourier transformation of a signal reveals periodicity in time-series data and indicates the frequencies of these periodical components. The resulting signals after the FFT are frequency spectrums , where v_t is the vital sign and ω is the frequency at which a complex sinusoid is computed.

PSD Process

The PSD $F_{PSD}(\omega)$ is calculated using  where $r(k)$is the autocovariance sequence of v_t and  denotes the complex-conjugate transpose of $v(t-k)$. The PSD characterizes the average power (ie, measure of signal strength) at a frequency ω in the signal. Specifically, for time-series data, the PSD uses the signal's autocorrelations to measure the power. Compared to FFT, which obtains the amplitudes of a signal's frequency components, the PSD of the signal delineates the power contained within the signal as a function of frequency.

Autocorrelation Process

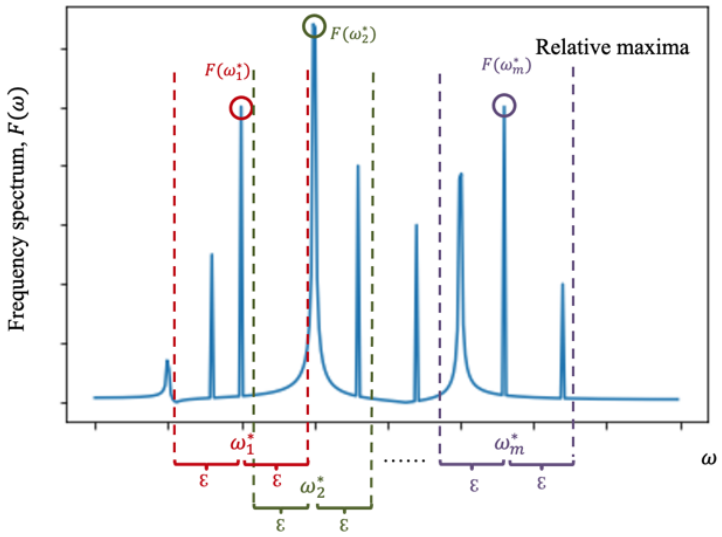
Autocorrelation measures the correlation between a signal and its delayed version with lag ω, which can be calculated using . It reveals the influence of the previous signal on the following signal in the sequence. When the signal does not repeat the sequence of values regularly after a fixed length of time, the autocorrelation coefficients tend to be small, which indicates the fluctuation of v_t. Otherwise, the autocorrelation coefficients tend to be large, which represents the stable status of health digital traces.

WT Process

The WT analyzes signals with a dynamic frequency spectrum, providing a high resolution in both the frequency domain and the time domain. The WT of the vital sign signal v_t is expressed using , where $\omega = (a, b)$ and $\psi(\cdot)$ is the mother wavelet (ie, a wavelike oscillation). Parameter a defines the scale (ie, how stretched a wavelet is) of the wavelet, and parameter b defines the time location (ie, where the wavelet is positioned in time) of the wavelet. We used 3 types of wavelets to generate frequency spectrums: Morlet wavelets (), complex Morlet wavelets (), and Mexican wavelets (). Morlet and complex Morlet wavelets were included because they are closely related to human perception of vision. Mexican wavelets were used as they are widely used as broad-spectrum source terms in WT analysis.

Feature Extraction Guided by Medical Domain Knowledge

Overview



Although signal processing techniques can enhance useful signals from ICU patients' health digital traces that contain aperiodic, noisy, intermittent, and transient time series, the results from signal processing, $X_{n\times w}$, are not ideal to use as input features of machine learning classifiers for ICU mortality prediction due to their high dimensionality. For predicting ICU outcomes, the valuable patterns are still hidden in the vast amount of information. Therefore, we extracted the most representative features from $X_{n\times w}$ for ICU outcome prediction by combining medical knowledge regarding the patterns and variability of ICU patients' vital signs (Multimedia Appendix 1). In addition, we took various statistical features from the time series v_t. The extracted features formed a new feature space, $X_{n\times l}$ (n=number of patients; l=the number of features), where $l<<w$ We evaluated the relative importance of the extracted features and selected those with the highest predictive power for ICU mortality. The selected features, $X_{n\times m}$ (n=number of patients; m=the number of selected features), were the input of the proposed ICU mortality prediction model.

Relative Extrema

On the basis of medical knowledge regarding vital signs' patterns and variabilities (Multimedia Appendix 1), we extracted the frequency spectrums' positions and values of the local maxima and local minima as the ICU mortality predicting features. Formally, we extracted (1) the value of the frequencies where the oscillations, , occur; and (2) their corresponding amplitudes, , as predictive features (see examples in Figure 2). Specifically, the relative extrema, (, ) is the local maximum (or local minimum). Namely,  for all values of ω within a threshold distance ε on the frequency spectrum, where ε is a small positive value. We extracted 1 relative extrema point ω^* within each distance range (–ε, ε). It should be noted that there are multiple ω^* on the entire frequency spectrum, , where t is the number of extrema. After we found all relative extrema, $F(\omega^*)$, satisfying the requirement, we obtained a vector . The top n maxima are defined as the largest n values on u (accordingly, the top n minima are defined as the smallest n values on u). When there were $<n$ elements in u, we adopted all available relative extrema (ie, m in total) as features and included $n-m$ missing values (see parameter selection in Table S1 in Multimedia Appendix 2).

XSL•FO
RenderX

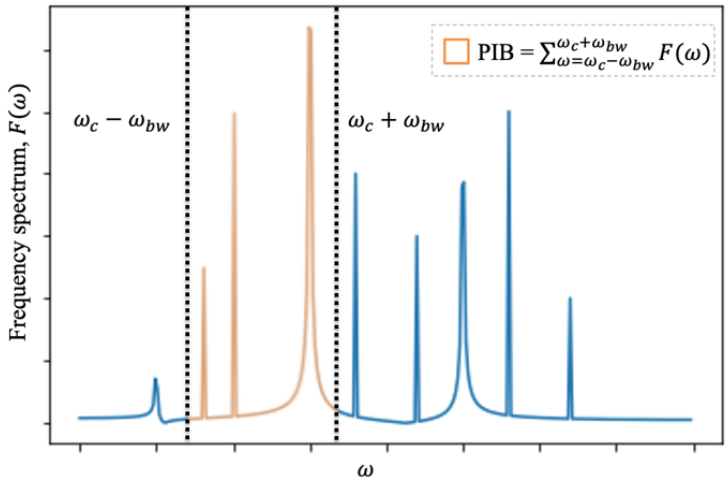


Figure 2. An example of relative maxima of the frequency spectrum.

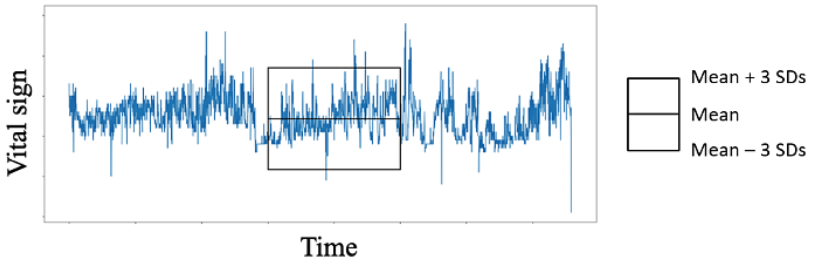
Power in Band

The power-in-band feature is the sum of the total power (see Multimedia Appendix 1 for more detail) within a frequency band (ie, frequency range). With a specified center frequency ω_c and bandwidth ω_{bw}, we can derive the low and high bounds, $\omega_c - \omega_{bw}$ and $\omega_c + \omega_{bw}$, respectively, of the frequency band. The power-in-band feature is [image_ref] (Figure 3). The power in band summarizes the strength of the signal in the frequency band by computing a single number. The benefits of using power-in-band features are 2-fold. First, the power-in-band feature summarizes the contribution of the given frequency band to the overall strength of the signal, which contains important information regarding vital signs' stabilities, which summary statistics may not be able to capture (see examples in Multimedia Appendix 1). Second, power in band is a simple yet powerful dimension reduction method for ICU mortality prediction. In practice, we computed the summation (ie, a number) over the different segments of a vector [$F(\omega_1)$, $F(\omega_2)$,..., $F(\omega_t)$] (ie, the vector represents the frequency spectrums transformed from a vital sign; see parameter selection in Table S2 in Multimedia Appendix 2).

Figure 3. An example of the power-in-band (PIB) feature of the frequency spectrum.

Statistical Features

Summary statistics are also used to outline and provide information on patients' health digital traces. For example, the mean of a signal is an estimate of the center of the entire signal. The SD and variance measure the spread extent of the signal from its average value. Taking a patient's heart rate as a simple example, a normal adult resting heart rate is between 60 and 100 beats per minute. Hence, the mean of the normal heart rate should also be within this range, and the SD should be <7. Abnormal heart rates can be an indicator of a deteriorating health condition. In this study, we calculated various statistic measures of ICU patients' vital signs as features for ICU mortality prediction (Multimedia Appendix 3).



Extreme Values of Moving Windows

The extreme values of the time series of vital signs over a given period usually indicate unfavorable health conditions as well. We propose a new predictive variable to detect the extreme values on the time-series data. We first created a series of

XSL•FO
RenderX

moving windows, and each window had *k* observations. With the *k* observations, we calculated the mean and SD (Figure 4). The observations that were not within 3 SDs of the mean were treated as extreme values [33]. Intuitively, the observations above and below the 3 SDs can be considered as a sudden rise and sudden drop in the vital signs, respectively, both of which have direct relations with patients' adverse outcomes [33]. We then took the *topn* extrema from the moving windows of vital signs, denoted as , where x^* is the event time and y^* is the value of the extrema. When the vital sign in the moving window had $<n$ relative extrema (ie, $<n$ data points were above and below the 3 SDs of the data in a given moving window), we set all available extreme points (ie, *m* data points) as features and included $n - m$ missing values (parameter selection can be found in Multimedia Appendix 2).

Figure 4. Example of the moving window on the time series of vital signs.

ICU Mortality Prediction Using ν-SVC

We defined the mortality prediction as a probabilistic classification problem . *X* denotes the input space, where

The input space *X* includes features obtained from the previous steps. The output space is defined as $Y = \{1: expired, 0: alive\}$ (ie, patient ICU discharge status). Our objective was to use a machine learning classifier to establish a mapping function, denoted as $f(x)$, that effectively maps the input data *X* to the output space *Y*. This mapping function will generate ICU mortality prediction results, represented as $Pr(Y|X)$, where *Pr* is the probability.

For our purposes, we used ν-SVC [34]. ν-SVC learns a maximum-margin decision function in kernel space while regulating model complexity through a single hyperparameter ν. The value of ν simultaneously (1) sets an upper bound on the proportion of training points permitted to lie inside or beyond the margin and (2) sets a lower bound on the proportion of support vectors that define the classifier. Thus, ν offers a direct, interpretable handle on the trade-off between training error and model sparsity without altering the underlying convex quadratic program. Among the multitude of machine learning prediction models, we opted for ν-SVC for 3 key reasons. The first is optimal prediction performance. ν-SVC retains the benefits of other SVC methods, frequently delivering superior performance across various applications. In our specific use case—predicting outcomes in the ICU—prediction performance is of utmost importance. The second reason is handling outliers effectively. Given the heterogeneity of ICU patient cohorts, outliers are common and can significantly impact the prediction results. ν-SVC adjusts the number of support vectors and the margin width based on data characteristics, making it more robust against outliers. The third reason is that it is better equipped to handle imbalanced datasets. In scenarios in which one class significantly outnumbers the others—a situation commonly observed in ICU patient cohorts (Table 3)—ν-SVC is adept at preventing overfitting and bias toward the majority class.

[a]The data records are from patients whose admission diagnoses were heart failure (HF), pulmonary sepsis, or renal sepsis. There were 17,025 total admissions (n=5282, 31.02% for HF; n=7308, 42.93% for pulmonary sepsis; and n=4435, 26.05% for renal sepsis). All vital signs used are taken directly from the electronic intensive care unit Collaborative Research Database Vital Periodic table.

[b]ICU: intensive care unit.

[c]Not applicable.

[d]The variable age in the electronic ICU dataset was set to >89 if the patients were aged >89 years. To calculate the mean, we set the ages of the patients aged >89 years to 90.

[e]When calculating the demographic statistics, we removed 11 records with irregular height (eg, 772 cm) or irregular weight (eg, 974 kg).

[f]SaO_2: arterial oxygen saturation.

[g]bpm: beats per minute; the number of times the heart beats per minute.

[h]The number of breaths a person takes per minute.

[i]ST1: estimated ST segment level 1 of the electrocardiogram (ECG).

[j]ST2: estimated ST segment level 2 of the ECG.

[k]ST3: estimated ST segment level 3 of the ECG.

We chose ν-SVC over deep learning models for 2 reasons. The first is constraints on data availability. In health predictive analysis, access to large volumes of high-quality training data from health care IT systems is not always guaranteed. However, supervised deep learning classifiers typically necessitate substantial amounts of such data for optimal performance. The second reason is complexity versus simplicity in model selection. Rudin [35] countered the common assumption that more complex models necessarily yield more accurate results, debunking the notion that a complicated “black box” is essential for optimal predictive performance. This is often a misconception, particularly with structured data possessing meaningful features. In such instances, there is frequently no significant difference in performance between more complex classifiers (eg, deep neural networks) and simpler ones given adequate preprocessing. Leveraging the structured and highly representative features obtained from previous steps, models with pattern recognition abilities such as CNNs or transformers are not necessary for our research problem. Furthermore, our generated features already incorporate the intricate time-series information, making RNN models, including LSTM and GRU, inapplicable in our case. Furthermore, other generative models such as generative adversarial networks or diffusion models are not suitable for our prediction task.

XSL•FO
RenderX

While we deemed ν-SVC a suitable classifier for our research setting, our proposed research design, involving medical knowledge–driven signal processing for feature extraction coupled with machine learning, offers distinct advantages in extracting meaningful input features beyond the confines of ν-SVC; other machine learning methods can also be used.

To select the most representative features, we used feature selection techniques (ie, ν-SVC with $l1$ penalties) before feeding the entire input feature space, denoted as $X_{n\times l}$, into the ν-SVC model. $l1$ penalties are beneficial for feature selection as they result in many estimated coefficients being 0, leaving only the most important features with nonzero coefficients. Our goal in selecting these features was to enhance the performance and accuracy of ν-SVC. Formally, for a set of features S, the feature selection method finds the optimal subset s of S by minimizing the loss function $\min_{s\subseteq S}\|Y - Pr(Y|X, X \in s)\|$, where $\|\cdot\|$ is the error estimation function. The classification mapping function Pr is determined by the feature selection methods. The selected features $X_{n\times m}$ are the input of the ICU mortality prediction model, where $m<l$.

Ethical Considerations

The eICU databases were deidentified, anonymized, and approved for sharing by the institutional review boards of both Beth Israel Deaconess Medical Center and the Massachusetts Institute of Technology. Data access was granted to an investigator after the completion of a National Institutes of Health course and successful passing of the associated human research participant protection examination. Given that the data are accessible to the public through the eICU Collaborative Research Database, the need for ethics approval and informed consent was waived. The contributing author SW obtained the necessary authorization to access the anonymized dataset and oversaw the meticulous data extraction process.

Results

Data Description

The ICU mortality prediction test bed comes from the eICU Collaborative Research Database [2], which includes data records from multiple hospitals across the United States. The proposed method was established on patients' health digital traces containing the time series of vital signs. The vital signs in the eICU Collaborative Research Database are consistently interfaced from bedside monitors, which are readily available and updated in real time. To reduce the impact of missing values, we mainly considered the following vital signs that were measured for >50% of patients in our dataset: SaO_2, heart rate, respiration, ST1, ST2, and ST3 (estimated ST segment level x of the ECG, where $x \in \{1, 2, 3\}$), as shown in Table 3. SaO_2 is useful in understanding the oxygen-carrying capacity of hemoglobin. It is particularly important in patients' care and management because low oxygen saturation can lead to many acute adverse effects on individual organ systems. Heart rate and respiration are indicators of the body's basic functions. ST1, ST2, and ST3 are estimated ST segment levels of the ECG.

To show the effectiveness and generalizability of the proposed method, we included ICU patients from 3 different patient cohorts in terms of ICU admission diagnoses: patients with congestive heart failure (HF), pulmonary sepsis, and renal sepsis or urinary tract infection (including bladder). The 3 diagnoses were the most prevalent ICU admission diagnoses in the eICU Collaborative Research Database. The total admissions were 17,025 (n=5282, 31.02% for HF; n=7308, 42.93% for pulmonary sepsis; and n=4435, 26.05% for renal sepsis). Due to the imbalance of the dataset (299/5282, 5.66% deceased for HF; 881/7308, 12.05% deceased for pulmonary sepsis; and 278/4435, 6.27% deceased for renal sepsis), we implemented a stratified 5-fold cross-validation for evaluation. The stratified k-fold cross-validation ensured that each fold was representative of the class proportions in the training dataset. In our research setting, it yielded better bias and variance estimates in cases of unequal class proportions. To alleviate the influence of the data imbalance issue during classifier training, we assigned different weights (; i=1 or 0) to the majority (ie, Y={0: *alive*}) and minority (Y={0: *expired*}) classes according to the skewed distribution of the classes. The purpose was to penalize minority class misclassification by assigning a greater class weight while decreasing weight for the majority class.

ICU Mortality Prediction Results

We evaluated the proposed framework for ICU mortality prediction using the first 24-hour time series of health digital traces (this aligns with APACHE IV, which forecasts ICU outcomes 24 hours after admission). We compared our method with four groups of benchmark methods:

1. Severity scoring systems, including APACHE IV [12], the best-performing scoring system that is already used in hospitals
2. Machine learning classifiers with statistical features [18-21]
3. Deep learning models, including 2 CNN models that have previously been used for ICU mortality prediction and have achieved state-of-the-art performance [22,23], as well as LSTM [24] and GRU [36], 2 RNN models that take vital signs in time sequence to estimate mortality rate
4. Time-series forecasting methods, the classic statistical time-series forecasting methods; following previous research [25], we fit the ARMA and ARIMA models on vital signs and took the estimated coefficients as the inputs of machine learning classifiers to predict mortality probabilities (details are available in Multimedia Appendix 2). The results are summarized in Table 4 (parameter specifications can be found in Multimedia Appendix 2).

[k]Not applicable.

The experiment yielded several findings. First, our method achieved the highest AUC, demonstrating a significant improvement compared to all the baseline methods. Second, our proposed method demonstrated a notable performance improvement of 17.6% compared to APACHE IV, which is the best-performing scoring system in ICU outcome prediction that is already used in hospitals. In contrast to our method, APACHE IV relies on more resource-demanding features for predictions, including laboratory test results (which can be time-consuming to obtain) and intensivists' assessments (which may not always be available). Our approach exhibited better performance while using fewer resources when compared to the best severity scoring system. Third, compared to the best-performing traditional machine learning model with feature engineering [19] (AUC=0.775), our method improved the AUC by 13.81%. The significant performance improvement achieved indicates the inadequacy of traditional statistical-based feature engineering methods in processing complex ICU vital sign time series and predicting ICU outcomes. Our proposed signal processing techniques, guided by medical knowledge, proved to be highly effective in extracting features and greatly benefited ICU outcome prediction. Fourth, despite the dominance of deep learning models in the field of data science and machine learning, all the deep learning–based baseline methods were significantly outperformed by our proposed method. A possible reason is our explicit extraction of valuable information from the patients' health digital traces, which facilitated the classifiers' identification of the relationship between the input space (ie, patients' health digital traces) and the prediction outcome (ie, ICU mortality), thus improving overall performance.

Another primary objective of this study was to introduce a new method for the effective extraction of patterns from the complex

XSL•FO
RenderX

time series of vital signs in patients' health digital traces. Therefore, we further compared the performance of different feature sets. The experiment yielded the following findings. First, the feature set we proposed included statistical features and signal processing features. We examined their effectiveness. We excluded statistical features and signal processing features and reconducted the evaluation. Using only signal processing features versus only statistical features, the predictive model reached AUCs of 0.828 and 0.749, respectively. The results indicate that both signal processing and statistical techniques can extract informative features and these extracted features are either more predictive than or comparable to the APACHE IV (AUC=0.750) features for ICU mortality prediction. Second, the obtained AUC scores of signal processing features (AUC=0.828) were higher than those of statistical features (AUC=0.749), validating the necessity of using signal processing techniques for decomposing the complex time series of health digital trace data and the necessity of the proposed medical knowledge–guided feature extraction methods. Third, to examine whether the proposed method can add value to existing systems such as APACHE IV, we merged the features generated by our method with other features available in the APACHE IV system. These features include patient demographics and other attributes available at ICU admission, which can have great value for ICU mortality prediction. We intentionally excluded variables that demand laboratory resources (eg, arterial blood gas) or assessments by intensivists (eg, GCS) to maintain resource efficiency in our prediction model. The new feature set attained an AUC of 0.886, demonstrating that the features generated using our method can be effectively incorporated into other ICU mortality prediction models. The subsequent model is expected to display enhanced predictive capability and reduce the demand for time-consuming or resource-intensive human evaluations.

To investigate the contributions of different vital signs and signal processing techniques toward predicting ICU outcomes, we aggregated the feature importance for each group. As shown in Table 3, heart rate, respiration, and SaO_2 exhibited the highest contribution compared to other vital signs in the mortality prediction task. These 3 vital signs are not difficult or expensive to measure in eICUs. In the eICU Collaborative Research Database, heart rate, respiration, and SaO_2 were constantly measured for >90% of patients. Furthermore, among all the proposed signal processing techniques, WT yielded the most informative features. A possible reason is that WT can reveal patterns from both the time and frequency domains simultaneously. In addition, autocorrelation provided the least instructive features. As a signal processing technique, autocorrelation is conceptually close to time-series forecasting algorithms such as ARMA and ARIMA. The unsatisfactory performance of autocorrelation reveals the fact that time-series forecasting algorithms can hardly capture sufficient information for ICU mortality prediction. This observation is also supported by our experiment using ARMA and ARIMA coefficients for prediction (Figure 5).

Figure 5. Summary of the importance of different feature types. The cells in the Statistics column contain the sum of feature importance across all statistical features for the corresponding vital sign, including SD, variance, mean, median, quantiles, min, max, and the first and last signal of the vital sign. Postanalysis: Assessing Predictive Features of ICU Mortality

One of the objectives of this work was to extract representative features from the complex time series of vital signs in ICU patients' health digital traces, which is accomplished by leveraging medical domain knowledge and using signal processing techniques to decompose the time-series data, enhance relevant signals, and minimize noise within the complex time series. In this section, we report on the postanalyses conducted to examine why our proposed method achieved better performance compared to other existing methods.

We first selected and compared 2 patients from our dataset as an illustrative example to demonstrate the feasibility of signal processing techniques and our proposed feature extraction methods in ICU outcome prediction (Table 5). According to medical knowledge, the worst vital sign values and fluctuating

XSL•FO
RenderX

vital signs all have direct relations with adverse ICU outcomes [12,37]. The health digital traces' fluctuating patterns of the 2 patients were distinct, and it was not intuitive to predict their ICU outcome based on their health digital traces (Table 5, Health digital traces—time series of vital signs). The SaO_2 of patient 1 dropped to 58% (the lowest value) and fluctuated at the beginning of her ICU stay. Her SaO_2 stabilized at approximately 840 minutes and stayed at 100%. The lowest SaO_2 value of patient 2 (80%) was better than that of patient 1. However, her SaO_2 did not stabilize during her 24-hour stay in the ICU as it continued to fluctuate.

Table 5. Illustrative example demonstrating the feasibility of the proposed feature sets.

	Patient 1 (outcome: alive)	Patient 2 (outcome: deceased)
Health digital traces—time series of vital signs		
Time-series decomposition using signal processing techniques (using wavelet transform as an example)		
	Shows distinct differences between the stable and unstable time series of SaO_2[a].	Shows unstable SaO_2 during the entire ICU[b] stay. Unstable vital signs have a direct relation with adverse ICU outcomes.
Example from the proposed feature set		
sao2_sudden-drop_value_1[c]	58% (less sudden changes)	82% (more sudden changes)
sao2_wt_morl_length5_power-in-band_1[d] (power-in-band feature; band_1: low-frequency band. A higher value of this feature indicates that the smooth part [ie, no fluctuation, indicating favorable health condition] of the vital sign is longer and the value of the smooth part of the vital sign is higher [ie, high SaO_2, indicating a favorable health condition])	13,378.21335	8985.535909
stat_sao2_last[e]	100 (the last value at the time of prediction is within the normal range)	85 (the last value at the time of prediction is NOT within the normal range)
Other features	There are many other features not included in this table as cases.	There are many other features not included in this table as cases.
Example from the APACHE[f] IV feature set		
Age (y)	79	83
Gender	Female	Female
Has active treatment	Yes	Yes
Has diabetes (diabetes is a chronic condition that may lead to adverse ICU outcomes)	Yes	No
GCS[g] score (depends on expert assessments; the higher the better)	6	15
Other features	There are many other features not included in this table as cases.	There are many other features not included in this table as cases.
Example from the statistical feature set		
stat_sao2_min[h] (the worst [minimum] value of the vital sign; the higher the SaO_2 the better)	58	82
stat_sao2_std[i] (the fluctuation [SD] of the vital sign; the lower the better)	6.05375	3.20926
Other features	There are many other features not included in this table as cases.	There are many other features not included in this table as cases.
Death probability at 24 h		
APACHE IV	86.4% (ICU mortality prediction result was wrong)	8.3%
Our method	31.8%	59.8% (ICU mortality prediction result was correct)

[a]SaO_2: arterial oxygen saturation.

[b]ICU: intensive care unit.

[c]sao2_sudden-drop_value_1: vital sign signal: SaO_2; feature extraction: extreme values within moving windows (sudden drops with an SD of 1).

[d]sao2_wt_morl_length5_power-in-band_1: vital sign signal: SaO_2; signal processing: wavelet transform using Morlet wavelets. Feature extraction: power in band (segment length of 5 and band_1).

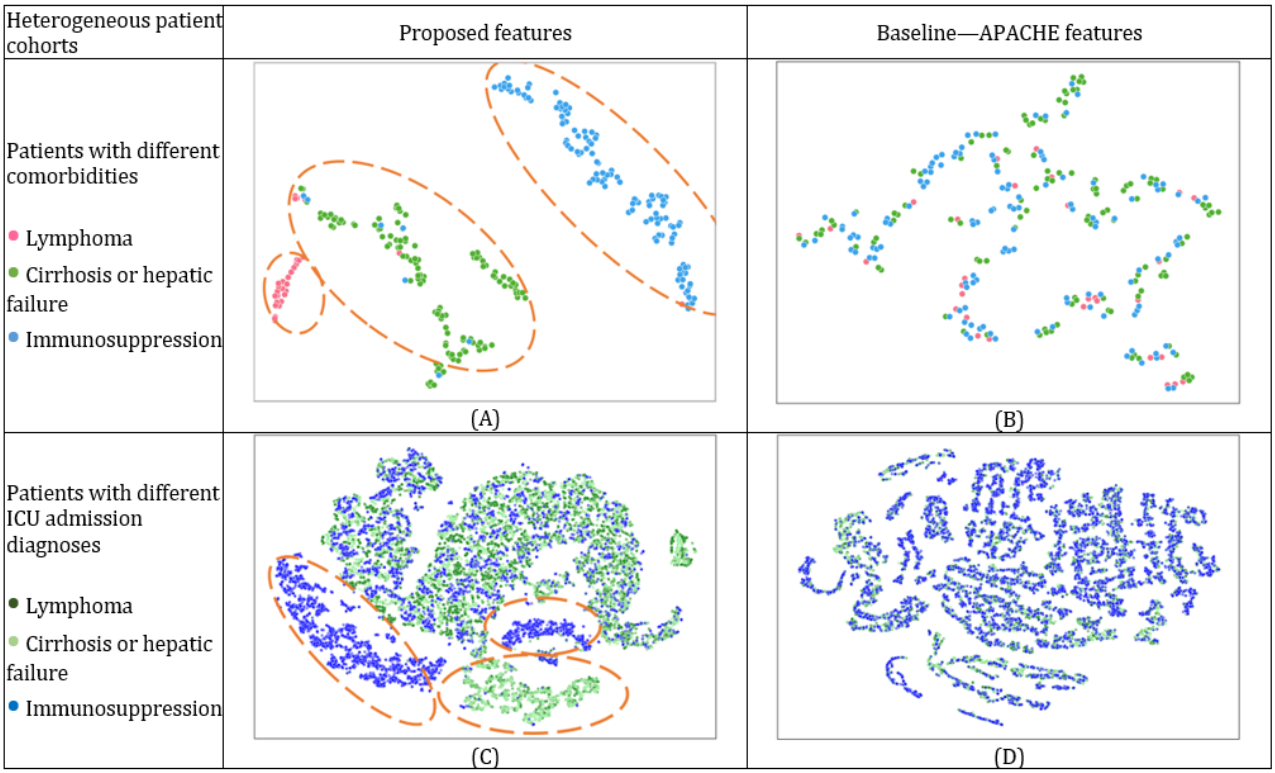
[e]stat_sao2_last: vital sign signal: SaO_2. Signal processing: statistical feature (the last value of the vital sign).

XSL•FO
RenderX

[f]APACHE: Acute Physiology and Chronic Health Evaluation.

[g]GCS: Glasgow Coma Scale.

[h]stat_sao2_min: the worst value of the vital sign.



[i]stat_sao2_std: the amount of variation in SaO_2.

The illustrative example reveals several important observations related to predictive features of ICU outcome predictions. First, APACHE IV only included the vital signs' worst measurements in the first 24 hours of ICU stay. For patient 1, it ignored the important healthy signal that the second half of the SaO_2 conveys, which caused APACHE IV to make a wrong inference (86.4% death probability, but patient 1 was alive at the time of discharge). In addition, APACHE IV did not capture the vital sign fluctuation of patient 2 and made a wrong prediction (8.3% death probability, but she died later). Moreover, the GCS score is a variable depending on expert evaluation in APACHE IV (the higher the better; 3 being the worst and 15 being the best). Patient 1's GCS score was lower than that of patient 2, but patient 1 survived, demonstrating that such a predictor is not always indicative of ICU outcomes. Second, in extant studies, researchers consider simple statistical features of vital signs (Table 5, Example from the statistical feature set). The *stat_sao2_min* variable indicates the worst value of the vital sign. The *stat_sao2_std* variable indicates the amount of variation in SaO_2, which represents the fluctuation in SaO_2. Both values suggest that patient 2 had a higher likelihood of survival. However, the actual ICU outcome differed from the prediction, showing that existing statistical features are inadequate in capturing complex patterns from ICU patients' digital traces. Third, the proposed framework can effectively identify meaningful patterns in ICU patients' health digital traces and lead to better ICU outcome predictions (Table 5, Example from the proposed feature set). The signal processing result of patient 1's SaO_2 shows the distinct differences between the stable and unstable time series (Table 5, Signal processing decomposition results). The proposed feature extraction methods, such as *sao2_sudden-drop_value_1* and *sao2_wt_morl_length5_power-in-band_1*, can properly capture the vital sign's stability information and result in correct prediction of patient outcomes. Overall, the example demonstrates the insufficiency of existing approaches and the motivation to identify more accurate indicators for predicting ICU outcomes. In the meantime, the proposed framework can catch patterns in the time series of vital signs that are difficult to detect using other methods, such as APACHE IV and statistical features. Our method can offer valid feature sets for the prediction of ICU outcomes.

Furthermore, patients from different cohorts exhibited distinct disease progressions. To evaluate the efficacy of the proposed features in representing ICU patients from heterogeneous cohorts, we visualized the proposed feature set and compared the resulting visualizations to those of the APACHE IV feature set. As shown in Figure 6, the proposed feature set can effectively distinguish patients with different comorbidities and patients with different ICU admission diagnoses (Figures 6A and 5C). In contrast, APACHE IV features were not able to discriminate between patients from different cohorts (Figures 6B and 5D). According to medical literature, different patient cohorts typically experience varying disease progression and outcomes [7]. Therefore, our method, which has strong capabilities to extract patterns and represent ICU patients from heterogeneous cohorts, can facilitate ICU outcome prediction (as we demonstrate in the ICU Mortality Prediction Results section).

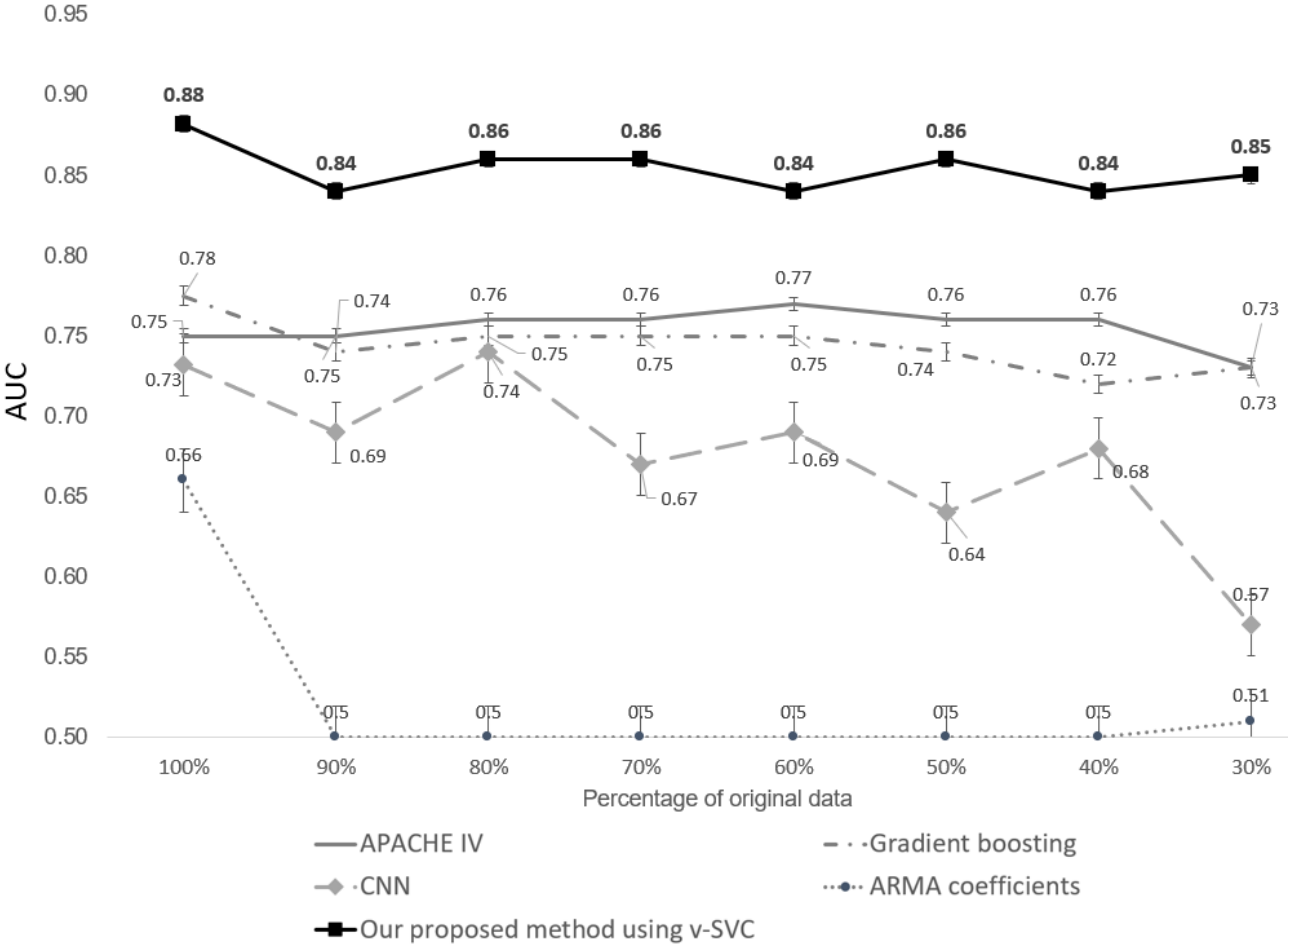
Postanalysis: The Impact of Limited Patient Data on Deep Learning Model Performance



Deep learning models exhibit superior performance due to their reliance on substantial computing power, advanced algorithmic capabilities, and extensive training data, enabling them to yield highly promising results across diverse domains. Nonetheless, patient data in health care predictive analysis, including ICU outcome prediction, are highly specific. ICU patients come from various diagnostic cohorts, have unique demographics and disease progressions, and may receive different levels of medical intervention. The integration of patient data must be executed with great care, making it impractical to acquire sufficient training data for complex deep learning models.

The benchmark methods used were the best-performing methods within each category, as outlined in Table 4.

In our experimental evaluation, we chose to focus on the 3 most prevalent patient cohorts (ICU admission diagnoses) within the eICU Collaborative Research Database. The number of patients per cohort had already reached the upper limit in this database (5282/17,025, 31.02% for HF; 7308/17,025, 42.93% for pulmonary sepsis; and 4435/17,025, 26.05% for renal sepsis), with other patient cohorts containing fewer patients. To our knowledge, the eICU Collaborative Research Database is already one of the largest publicly available ICU databases. In contrast, in other problem domains, such as natural language processing or image processing, the training data for deep learning models typically extend into the millions or even billions. In the aforementioned 3 patient cohorts, when using the complete dataset, deep learning models did not outperform our approach. To explore the limitations and boundaries further, we systematically reduced the original dataset (to 90%, 80%, 70%, 60%, 50%, 40%, and 30%) to observe the performance variations of our proposed method and the benchmark methods, as illustrated in Figure 7 [12,19,21,23]. The results showed that (1) our proposed method consistently outperformed all benchmark methods, (2) traditional machine learning approaches with feature engineering and scoring systems also demonstrated better performance compared to deep learning methods, and (3) deep learning methods failed to converge when 30% of the original data were available.

XSL•FO
RenderX

Figure 7. Evaluation of the proposed method and baseline methods. APACHE: Acute Physiology and Chronic Health Evaluation; ARMA: autoregressive moving average; AUC: area under the curve; CNN: convolutional neural network; SVC: support vector classification.

Moreover, we conducted tests on our proposed method and the benchmark methods using 3 small patient cohorts (in terms of ICU admission diagnosis). It was noted that obtaining satisfactory performance results using deep learning methods posed a challenge for these smaller patient cohorts. Nevertheless, our approach (as well as other traditional machine learning methods with feature extraction) exhibited stable performance over various patient cohorts (Table 6). The model parameters are listed in Table S3 in Multimedia Appendix 2.

v-SVC[i]	0.978	0.989	0.981

[a]ICU: intensive care unit.

[b]AUC: area under the curve.

[c]APACHE: Acute Physiology and Chronic Health Evaluation.

[d]GRU: gated recurring unit.

[e]CNN: convolutional neural network.

[f]LSTM: long short-term memory.

[g]ARMA: autoregressive moving average.

[h]ARIMA: autoregressive integrated moving average.

[i]SVC: support vector classification.

The aforementioned 2 experiments illustrate that, in health care predictive analysis, particularly in ICU outcome prediction, when acquiring a large amount of training data is not feasible, the limitations of deep learning models become evident. In contrast, our proposed research design, which involves medical knowledge–driven feature extraction coupled with machine learning, holds significant potential owing to its efficiency.

Discussion

Principal Findings

ICU patients' health digital traces contain complex time-series data and patterns. It is essential to find representative features to develop predictive models for better ICU outcome predictions. Guided by signal processing techniques and medical domain knowledge, we propose a novel method to repurpose and effectively extract features with strong predictive power from patients' health digital traces for ICU mortality prediction. We systematically evaluated the proposed method using a real-world multicenter ICU database from the perspective of feature effectiveness and prediction accuracy. The proposed method efficiently extracted representative features from heterogeneous patient cohorts. The ICU outcome prediction results significantly outperformed those of state-of-the-art benchmarks.

Our contribution lies in incorporating medical knowledge to guide the selection of the most suitable signal processing techniques and feature extraction methods for predicting ICU outcomes. Our approach presents generalizable design principles for research scenarios with limited training data, demonstrating how integrating domain knowledge into signal processing and predictive model design enhances performance. Our work has important implications for health care operation management. We contribute to the emerging field of using digital traces from information systems to address challenges with significant implications for health care [1]. Specifically, we present a new feature extraction method that uses patients' digital traces retrieved from health IT systems to predict ICU mortality

XSL•FO
RenderX

accurately. Practically, accurate prediction of ICU outcomes is important. It indicates when patients may require heightened attention, care, and interventions; therefore, all essential resources, including personnel, equipment, and medications, are readily available to ensure the provision of comprehensive support for the patient.

While the results are encouraging, the proposed method is not without limitations. First, more vital sign data (eg, the central venous pressure and pulmonary artery pressure) were not included due to the high missing rate. The predicting power of these vital sign data can be evaluated in the future. Next, our method could be enhanced by developing a more comprehensive model that incorporates individual patient characteristics such as medical history and genetic information. By doing so, our method holds the potential to evolve into a generalized mortality prediction model tailored to each patient's unique profile.

Conclusions

To conclude, as the Fourth Industrial Revolution evolves, digital tools create an influx of data. In health care, this trend has transformed ICUs by enabling the collection of real-time patient health data, leading to critical advances in ICU outcome predictions—a task with high stakes due to patients' rapid disease progression and high mortality rates. The availability of digital health data provides new opportunities to refine these prediction models. This study created a new feature extraction method that aims to enhance the accuracy of ICU outcome predictions by repurposing digital trace data from ICU patients. The resulting method outperformed existing ICU outcome prediction models. Our study has important implications for health care operation management by using digital traces from health care information systems to solve problems with societal implications and leveraging specific domain knowledge to create innovative and impactful artifacts. Practically, the proposed method efficiently extracted representative features, facilitating ICU outcome prediction.

Abstract

Background: Clinical notes house rich, yet unstructured, patient data, making analysis challenging due to medical jargon, abbreviations, and synonyms causing ambiguity. This complicates real-time extraction for decision support tools.

Objective: This study aimed to examine the data curation, technology, and workflow of the named entity recognition (NER) pipeline, a component of a broader clinical decision support tool that identifies key entities using NER models and classifies these entities as present or absent in the patient through an NER assertion model.

Methods: We gathered progress care, radiology, and pathology notes from 5000 patients, dividing them into 5 batches of 1000 patients each. Metrics such as notes and reports per patient, sentence count, token size, runtime, central processing unit, and memory use were measured per note type. We also evaluated the precision of the NER outputs and then the precision and recall of NER assertion models against manual annotations by a clinical expert.

Results: Using Spark natural language processing clinical pretrained NER models on 138,250 clinical notes, we observed excellent NER precision, with a peak in procedures at 0.989 (95% CI 0.977-1.000) and an accuracy in the assertion model of 0.889 (95% CI 0.856-0.922). Our analysis highlighted long-tail distributions in notes per patient, note length, and entity density. Progress care notes had notably more entities per sentence than radiology and pathology notes, showing 4-fold and 16-fold differences, respectively.

Conclusions: Further research should explore the analysis of clinical notes beyond the scope of our study, including discharge summaries and psychiatric evaluation notes. Recognizing the unique linguistic characteristics of different note types underscores the importance of developing specialized NER models or natural language processing pipeline setups tailored to each type. By doing so, we can enhance their performance across a more diverse range of clinical scenarios.

Introduction

Background

Clinical decision support (CDS) tools play a vital role in improving quality of care and patient safety by providing clinicians with real-time patient data and evidence-based guidance. In the 1960s and 1970s, paper-based diagnostic systems were introduced. They used some rules to match a patient's symptoms with a set of possible diagnoses based on data from previous patients. One of the earliest examples of a paper-based diagnostic system was the Symptom Sorting Program, developed by Weed in 1968 [1]. In the 1980s, electronic medical records began to emerge, offering greater flexibility and more extensive datasets. Electronic medical records enabled clinical informaticists to collect and store patient data more efficiently, paving the way for the development of advanced CDS tools. One of the earliest examples of an electronic CDS tool was the HELP system, which was introduced in 1983 at the Latter-Day Saints Hospital in Salt Lake City, Utah [2]. These days CDS tools use a variety of technologies, including artificial intelligence, natural language processing (NLP), and machine learning, to analyze patient data and provide relevant recommendations to improve clinical effectiveness, optimize patient safety, and reduce the risk of errors [3].

There are several types of inputs coming from electronic health record (EHR) platforms that can be used to develop a CDS tool, including structured (eg, laboratory results and vital signs), semistructured (eg, nursing flow sheets), and unstructured (eg, clinical notes) data. Clinical notes and reports contain valuable patient data but can be challenging to analyze due to their unstructured nature. Clinical notes usually contain unorganized and inconsistent data with free-form text that make it difficult to extract the relevant information automatically. There are medical terms, abbreviations, and synonyms in clinical notes resulting in ambiguity and misinterpretation. Extracting clinical insights from the large volume of unstructured data can be time consuming, which can have a significant impact on the real-time applicability of decision support tools [4].

NLP is a branch of artificial intelligence focused on enabling computers to understand, interpret, and generate human language. In the context of clinical notes, NLP techniques can be used to extract information from unstructured text, including named entity recognition (NER), which identifies and extracts entities such as diseases, signs and symptoms, and treatments [5]. In recent years, deep learning–based NER models in the clinical domain have reached performance levels that make them suitable for developing CDS tools with sufficient reliability [6]. For instance, Spark NLP [7] is an open-source library built on Apache Spark that provides various tools and pretrained models for NLP tasks, such as NER [8,9], entity assertion, and entity relationship extraction. However, developing and deploying such CDS tools pose various challenges that require careful consideration [10]. In this paper, we discuss some of the key challenges and best practices for developing and deploying NER-based CDS tools in clinical settings.

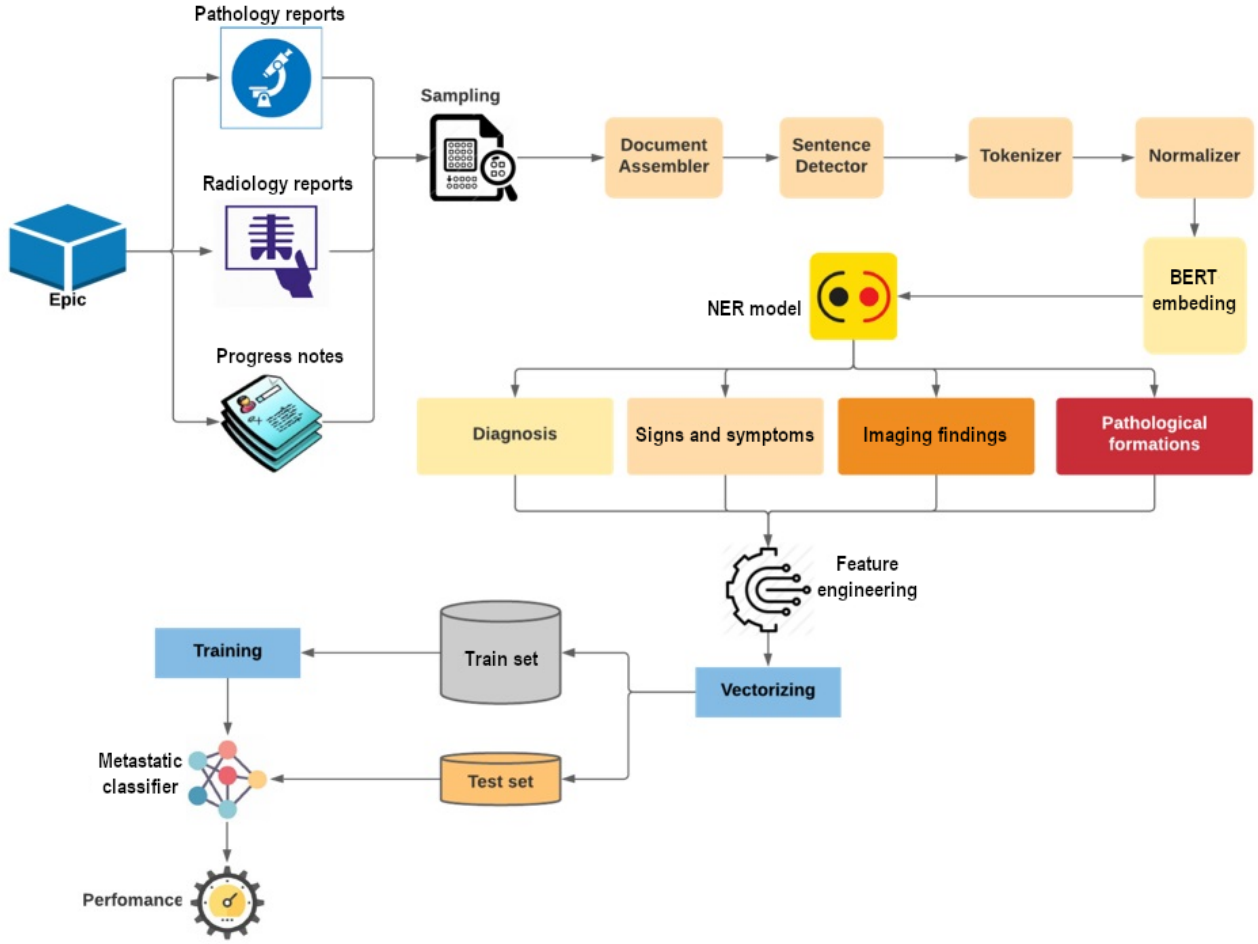
Challenges of NER-Based CDS Tools

There are 5 main areas of challenges in the development and deployment of NLP-based CDS tools: note ingestion and curation, technology, computational workflow, clinical workflow, and user adoption. In this paper, our main focus is on data curation, technology, and computational workflow. Clinical note ingestion and curation can affect the performance of NLP models, and the choice of technology can impact scalability and reproducibility. To address the challenges we are sharing the best practices coming from the lessons we learned from our practical experiences.

Methods

Ethical Considerations

Data used during this study was managed following Health Insurance Portability and Accountability Act–compliant procedures based on retrospective anonymized electronic healthcare records datasets. Given the analysis was purely focused on computational performance and overall performance of information extraction models and not related with any clinical consideration we concluded that this study did not involve human subjects.



CDS Application Architecture

The work presented here is part of a larger CDS system designed to enhance patient care through timely data curation and patient-level risk stratification, with its computational flow shown in Figure 1. A key component of this system was the NER pipeline, which focuses on extracting essential clinical entities from unstructured notes, including progress notes, radiology reports, and pathology reports. Once relevant entities were identified through NER, these extracted entities were subsequently used as inputs to machine learning classifiers that support clinical decision-making, offering actionable insights to clinicians at the point of care.

The NER pipeline itself comprises 2 main components: the *note ingestion pipeline* and the *NLP pipeline*. This section provides an overview of the architecture of this NER pipeline, which was implemented for oncology and psychiatry CDS tools to generate risk scores for metastatic disease and the likelihood of developing episodes of aggression. However, the scope of this paper is limited to presenting the entity extraction process without going into the specifics of the downstream classification components that use this information. The description and validation of these downstream components that complete the CDS tool will be the subject of future publications.

XSL•FO
RenderX

Figure 1. Computational flow.

Note Ingestion Pipeline

Different clinical notes (eg, progress note, care note, and consult note) and reports (eg, radiology impression and pathology report) were ingested from various EHR modules (Epic) such as Clinical Notes, Radiology Information System (RIS), and pathology information system. A cross-platform interface engine (Mirth Connect) [11] was used for note interfacing. Mirth stored the Health Level 7 (HL7) messages in a NoSQL database (MongoDB), and a Health Level 7 parser (Smolder) [12] extracted and decrypted these notes before saving them into the NoSQL database.

A Spark service then read the raw notes and stored them in a Spark Dataframe, creating a unified view at the desired level, which can be patient, visit, or bed level, based on the specifications of the use cases. Similar to most data elements in an EHR, such as laboratory results and vital signs, clinical notes and reports are considered observational data. To use them as inputs for modeling, specific sampling logic needs to be applied to optimize the learning rate during the training phase.

The following sampling logic was applied to select relevant clinical notes and compile a comprehensive text corpus for the NLP pipeline. Notes were first organized by type, and then, a random sampling was performed within each category to ensure a diverse selection. Progress care notes, which are typically longer and contain more clinical entities, were oversampled to capture a wide variety of detailed clinical information. Conversely, radiology and pathology reports, known for their brevity, were undersampled to maintain their typical representation in clinical workflows. This stratified approach created a balanced training dataset that exposed the model to a representative mix of clinical scenarios while preserving the natural variation in note types.

NLP Pipeline

The NLP pipeline is a series of interconnected modules designed and developed to process clinical notes and extract predefined sets of medical terms using pretrained NER models. The pipeline consists of several key components, including the document module, sentence module, tokenizer module, embedding model, and NER models.

The document module handles the input of clinical notes and ingests them into a Spark DataFrame. The sentence module then further segments these documents into separate sentences, enabling more granular analysis. The tokenizer module plays a crucial role in splitting sentences into individual words or tokens, facilitating subsequent analysis and processing. The embedding module focuses on transforming the tokenized words into numerical representations, often leveraging techniques such as word embeddings or contextualized embeddings. This step allows the pipeline to capture semantic meaning and context within the text. Finally, the NER module is a vital component that identifies and classifies named entities within clinical notes, such as diagnoses, signs and symptoms, medications, and

XSL•FO
RenderX

electrocardiography findings. This module uses pretrained NER models to accurately recognize and extract relevant entities from the text.

To execute the NLP pipeline efficiently, it is often implemented using Spark NLP [13], a powerful NLP library built on top of Apache Spark [14]. This choice allows the pipeline to leverage the distributed computing capabilities of Apache Spark, enabling faster and scalable processing of large volumes of clinical notes.

By using this NLP pipeline with its various modules and pretrained models [15], health care professionals and researchers can automate the extraction of important information from clinical notes, such as medical conditions, treatments, patient outcomes, and even some complex information (eg, response to treatment). This approach streamlines the analysis process, facilitates research, and enhances decision-making in the health care domain.

Performance Measurement

In this section, we present the methodology and metrics used to measure the performance of the note ingestion and curation pipeline and NLP pipeline. The server on which we ran the pipelines was an Intel Xeon (R) Gold 5120 central processing unit (CPU) @ 2.20 GHz with 56 processors, 14 CPU cores, and 187 Gb memory size. We ingested and curated progress and care notes, radiology reports, and pathology reports. We split them into 5 batches, each with notes of 1000 unique patients, and measured the number of notes and reports per patient, the number of sentences, token size, runtime, CPU use, and memory use per note type.

We also assessed the precision (positive predictive value) of the pretrained NER models in identifying 4 entities: disease, symptom, drug, and procedure. To achieve this, a clinical expert reviewed a random sample of clinical notes containing entities identified by the pretrained NER models, classifying each prediction as a true positive or false positive. The assertion model developed specifically for this project was evaluated by a clinical expert, who reviewed 342 randomly selected sentences in which an entity was identified and marked as present or absent. The expert then confirmed whether the assertion generated by the model was correct.

Results

Clinical Note Characteristics

Our analysis of a corpus comprising 138,250 notes from 5000 patients randomly selected from those aged >18 years admitted to the Mount Sinai Hospital revealed distinct characteristics for each type of note.

The distribution of notes per patient was positively skewed across all note types, with pathology notes ranging from 1 to 17, progress care notes from 1 to 99, and radiology notes from 1 to 88. The median number of notes per patient was 1 (interdecile range 1-2) for pathology notes, 15 (interdecile range 5-47) for progress care notes, and 3 (interdecile range 1-11) for radiology notes. Moreover, 90% (4500/5000) of the patients had 1 or 2 pathology notes, 5 to 47 progress care notes, and 1 to 11 radiology notes. As shown in Table 1, there were differences in the average number of notes per patient among the different types of notes. Progress care notes were the most prevalent, averaging 21.16 (95% CI 20.63-21.69) notes per patient, followed by radiology notes with 5.02 (95% CI 4.85-5.19) and pathology notes with 1.47 (95% CI 1.44-1.50).

Upon closer examination of the notes themselves, we found that pathology notes were the highest in terms of the number of sentences, averaging 23.85 (SD 22.78; median 17) sentences per note, followed by progress care notes with 17.14 (SD 21.57; median 11) sentences per note. In contrast, the number of individual sentences in radiology notes was much lower, with an average of 4.77 (SD 6.87; median 3) sentences per note.

However, our analysis of sentence length based on note type revealed that progress and care notes contained longer sentences, averaging 36.46 (SD 75.57; 95% CI 36.35-36.57) tokens per sentence. In comparison, radiology and pathology notes were less than half the length, with 11.83 (SD 8.56; 95% CI 11.79-11.87) and 12.16 (SD 8.83; 95% CI 12.11-12.21) tokens per sentence, respectively. Although the difference in sentence length between pathology and radiology notes was statistically significant, the practical implications were minimal.

Interestingly, when examining the median number of tokens per sentence, the differences between pathology (10 tokens), progress care (12 tokens), and radiology notes (10 tokens) were not significant in practical terms. The difference in means was driven by the existence of some long sentences in the progress care notes, with an interdecile range of 4 to 85 tokens. For pathology and radiology notes, the ranges were 3 to 23 and 3 to 22 tokens, respectively.

Statistically significant differences were observed in the number of clinical entities per sentence and the proportion of tokens constituting a clinical entity (clinical entity density).

Progress and care notes exhibited the highest clinical entity density, with 8.01 (SD 24.05; 95% CI 7.98-8.05) clinical entities per sentence and 21.97% (SD 1.66%; 95% CI 21.97-21.99%) of tokens forming a clinical entity chunk. Radiology notes contained a quarter of the number of clinical entities per sentence (2.06; SD 2.65; 95% CI 2.05-2.08) but had a comparably lower entity density (16.92%; SD 6.47%; 95% CI 16.88-17.04%). Conversely, pathology notes had the lowest number of clinical entities per sentence (0.53%; SD 1.07; 95% CI 0.53-0.54) and the smallest proportion of tokens as part of a clinical entity chunk (4.52%; SD 1.31%; 95% CI 4.49-4.55%).

Again, the higher average number of entities found in the progress and care notes, when compared to radiology notes, was driven by a subgroup of sentences with an unusually high number of clinical entities. The median number of clinical entities per sentence was the same for both types of notes (2 entities). However, the range was wider for progress and care notes (0-15 clinical entities per sentence) compared to radiology notes (0-5 clinical entities per sentence).

Entities, n	94,075	14,531,843	247,319
Notes per patient, mean; SD (95% CI)	1.47; 1.08 (1.44-1.50)	21.16; 19.12 (20.63-21.69)	5.02; 6.13 (4.85-5.19)
Sentences per note, mean; SD (95% CI)	23.85; 22.78 (23.33-24.37)	17.14; 21.57 (17.01-17.27)	4.77; 6.87 (4.69-4.86)
Tokens per sentence, mean; SD (95% CI)	11.83; 8.56 (11.79-11.87)	36.46; 75.57 (36.35-36.57)	12.16; 8.83 (12.11-12.21)
Entities per sentence, mean; SD (95% CI)	0.53; 1.07 (0.53-0.54)	8.01; 24.05 (7.98-8.05)	2.06; 2.65 (2.05-2.08)
Notes per patient, mean (interdecile range)	1 (1-2)	15 (5-47)	1 (1-11)
Sentences per note, mean (interdecile range)	17 (8-46)	11 (1-42)	3 (1-9)
Tokens per sentence, mean (interdecile range)	10 (3-23)	12 (4-85)	10 (3-22)
Entities per sentence, mean (interdecile range)	0 (0-2)	2 (0-15)	2 (0-5)
Clinical entity density %; SD (95% CI)	4.52; 1.31 (4.49-4.55)	21.98; 1.66 (21.97-21.99)	16.92; 6.47 (16.88-17.04)

NER Performance

We used a set of pretrained NER models to identify 4 types of clinical entities: diseases (n=340), drugs (n=173), procedures (n=281), and symptoms (n=4412). As we only reviewed the actual output of the NER models and did not annotate a gold standard corpus, other metrics are not available for evaluation. The highest precision was achieved for procedure entities (0.989; SD 0.098; 95% CI 0.977-1.000), followed by diseases (0.918; SD 0.277; 95% CI 0.888-0.947) and symptoms (0.929; SD 0.254; 95% CI 0.922-0.937). Drug entities exhibited significantly lower precision (0.821; SD 0.382; 95% CI 0.764-0.878). We also implemented an assertion model to categorize whether an entity was present or absent (n=342). The model demonstrated a recall (sensitivity) of 0.922 (SD 0.264; 95% CI 0.894-0.950), a precision (positive predictive value) of 0.828 (SD 0.377; 95% CI 0.788-0.868), a specificity of 0.866 (SD 0.340; 95% CI 0.830-0.902), a negative predictive value of 0.941 (SD 0.241; 95% CI 0.915-0.966), an accuracy of 0.889 (SD 0.311; 95% CI 0.856-0.922) and an F_1-score of 0.872. The system used in this experiment was equipped with an Intel Xeon Gold 5120 CPU, operating at a speed of 2.20 GHz. It featured 56 processors, arranged into 14 CPU cores, each running at approximately 2599.877 MHz. The setup also included a substantial memory capacity of 187 GB, ensuring sufficient resources for handling the data processing demands. The compute time measurements presented are specific to the previously described hardware setup and may vary across different computational environments.

We opted for a CPU-based setup instead of a graphics processing unit due to the highly sensitive nature of the data derived from EHRs. In many organizations, it is preferable to run such processes on premises to ensure data security and confidentiality, minimizing the need to share data with external infrastructures. This practical constraint often means that graphics processing units are not easily available, making a CPU setup both a feasible and secure option for processing sensitive clinical information directly within the organization's own hardware environment.

The process involved dividing each note type into 5 mini-batches, with each batch containing all notes from 1000 patients. We further partition each mini-batch into 100 partitions. This results in each partition containing 10 sequences. This methodology significantly enhances our capability for parallel processing. The logging frequency was set to every 5 seconds. In terms of runtime per mini-batch, radiology and pathology notes averaged 24 and 33 seconds, respectively. Contrastingly, the average runtime for progress and care notes was significantly higher, clocking in at 1498 seconds. This means that progress and care notes required approximately 42 times more time than pathology notes and approximately 56 times more than radiology notes.

One key finding was that the average number of tokens in progress and care notes was approximately 30 times more than in pathology notes and approximately 31 times more than in radiology notes. Hence, this substantial increase in runtime for progress and care notes was anticipated. The experiment clearly demonstrates a linear relationship between runtime and the size of the notes. The mean, SD, and percentile values of computing time for each type of clinical note are presented in Table 2.

Figure 2 presents a graph of CPU use. We noticed similar patterns of CPU use for both radiology and pathology notes, fluctuating between 20% and 80%. By contrast, CPU use for progress and care notes ranged from 5% to 80% but consistently remained at the higher end of this spectrum. This was an anticipated outcome, given that the token size of progress and care notes is considerably larger than that of the other note types.

Discussion

Principal Findings

The development and deployment of CDS tools using the NER approach presents numerous challenges and opportunities. We believe that our work contributes to the knowledge in this field in several significant ways.

In contrast to previous studies focused on specific clinical note types, our analysis includes progress care notes, radiology reports, and pathology notes, enabling a comprehensive comparison of linguistic features, entity density, and NER

XSL•FO
RenderX

performance across these distinct categories. The findings emphasize the necessity of tailored NLP pipelines, as progress care notes, for instance, require significantly greater computational resources and processing time than radiology or pathology notes. The notably higher clinical entity density observed in progress care notes, compared to radiology and pathology reports, further highlights the variability in NER performance across clinical domains and reinforces the need for context-specific optimization approaches. This underscores a gap in existing NER optimization strategies that general-purpose models may fail to address.

Moreover, our study extends beyond traditional accuracy metrics by providing detailed computational insights, including compute times, CPU use, and memory use, which are essential for optimizing real-time CDS applications.

Characteristics of Different Clinical Notes

This study provides a comprehensive understanding of the characteristics and linguistic composition of different types of clinical notes. Our analysis revealed long-tail distributions in terms of notes per patient, note length, and clinical entity density. Therefore, the 90th percentile could serve as a practical benchmark when determining the necessary context length for various NLP tasks on this type of clinical note–based corpus. It is more practical and logical to design NLP systems to accommodate 90% of the cases, excluding outliers with an unusually large number of notes per patient or exceptionally lengthy notes and sentences.

We identified significant differences in note length, sentence length, and the presence and density of clinical entities among the note types. These differences likely stem from the distinct clinical contexts in which these notes are generated. One possible explanation is the difference in focus between patient care specialties and diagnostic specialties. For example, progress care notes are typically authored by clinicians involved in ongoing patient care, such as internal medicine or critical care physicians. These notes are more narrative and detailed, documenting the patient's daily progress, treatment plans, and responses to therapy. This structure results in a greater number of clinical entities associated with patient management, while the longer sentence and note lengths reflect the complexities of continuous care.

In contrast, radiology and pathology reports are usually created to interpret specific tests or procedures. Therefore, they are shorter and more structured, with fewer entities per sentence, as they summarize diagnostic findings rather than provide a holistic account of the patient's clinical status. The lower density of clinical entities in these notes likely reflects the narrower focus on reporting test results instead of capturing comprehensive patient management. It is also plausible that for other entity types more pertinent to pathology reports, such as anatomical structures, sizes, or locations, the entity density would be higher within this specific type of notes.

Patients typically had a single pathology note, and only 10% (4500/5000) of patients had >2 pathology reports, likely reflecting the definitive nature of pathology results in diagnosing a medical condition. In contrast, the median number of radiology reports was 3. This observation suggests that medical imaging tests are used not only for diagnostic purposes but also for reassessment and follow-up.

When analyzing the distribution of sentence lengths, we observed peaks at specific values that did not align with the expected statistical distribution. A qualitative analysis of these sentences revealed that they were primarily related to copied or templated content. For instance, within the corpus, 7521 sentences consisted of the following 20 tokens: "Attending physician note: \n I have personally reviewed the images and resident's interpretation \n thereof and agree with the findings." This finding is consistent with the well-documented phenomenon of redundancy in clinical notes [16,17].

Optimization Strategies and Workload Distribution

Overview

In NLP, particularly in deep learning–based NER systems such as bidirectional long short-term memory and conditional random fields, sentence length plays a pivotal role. This is because sentences are the primary units of processing in such architectures, contrasting with large language models where the context window can encompass longer text spans. Consequently, for deep learning NER, overly long or short sentences can impact the model's ability to accurately recognize and categorize entities, emphasizing the need for optimal sentence segmentation.

One significant finding of this study is the variation in processing times across different types of clinical reports, as described in Table 2. This variation indicates the complexity and diverse nature of different report types and highlights the need for tailored optimization strategies to improve efficiency. However, progress and care notes exhibited considerably higher runtime. This discrepancy suggests that progress and care notes may contain more extensive and detailed information compared to other report types, which requires greater memory allocation for processing. The observed CPU use across all 3 processing tasks, including pathology, radiology, and progress and care notes, remained relatively consistent, as depicted in Figure 2. This consistent CPU use indicates a balanced workload distribution during the processing of clinical reports. However, further optimization could be explored to ensure efficient use of computational resources and enhance overall system performance.

These findings emphasize the need for tailored optimization strategies for different report types to achieve optimal processing times and resource use. In addition, it underscores the importance of allocating sufficient memory resources, particularly for more complex report types such as progress and care notes. There are some suggestions related to optimization strategies, inlucding the following:

NoteType-Specific Preprocessing

The goal of this approach is to identify and prioritize key sections or entities within each report type to streamline the processing pipeline. Different note types varied significantly in their entity densities and sequence lengths. This variety not only

XSL•FO
RenderX

impacts processing times but also requires tailored preprocessing strategies.

Pathology and radiology notes, while generally shorter, may not necessarily contain fewer entities; rather, they tend to have a higher density of specific entities such as anatomical sites, size, and histological types, as covered in this paper. Conversely, longer progress care notes, replete with intricate details of patient care, pose a greater challenge due to their extended runtime and larger data volumes. Therefore, computational optimization strategies for these notes must account not just for the type of document but also for the specific entities targeted for extraction. Given this context, these progress notes necessitated nuanced preprocessing, including segmentation into smaller parts, to ensure efficient handling.

Therefore, the key takeaway is the need for flexible preprocessing strategies, adaptable to the specific characteristics of each note type, to ensure both efficiency and accuracy in processing diverse clinical notes.

Algorithmic Optimization

The goal of this approach is to explore and fine-tune NER models to suit the specific requirements of each note type. Different report types may have distinct patterns or structures, and optimizing the algorithms accordingly can lead to more accurate and efficient processing. This may involve leveraging domain-specific knowledge, incorporating machine learning techniques, or adopting advanced NER models to enhance performance.

Resource Allocation Optimization

It is advisable to allocate computational resources, such as memory and processing power, based on the requirements of each report type. Because different report types may have varying complexities and information densities, it is crucial to optimize resource allocation accordingly. If the progress care notes contain a greater number of tokens per sentence (ie, longer sequences), this leads to an extended runtime. In such a situation, increasing computational resources and memory allocation could prove to be an effective strategy. Alternatively, we could also consider decreasing the mini-batch size and carrying out distributed processing for each. This method could potentially mitigate the runtime bottleneck issue. Such strategies become particularly vital when these tools are implemented in real-time or near–real-time environments.

Performance of the NER Models

The implemented NER models demonstrated promising precision in identifying clinical entities, with procedures showing the highest precision. The assertion model also exhibited a high level of accuracy in categorizing the presence or absence of entities, highlighting the potential of NLP tools in processing and comprehending complex clinical data.

Recall (sensitivity) was not evaluated in this project for NER models, as it would have required a significant manual annotation effort beyond the primary objectives of the study. Pretrained NER models used in this study have been reported to achieve high F_1-scores (0.96 for disease and drug entities and 0.86 for procedure and symptom entities [8]), indicating presumably adequate recall for our research aims. Regarding the potential impact of recall on comparing entity density across different document types (eg, pathology, progress notes, and radiology), we hypothesize that recall performance is likely consistent across these document types. This consistency is expected, as the NER model was pretrained on data from a wide variety of clinical documents [9], suggesting that any recall-related misclassifications would be nondifferential across document types. Therefore, we do not anticipate that variations in recall would significantly affect our conclusions on entity density differences among document types.

Conclusions

Given the promising findings of our study, it is crucial to pursue further research in this domain. We encourage additional exploration of the application and optimization of NLP tools in clinical contexts. Future studies should consider expanding the range of clinical entities under consideration and further investigate the phenomena of redundancy and the effects of templated content within clinical notes.

Moreover, further research could analyze different types of clinical notes that were not included in our study, such as discharge summaries or psychiatric evaluation notes. Understanding the linguistic characteristics of these notes could expand the applicability of NLP tools and enhance their performance across a broader range of clinical scenarios.

In conclusion, this study provides valuable insights into the development and deployment of CDS tools using NER. The variation in processing times, memory use, and CPU use across different report types underscores the importance of tailored optimization strategies and resource allocation. These lessons contribute to the overall knowledge base for designing effective CDS tools and inform future research and development efforts in this domain.

Authors' Contributions

VK, DT, PT, AK, JB, FYC, and GR revised the manuscript for important intellectual content. AK conceived the study. FYC collected data sources and conducted modeling and experiments. FYC, JB, and VK analyzed and validated data and results. JB and AK wrote the manuscript.

Abstract

Background: Medical image analysis plays a critical role in brain tumor detection, but training deep learning models often requires large, labeled datasets, which can be time-consuming and costly. This study explores a comparative analysis of machine learning and deep learning models for brain tumor classification, focusing on whether deep learning models are necessary for small medical datasets and whether self-supervised learning can reduce annotation costs.

Objective: The primary goal is to evaluate trade-offs between traditional machine learning and deep learning, including self-supervised models under small medical image data. The secondary goal is to assess model robustness, transferability, and generalization through evaluation of unseen data within- and cross-domains.

Methods: Four models were compared: (1) support vector machine (SVM) with histogram of oriented gradients (HOG) features, (2) a convolutional neural network based on ResNet18, (3) a transformer-based model using vision transformer (ViT-B/16), and (4) a self-supervised learning approach using Simple Contrastive Learning of Visual Representations (SimCLR). These models were selected to represent diverse paradigms. SVM+HOG represents traditional feature engineering with low computational cost, ResNet18 serves as a well-established convolutional neural network with strong baseline performance, ViT-B/16 leverages self-attention to capture long-range spatial features, and SimCLR enables learning from unlabeled data, potentially reducing annotation costs. The primary dataset consisted of 2870 brain magnetic resonance images across 4 classes: glioma, meningioma, pituitary, and nontumor. All models were trained under consistent settings, including data augmentation, early stopping, and 3 independent runs using the different random seeds to account for performance variability. Performance metrics included accuracy, precision, recall, F_1-score, and convergence. To assess robustness and generalization capability, evaluation was performed on unseen test data from both the primary and cross datasets. No retraining or test augmentations were applied to the external data, thereby reflecting realistic deployment conditions. The models demonstrated consistently strong performance in both within-domain and cross-domain evaluations.

Results: The results revealed distinct trade-offs; ResNet18 achieved the highest validation accuracy (mean 99.77%, SD 0.00%) and the lowest validation loss, along with a weighted test accuracy of 99% within-domain and 95% cross-domain. SimCLR reached a mean validation accuracy of 97.29% (SD 0.86%) and achieved up to 97% weighted test accuracy within-domain and 91% cross-domain, despite requiring 2-stage training phases involving contrastive pretraining followed by linear evaluation. ViT-B/16 reached a mean validation accuracy of 97.36% (SD 0.11%), with a weighted test accuracy of 98% within-domain and 93% cross-domain. SVM+HOG maintained a competitive validation accuracy of 96.51%, with 97% within-domain test accuracy, though its accuracy dropped to 80% cross-domain.

Conclusions: The study reveals meaningful trade-offs between model complexity, annotation requirements, and deployment feasibility—critical factors for selecting models in real-world medical imaging applications.

KEYWORDS

machine learning; deep learning; self-supervised learning; computer vision; brain tumor image

Introduction

Brain tumors, characterized by the abnormal growth of brain cells, pose significant health risks and can result in severe neurological dysfunction or death if not detected early [1,2]. Timely and accurate diagnosis is essential for effective treatment and improved patient outcomes [3]. Magnetic resonance imaging (MRI) is the widely used modality for capturing high-resolution brain images. However, the manual review of hundreds of MRI scans to identify tumors is time-consuming and error-prone, posing a considerable challenge for radiologists [3]. In this context, machine learning and deep learning approaches have demonstrated promising potential in improving diagnostic accuracy and efficiency [3].

Recent studies have increasingly focused on leveraging machine learning and deep learning for medical image classification tasks, including brain tumor detection [3-5]. However, selecting the appropriate type of model for small medical image datasets remains a challenge.

To address this challenge, we conducted a comparative analysis of 2 publicly and independent available MRI brain tumor datasets; our study included 1 classical machine learning model—support vector machine (SVM) with histogram of oriented gradients (HOG) features [6,7], and 3 deep learning models—convolutional neural network (CNN) based on ResNet18 [8], a vision transformer (ViT) based on ViT-B/16 [9], and a self-supervised learning (SSL) model based on Simple Contrastive Learning of Visual Representations (SimCLR) [10]. These models were selected to represent 4 distinct paradigms in medical image classification. SVM+HOG represents traditional feature engineering approaches with low computational requirements. ResNet18, a well-established CNN, is known for its strong baseline performance in small- to medium-sized datasets. ViT-B/16 introduces global attention mechanisms capable of capturing long-range dependencies. SimCLR enables representation learning from unlabeled data, offering potential benefits in annotation-scarce clinical settings. Each type of model offers unique advantages and limitations when applied to small medical image datasets [11], making them ideal for a trade-off comparative analysis.

To assess the applicability of trade-offs in small medical image datasets, five analytical perspectives were considered: (1) training behavior and convergence [12], (2) train and validation data performance [13], (3) generalization: within- and cross-domains [14], (4) visual interpretation via saliency maps [15], and (5) real-world cost, complexity, and deployment feasibility [11,16].

This comparative study aims to provide practical insights for both machine learning researchers and health care practitioners by identifying reliable, scalable, and computationally efficient artificial intelligence (AI) solutions for medical imaging applications.

Methods

Study Overview

This study investigates the trade-offs between traditional machine learning and deep learning approaches, including SSL, for brain tumor classification. The analysis was conducted using a primary medical imaging dataset [3,11]. To evaluate robustness and generalization capabilities, the models were assessed on unseen test data under both within-domain and cross-domain scenarios, simulating real-world deployment conditions.

Dataset Description

The primary dataset used for training and validation is the Brain Tumor MRI Image Dataset (T1-weighted, 2D), an open-source resource hosted on Figshare [17]. It comprises a total of 2870 magnetic resonance images, categorized into 4 subsets: glioma (826 images), meningioma (822 images), pituitary (827 images), and no tumor (395 images).

To assess cross-domain generalization, we used a cross dataset of brain tumor magnetic resonance images (T1-weighted, 2D) compiled from multiple publicly available repositories, including Kaggle and Roboflow [18]. While the original dataset contains a mixture of computed tomography and MRI scans, only the MRI subset was retained for evaluation in this study. This cross dataset introduced natural domain shifts due to variations in image size, patient demographics, and file formats (eg, JPG and JPEG), thereby providing a realistic benchmark for evaluating generalization performance.

Data Processing

The primary image dataset was partitioned into training, validation, and test sets. Within each partition, images were further organized into “tumor” and “no tumor” categories. Tumor (2475 images) was split into training, validation, and test datasets in a 70:15:15 ratio, while no tumor (395 images) was split using the same proportion.

The cross dataset was originally organized into “healthy” and “tumor” folders; these were relabeled as “no tumor” and “tumor,” respectively, to maintain consistency with the structure of the primary dataset. To prevent data leakage and ensure unbiased evaluation of generalization performance, the phash algorithm [19] was applied to compare each cross-dataset image with the training images; any visually identical or nearly identical images were removed from the cross dataset. After duplication, 3351 cross-dataset magnetic resonance images remained, including 2123 tumor and 1228 no tumor. All images were mapped to binary labels: 1 for “tumor” and 0 for “no tumor” cross dataset.

Model Designing

Support Vector Machine + Histogram of Oriented Gradients

We applied an SVM classifier in combination with HOG feature extraction to classify brain tumor images. HOG was used to extract edge and shape information by analyzing the distribution of gradient orientations across localized regions of the image [6]. Because HOG effectively captures fine-grained structural patterns, it is particularly suitable for identifying tumor boundaries, which exhibit strong and localized gradient variations.

Following HOG-based feature extraction, the resulting feature vectors were fed into an SVM, a supervised learning algorithm widely recognized for its effectiveness in binary classification tasks [20]. In this study, we used a linear kernel since tumor and nontumor images exhibit distinct and approximately linearly separable gradient patterns in the HOG feature space [7].

Convolutional Neural Network (ResNet18)

A CNN based on ResNet18 was applied for brain tumor image classification. ResNet18 is a widely used deep learning architecture that integrates residual learning to mitigate the vanishing gradient problem [8]. It comprises 17 convolutional layers followed by a fully connected classification layer. Compared to traditional CNN models, the key advantage of ResNet18 lies in its use of 4 residual blocks, each consisting of 2 convolutional layers combined with batch normalization and rectified linear unit activation. Residual connections directly add the input of a block to its output, enabling the network to learn residual mappings and maintain a strong gradient flow during backpropagation [8,12] and mitigating the vanishing gradient issue. This feature makes ResNet18 particularly suitable for complex medical image tasks [21].

The residual block follows the logic: $y=F(x)+x$, where $F(x)$ represents the convolutional transformation applied to the input x. The term x is passed directly to the next layer through a skip connection, allowing the network to learn residual mappings and maintain effective gradient flow.

To improve model generalization and mitigate overfitting, data augmentation techniques were applied during the training process [22]. These argumentations included random affine transformations with shear up to ±5 degrees, random scaling between 95% and 105%, and small random rotation up to ±3 degrees. In addition, 50% (n=866) of images were randomly flipped horizontally and 30% (n=520) vertically, and a Gaussian blur was applied using a kernel size of 3 with a sigma value randomly selected from the range 0.1 to 1.0. Furthermore, the images were resized on the shortest side to 224 pixels, followed by a center crop to ensure a consistent input size of 224×224. Finally, the images were converted to a tensor and normalized to pixel intensity values, using a mean of 0.5 (SD 0.5).

The validation data were preprocessed with minimal transformations, including resizing, center cropping, tensor conversion, and normalization with the same parameters. For fine-tuning, all pretrained layers except the last 3 residual blocks and the fully connected layer were frozen; these 4 layers were fine-tuned to adapt to the binary classification task. The fully connected layer was modified with randomly incorporating a 40% dropout rate, followed by a linear layer with 2 outputs corresponding to the tumor and no-tumor classes.

Vision Transformer (Vit-B/16)

ViT models are widely used in computer vision by leveraging self-attention mechanisms to capture long-range dependencies across an entire image [9]. Unlike CNNs, which learn hierarchical feature representations via local receptive fields, ViTs partition an image into nonoverlapping patches and process them as flattened tokens [9]. Those tokens are then passed through multiple transformer encoder layers, where multihead self-attention models both local and global relationships within the image.

In this study, we fine-tuned ViT-B/16 model by unfreezing the last 5 transformer encoder layers along with the classification head to better capture the complex long-range dependencies. ViT-B/16 comprises 12 self-attention heads with a hidden dimension of 768 [9]. Within each encoder layer, the feed-forward network includes 2 fully connected layers with Gaussian error linear unit activations, expanding the hidden dimension from 768 to 3072 before projecting it back to 768 [23].

Self-Supervised Learning (SimCLR)

SSL enables models to learn robust feature representations directly from unlabeled data. In this study, we applied SimCLR, which learns meaningful feature representations by maximizing agreement between different augmented views of the same image (positive pairs) while minimizing similarity between views of different images (negative pairs) through a contrastive loss in the latent space [10]. This approach enables the encoder to extract invariant and discriminative features, which are subsequently leveraged for downstream classification tasks [24].

During the pretrained phase, we applied various augmentations to generate 2 augmented views of the same image, denoted as x_i and x_j. These augmented images were then passed through a ResNet18-based encoder to extract feature representations. The embeddings were mapped into a lower-dimensional space using a projection head, which minimized the distance between the positive pairs, x_i and x_j, while maximizing the similarity from all other views using contrastive loss (normalized temperature-scaled cross entropy loss) [25].

Following pretraining, we performed a linear evaluation: the encoder was frozen, and a fully connected linear layer classifier was trained on top using supervised labels to evaluate the learned representations.

Model Training

Support Vector Machine + Histogram of Oriented Gradients

The SVM+HOG model was trained and validated over 3 independent runs using different random seeds to ensure robustness. For each run, the training and validation datasets were first loaded and shuffled, and then, HOG was applied to each image after resizing to 128×128 pixels. The images were

XSL•FO
RenderX

divided into small cells with 16×16 pixels, and a histogram of gradient orientations was computed per cell. Histograms were normalized across blocks with 2×2 cells to improve contrast robustness [6]. The resulting HOG feature vector was flattened into a 1D array with a length of 1764 features (f_1, f_2, ... f_{1764}), representing the gradient information distribution captured from different parts of the image, preserving local shape information. No channel conversion was needed, as these tumor images were in grayscale format.

A support vector classifier from scikit-learn was used, with the default regularization parameters (C=1.0) and hinge loss [26]. Performance was evaluated on a validation dataset after each run. The training process was repeated across 3 independent runs, and accuracy was recorded for each run. The model with the highest validation accuracy across the 3 runs was selected and saved for testing.

Convolutional Neural Network (ResNet18)

The ResNet18 model was trained using Adam optimizer with a learning rate of 1×10^{-4} and a weight decay of 1×10^{-5}; the classification task was optimized using a cross-entropy loss function, with labeling smoothing set to 0.05 [27,28]. To dynamically adjust the learning rate, a ReduceLROnPlateau scheduler was applied, which reduced the learning rate by a factor of 0.5 if the validation loss failed to improve over 3 consecutive epochs [29]. To prevent overfitting, early stopping was used: training terminated if validation loss failed to improve by at least 0.001 over 4 consecutive epochs. The model was trained for up to 35 epochs with a batch size of 32.

Model performance was monitored at each epoch, and the best-performing checkpoint based on the lowest validation loss from each run was saved. To ensure robustness and reproducibility, training was repeated across 3 independent runs with different random seeds. The results were reported as the mean and SD of accuracy and loss across the best-performance models from each run. After completing all 3 runs, the model with the best validation loss across runs was selected for evaluation on the unseen test data.

Vision Transformer (Vit-B/16)

For the ViT-B/16 model, we adopted the same data augmentation strategy used for ResNet18 to maintain experimental consistency. Due to ViT-B/16's higher parameter count, the learning rate was increased to 3×10^{-4} to accelerate convergence [9]. The CosineAnnealing scheduler was used instead of ReduceLROnPlateau to achieve smoother decay, which is typically advantageous for transformer architectures [30]. The model was trained for up to 50 epochs, with early stopping patience set to 6 and batch size set to 32. Training was repeated 3 times with different seeds. The best checkpoint per run based on validation loss was saved, and the overall best-performing model was selected for testing.

Self-Supervised Learning (SimCLR)

SimCLR was pretrained to learn image representations using contrastive learning [10]. The ResNet18-based encoder produced a 512-dimensional embedding vector, which was then passed through a projection head consisting of 2 linear layers and rectified linear unit activation, reducing the vector to 128 dimensions. Pretraining used Adam optimizer, learning rate 1×10^{-4}, weight decay 1×10^{-5}, a batch size of 128, and up to 200 epochs. The Data Loader was configured with num_works equal to 4 to parallelize data loading and accelerated training. A ReduceLROnPlateau scheduler and early stopping were used [29]. After pretraining, the encoder was frozen, and a linear classifier was trained for 50 epochs with a batch size of 32. Training was repeated 3 times with different seeds, and the best checkpoint per run was saved. The overall best-performing model across runs was used for evaluation on the unseen test dataset.

Model Evaluation

To ensure a fair and reproducible comparison across all models, we evaluated their performance from 5 perspectives: training behavior and convergence, training and validation data performance, generalization: within- and cross-domains, visual interpretation via saliency maps, and real-world cost, complexity, and deployment feasibility.

For training behavior and convergence, we monitored epoch-wise training and validation accuracy and loss. Because early stopping caused different runs to terminate at varying epochs, shorter training runs were padded to match the maximum number of epochs while excluding padded values from the statistics. This approach enabled a consistent assessment of convergence stability across models.

For training and validation data performance, we compared training and validation accuracy, training and validation loss, and training time across models on the primary dataset. Accuracy and loss were computed on both the training and validation sets to assess potential overfitting and robustness. Training time was also recorded to evaluate computational efficiency. Furthermore, classification performance on the validation data was assessed using precision, recall, F_1-score, and support for each class (tumor and nontumor), along with macro and weighted averages and overall accuracy.

For generalization within- and cross-domains, we assessed classification performance and confusion matrices on the unseen test datasets from both the primary and cross-domains. To better simulate real-world conditions, no test-time augmentations or artificial noise were applied during evaluation. To ensure reproducibility of the test-time results, all random seeds were fixed to 42 at the start of each model evaluation. Each model was evaluated using the best-performing weights obtained during training.

For visual interpretation via saliency maps, we examined model interpretability and generalization by visualizing the regions of the input images that most influenced classification decision. Saliency maps were generated for the same tumor and nontumor images from the primary dataset across all 4 models to ensure consistency in comparison. Similarly, 1 tumor and nontumor image from the cross dataset were used to examine how each model attended to relevant features across models.

Finally, for real-world cost, complexity, and deployment feasibility, we assessed each model's computational resource

XSL•FO
RenderX

requirements, training and inference efficiency, and practicality for integration into real-world clinical workflows.

Ethical Considerations

This study did not involve human or animal participants. Institutional review board approval, informed consent, data confidentiality, and participant compensation were not applicable.

Results

Training Behavior and Convergence

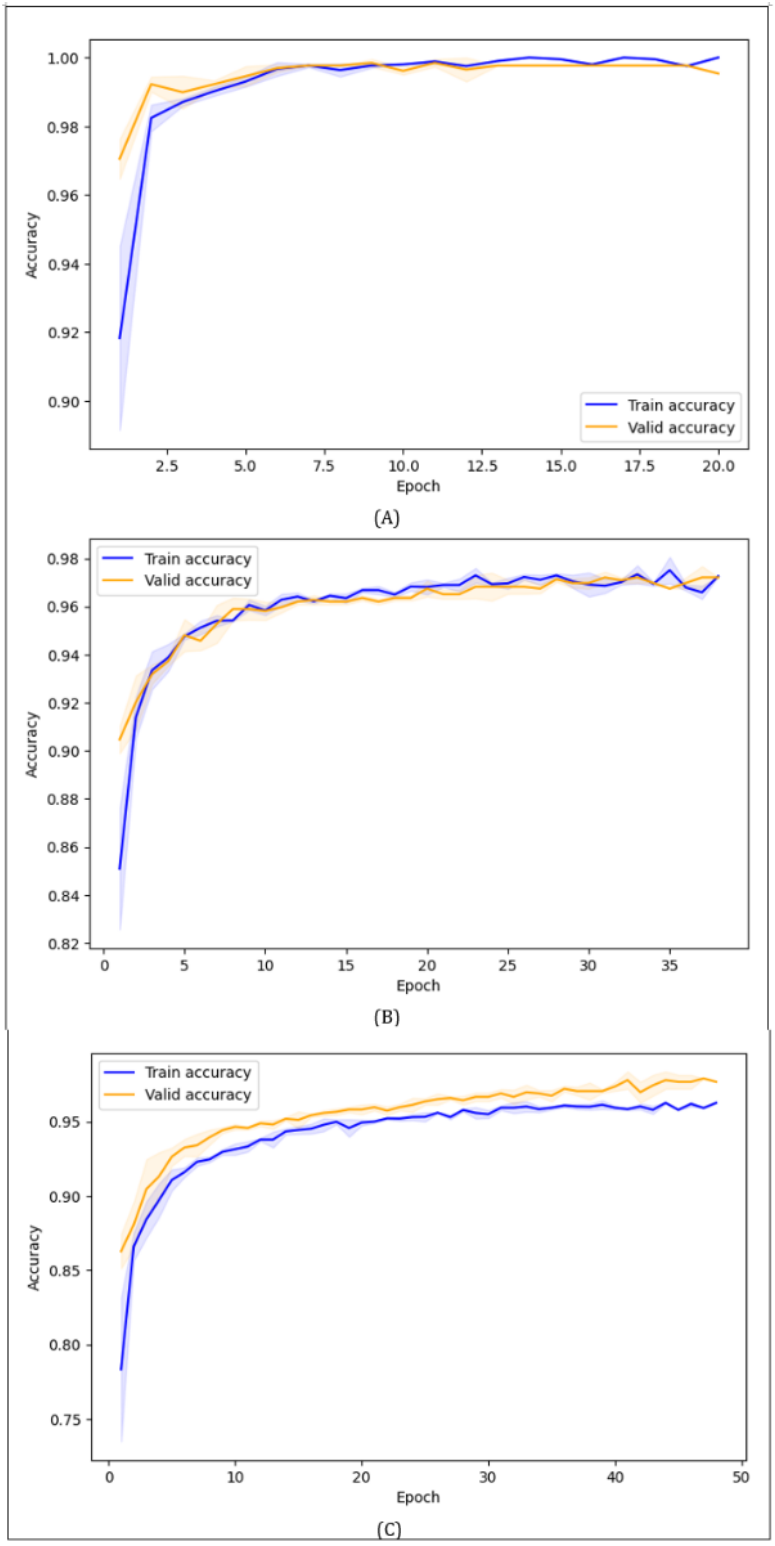

Figure 1 shows the training and validation accuracy across epochs for (A) ResNet18, (B) ViT-B/16, and (C) SimCLR, while Figure 2 presents the corresponding training and validation loss curves. Across the deep learning models, training and validation accuracy increased steadily during early epochs and gradually plateaued toward the later stages of training. Additionally, the training and validation curves remained closely aligned, with only small fluctuations, indicating stable learning progress. Similarly, training and validation loss decreased consistently over time, with validation loss typically remaining slightly lower or close to training loss. These trends demonstrated that ResNet18, ViT-B/16, and SimCLR achieved stable convergence without significantly overfitting or underfitting. The SVM+HOG does not have an epoch-based training process; hence, no convergence curve was shown.

Additionally, due to early stopping, different runs of the same deep learning models terminated at varying epochs, and the maximum number of training epochs observed across the 3 runs was 20 for ResNet18, 38 for ViT-B/16, and 48 for SimCLR.

Notably, across all deep learning models, training accuracy was slightly lower than validation accuracy, and training loss was slightly higher or close to the validation loss. This was due to the use of data augmentation during training, which introduced random transformations such as cropping, flipping, and Gaussian blur to improve generalization. These argumentations made the training more challenging, whereas validation data remained nonaugmented, leading to relatively easier and more consistent predictions.

Training and Validation Data Performance

Table 1 summarizes the training and validation performance across 4 models. Among deep learning models, ResNet18 achieved the highest validation accuracy (mean 99.77%, SD 0.00%) with the lowest validation loss (mean 12.58%, SD 0.21%), demonstrated strong convergence and stability. ViT-B/16 and SimCLR also performed well, achieving mean validation accuracies of 97.36% (SD 11%) and 97.29% (SD 86%), respectively, though their slightly higher training and validation losses indicated slower convergence compared to ResNet18. For the classical model SVM+HOG, mean validation accuracy reached 96.51% (SD 0.00), indicating no overfitting or underfitting.

XSL•FO
RenderX

Table 1. Training and validation performance comparison across 4 models.

Model	Training time (seconds)	Training accuracy (%), mean (SD)	Validation accuracy (%), mean (SD)	Training loss (%), mean (SD)	Validation loss (%), mean (SD)
SVM[a]+HOG[b]	78	—[c]	96.51 (0.00)	—	—
ResNet18	529	99.80 (0.08)	99.77 (0.00)	13.25 (0.19)	12.58 (0.21)
ViT-B/16[d]	2014	97.05 (0.46)	97.36 (0.11)	19.12 (0.43)	17.97 (0.21)
SimCLR[e]	2923	96.02 (0.22)	97.29 (0.86)	20.49 (0.38)	17.84 (0.28)

[a]SVM: support vector machine.

[b]HOG: histogram of oriented gradients.

[c]Not available.

[d]ViT: vision transformer.

[e]SimCLR: Simple Contrastive Learning of Visual Representations.

Regarding computational efficiency, SimCLR required the longest training time (2817 seconds), due to its self-supervised pretraining and linear evaluation phases, followed by ViT-B/16 (912 seconds) and ResNet18 (474 seconds), while SVM+HOG trained extremely fast (75 seconds) but lacked fine-tuning capabilities. We used an NVIDIA RTX A6000 graphics processing unit (GPU) during training, so the runtime may vary depending on the reviewer's GPU or central processing unit setup and use, despite consistent code and hyperparameters.

Detailed visual comparisons of training and validation accuracy, loss, and training time charts are provided in Multimedia Appendix 1. In the figure, the top bar chart shows training and validation accuracy across models, the middle bar chart shows the training and validation loss across models, and the bottom bar chart shows training time comparison across models.

Table 2 summarizes the validation classification table, showing strong and consistent performance across all 4 models. Because the primary brain tumor dataset was imbalanced, with 59 no tumor samples and 371 tumor samples, we focused on weighted average metrics, including precision, recall, and F_1-score, which accounted for class imbalance by weighting results based on class size.

Table 2. Comparison of classification performance on the validation data.

Model	Precision (weighted average)	Recall (weighted average)	F_1-score (weighted average)	Overall accuracy
SVM[a]+HOG[b]	0.96	0.97	0.96	0.97
ResNet18	1.00	1.00	1.00	1.00
ViT-B/16[c]	0.97	0.97	0.97	0.97
SimCLR[d]	0.98	0.98	0.98	0.98

[a]SVM: support vector machine.

[b]HOG: histogram of oriented gradients.

[c]ViT: vision transformer.

[d]SimCLR: Simple Contrastive Learning of Visual Representations.

ResNet18 achieved the highest overall performance, with 100% accuracy, 100% weighted precision, 100% weighted recall, and 100% weighted F_1-score. SimCLR, ViT-B/16, and SVM+HOG also demonstrated strong performance, with weighted F_1-scores ranging from 96% to 98%, precision between 96% and 98%, and recall between 97% and 98%. These results demonstrated strong discriminative ability across models on the validation data and established a solid baseline for subsequent evaluations on unseen test data within- and cross-domains.

For detailed classification table reports for all models on the primary domain validation sets, please refer to Multimedia Appendix 2. The figure presents classification metrics including precision, recall, F_1-score, and support for each class (tumor and nontumor) across 4 models, along with macro and weighted averages and overall accuracy. ResNet18 achieved perfect classification performance, while ViT-B/16 and SimCLR showed similarly high results. SVM+HOG showed slightly lower performance, especially in recall for the nontumor class.

Generalization: Within- and Cross-Domains

Table 3 summarizes the comparison of classification performance on the unseen test data within- and cross-domains, demonstrating the strong and consistent performance across all models for both primary and cross datasets.

XSL•FO
RenderX

Table 3. Comparison of classification performance on the test data within- and cross-domains.

Model and dataset	Precision (weighted average)	Recall (weighted average)	F_1-score (weighted average)	Overall accuracy
SVM[a]+HOG[b]				
Primary	0.97	0.97	0.97	0.97
Cross dataset	0.80	0.80	0.80	0.80
ResNet18				
Primary	0.99	0.99	0.99	0.99
Cross dataset	0.96	0.95	0.95	0.95
ViT-B/16[c]				
Primary	0.98	0.98	0.98	0.98
Cross dataset	0.93	0.93	0.93	0.93
SimCLR[d]				
Primary	0.97	0.97	0.97	0.97
Cross dataset	0.92	0.91	0.91	0.91

[a]SVM: support vector machine.

[b]HOG: histogram of oriented gradients.

[c]ViT: vision transformer.

[d]SimCLR: Simple Contrastive Learning of Visual Representations.

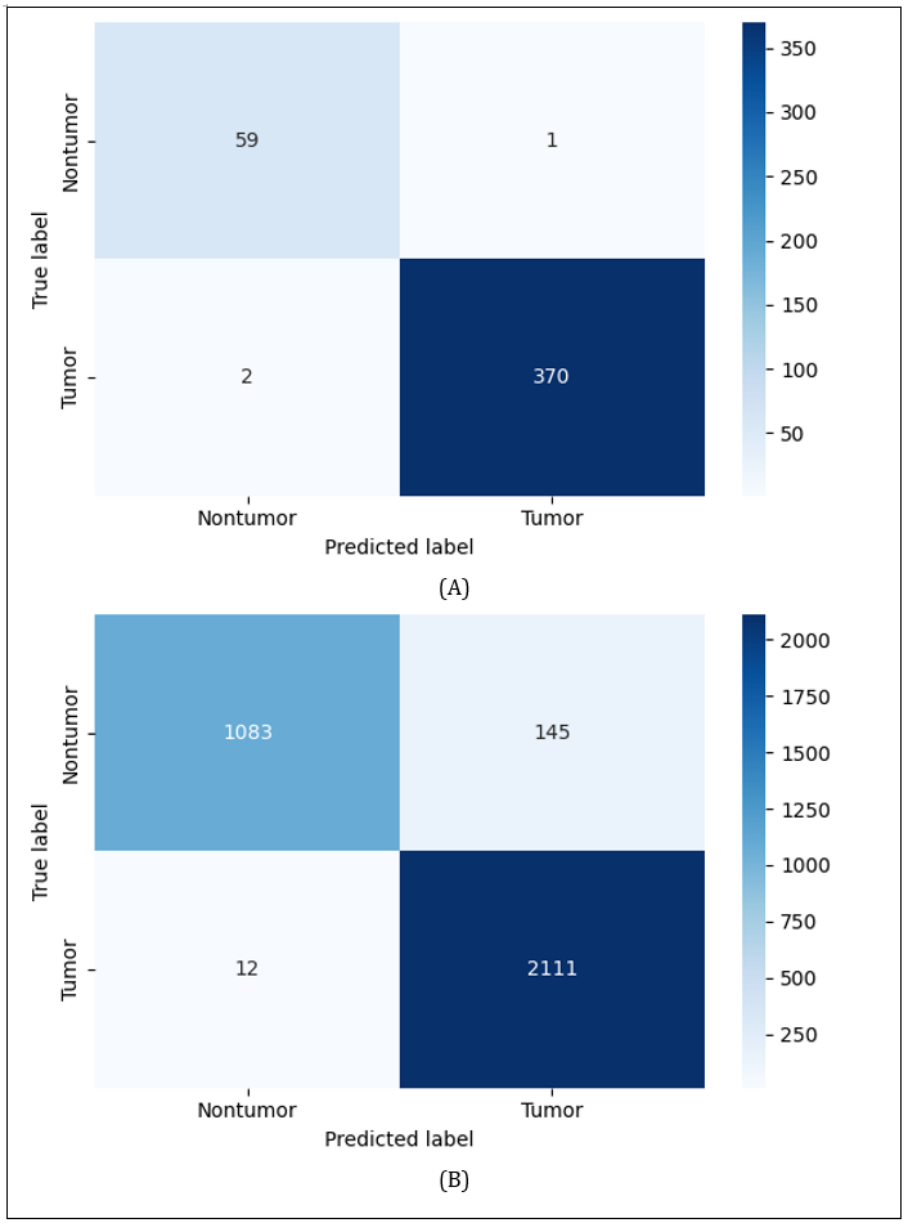
Both test data have imbalanced class distributions, including 60 nontumor and 372 tumor cases in the primary dataset and 1228 nontumor and 2123 tumor cases in the cross dataset. We applied weighted average metrics to evaluate the performance of the classification results. Across both datasets, ResNet18 consistently outperformed the other models, achieving the highest overall accuracy of 99%, along with the best weighted precision, recall, and F_1-score on the primary dataset. On the cross dataset, these metrics slightly dropped to 95%. ViT-B/16 dropped from 98% within-domain to 93% cross-domain, and SimCLR dropped from 97% to 91%.

In contrast, SVM+HOG showed a sharp performance drop, with overall accuracy, precision, recall, and F_1-score decreasing from 97% on the primary dataset to 80% on the cross dataset. This decline indicated SVM+HOG's limited ability to generalize to new domains, likely due to its reliance on hand-crafted features rather than deep learning representations.

Notably, the models' training behavior showed no signs of overfitting or underfitting as observed in Figures 1 and 2, indicating that the performance dropped not due to poor generalization during the training process but rather due to domain shift, including differences in patient demographics, imaging conditions, and equipment between the primary and cross datasets. Overall, ResNet18, ViT-B/16, and SimCLR maintained strong performance, demonstrating robust generalization within- and cross-domains, whereas SVM+HOG showed limited generalization under domain shift.

The detailed classification table reports for all models on the primary domain test sets and the cross-domain test sets are present in Multimedia Appendices 3 and 4, respectively.

Multimedia Appendix 3 represents classification metrics including precision, recall, F_1-score, and support for each class (tumor and nontumor) on the test set across 4 models, along with macro and weighted averages and overall accuracy on the primary domain. ResNet18 also achieved the highest metrics overall, with 99% overall accuracy. ViT-B/16 followed closely, with a weighted average of 98% across precision, recall, and F_1-score. SVM+HOG also performed well in the test data, with an overall accuracy of 97%, but slightly dropped on precision and F_1-score of the nontumor class. SimCLR achieved a weighted average of 97% across metrics, still indicating strong performance on the primary dataset.



Multimedia Appendix 4 represents classification metrics including precision, recall, F_1-score, and support for each class (tumor and nontumor) across 4 models, along with macro and weighted averages and overall accuracy on the cross-domain. ResNet18 remained the best performer, achieving a weighted precision, recall, and F_1-score of 96% and an overall accuracy of 95%. ViT-B/16 followed with a weighted average of 93% for all metrics. SimCLR showed a moderate drop. SVM+HOG, with all weighted metrics, dropped to 80%, especially the lower recall on the nontumor class with 64%. These results indicated the strong robustness of deep learning models.

Figure 3 shows the confusion matrices of the ResNet18 evaluation on test sets from both the (A) primary domain and (B) cross-domain. On the primary domain, ResNet18 achieved highly reliable predictions, correctly identifying 370 tumors and 59 nontumors, with only 3 misclassified samples. However, on the cross dataset, the number of false positive cases increased sharply to 145 nontumor images that were incorrectly predicted as tumor images, while false negative cases remained low, with 12 tumor images being mis-predicted as nontumor images. This discrepancy may reflect shifts in data distribution that the cross dataset was not exposed during the training and validation process, and the model was trained and validated only on the

XSL•FO
RenderX

primary dataset. Therefore, the cross dataset may contain different imaging conditions, such as brightness, noise level, and patient demographics, which can affect the appearance of nontumor brain structures and could cause nontumor images to be overdiagnosed as tumor images, even though the model's training behavior showed no signs of overfitting or underfitting.

Figure 3. The confusion matrices of the ResNet18 evaluation on the unseen test set from the (A) primary domain and (B) cross-domain.

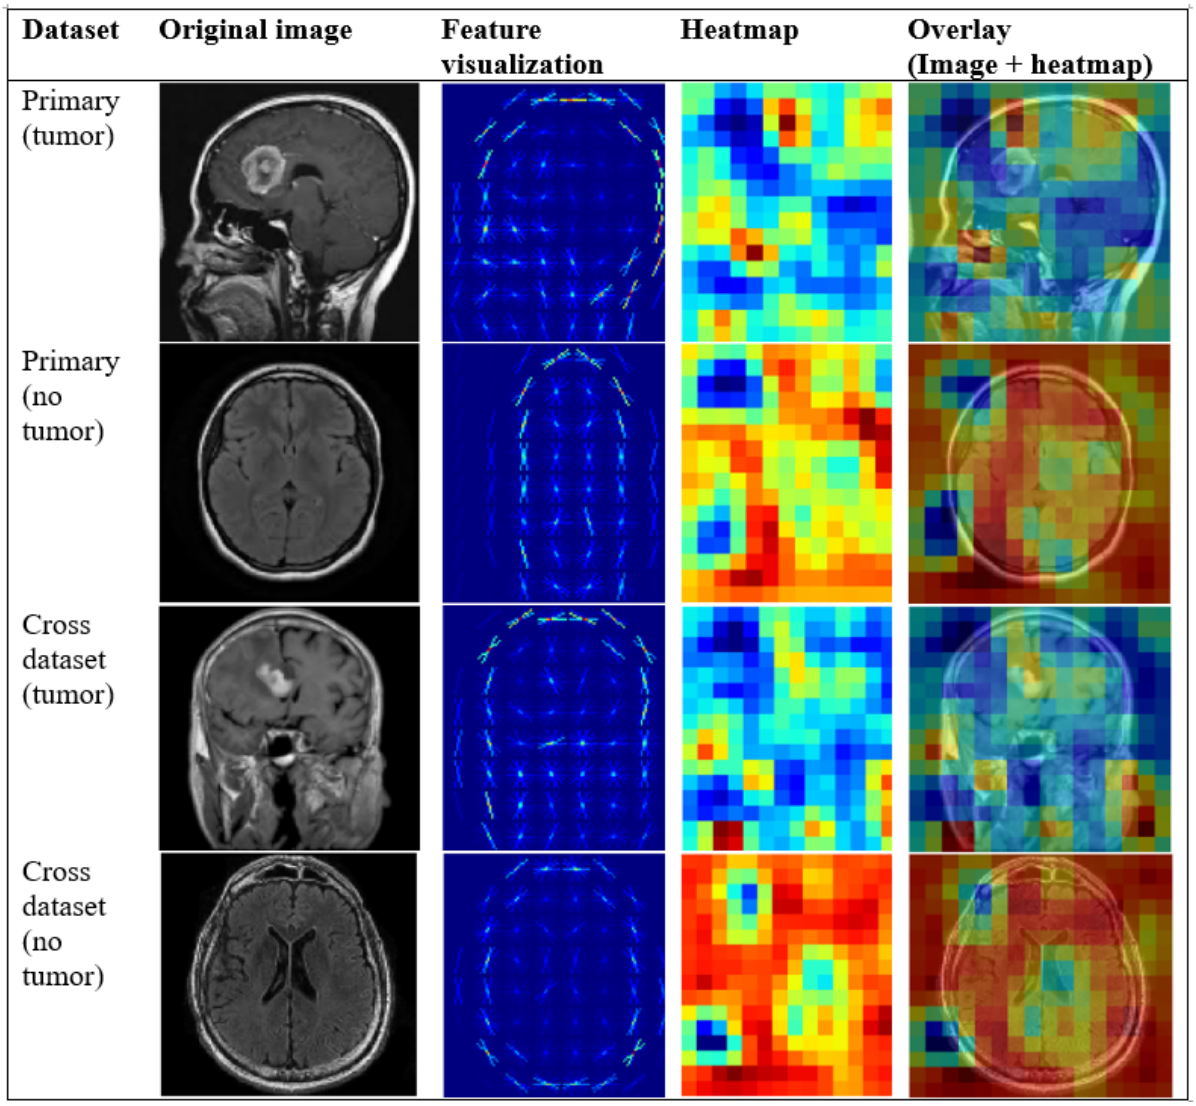
To conserve space and avoid redundancy, we presented only the confusion matrices on unseen test data of the best performing on ResNet18 across both the primary and cross datasets in the main text, while other confusion matrices for other models are presented in Multimedia Appendix 5 (SVM+HOG), Multimedia Appendix 6 (ViT-B/16), and Multimedia Appendix 7 (SimCLR).

Multimedia Appendix 5 presents the confusion matrices of the SVM+HOG model evaluated on unseen test data from the (A) primary and (B) cross datasets. On the primary dataset, the model correctly classified 54 nontumors and 365 tumor images, achieving good performance. However, its generalization cross-domains was limited, and on the cross dataset, performance dropped to 80% overall accuracy, and the number of false positives increased to 436 and false negatives increased to 226. This indicated that SVM+HOG performed well within the primary domain but more sensitive to domain shift compared to deep learning models, likely due to its reliance on hand-crafted features.

Multimedia Appendix 6 presents the confusion matrices of the ViT-B/16 model evaluated on unseen test data from the (A) primary and (B) cross datasets. ViT-B/16 achieved strong classification performance on both the primary and cross datasets, though some domain shift was observed. The primary dataset performed well with minimal false counts, and on the cross dataset, the performance slightly dropped, with an overall high accuracy of 93%, while the output retained high sensitivity tumor detection. The increase in false positives indicated some sensitivity to domain shift. Generally, ViT-B/16 generalized reasonably well cross-domain.

XSL•FO
RenderX

Multimedia Appendix 7 presents the confusion matrices of the SimCLR model evaluated on unseen test data from the (A) primary and (B) cross datasets. SimCLR showed solid classification performance on the primary and cross datasets. However, on the cross dataset, the number of false positives increased and indicated that SimCLR's generalization ability is more sensitive to domain shifts compared to other deep learning models.



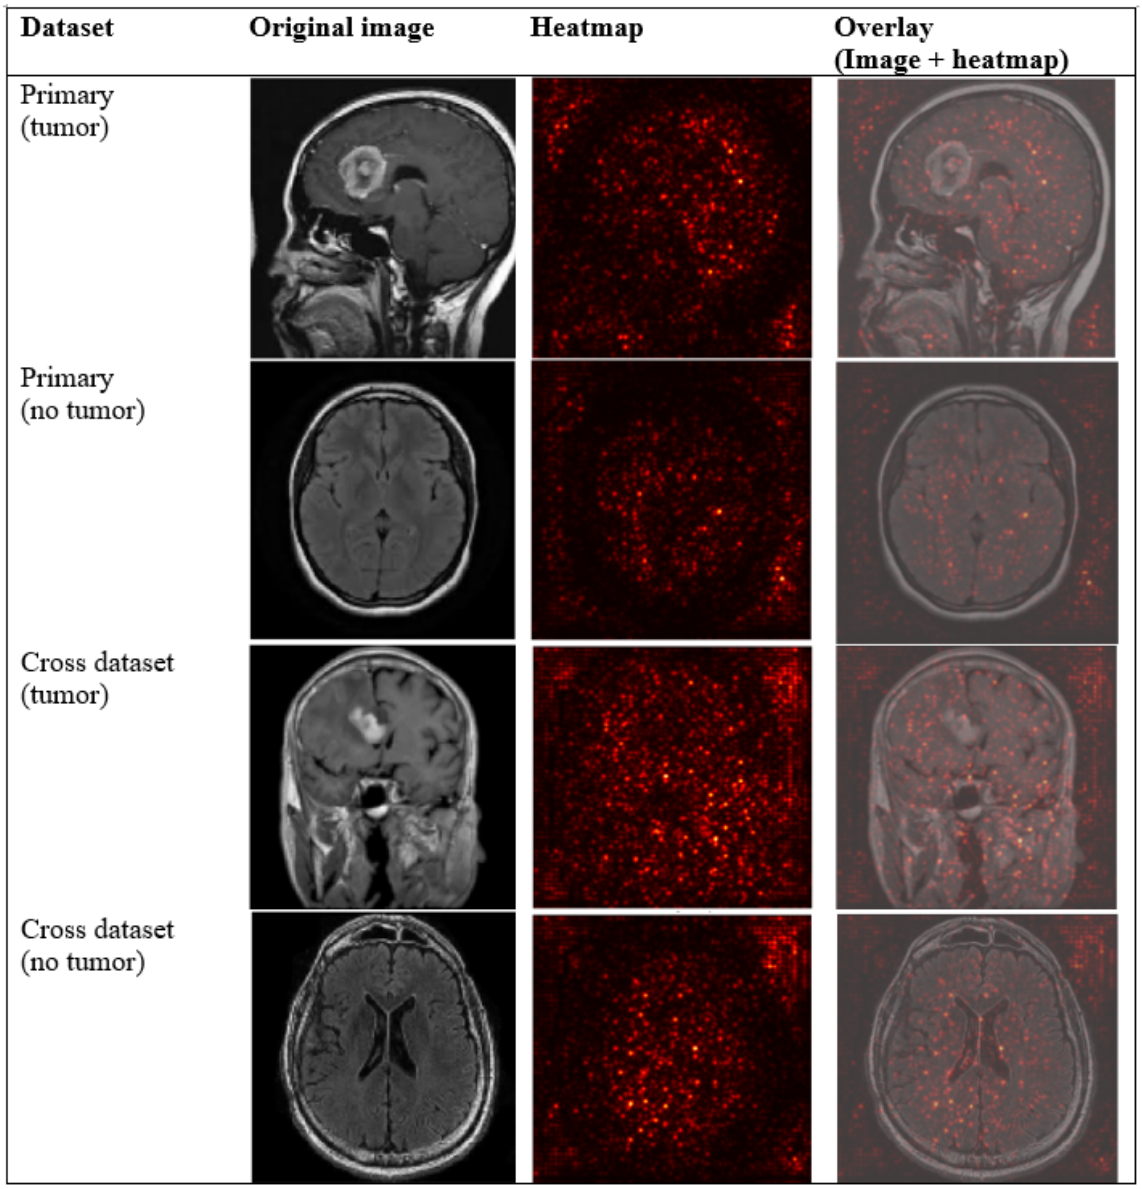
Visual Interpretation via Saliency Maps

To better understand how each model identifies tumor-related feature, we applied visual interpretation techniques on selected images from both the primary and cross datasets. Saliency maps were generated to highlight regions that are most influential to model predictions. As SVM+HOG is a nondifferentiable model, we did not apply gradient-based saliency map [15], as we used for ResNet18 and SimCLR models, or attention rollout [31], as we used for ViT-B/16 model. Instead, we applied occlusion sensitivity [14] analysis for generating saliency maps on both tumor and nontumor images.

On the primary dataset, we selected 1 tumor image "m1 (160).jpg" and 1 nontumor image "image (28).jpg." On the cross dataset, we chose 1 tumor image "tumor (49).jpg" and 1 nontumor image "mri_healthy (1853).jpg." These 4 images were unseen test images, and their predicted labels match the true labels.

Figure 4 shows the visualization of SVM+HOG model features and occlusion sensitivity maps. We applied occlusion sensitivity [14] analysis to occlude patches of the input image to evaluate the drop in the SVM's prediction probability, indicating the importance of each region for the classification prediction. In the overlay image, localized red or yellow regions indicated high sensitivity, which means occluding these regions significantly reduced the predicted probability of the tumor class. Blue and green regions indicated low sensitivity, which means occluding these regions had little or no impact on the model's prediction.

Figure 4. Visualization of SVM+HOG model features and occlusion sensitivity maps. Each row showed an example from the primary or cross dataset, categorized by tumor or nontumor class. The four columns displayed (1) the original magnetic resonance image, (2) the featural visualization, (3) the computed heatmap, and (4) the overlay of the heatmap on the original image. HOG: histogram of oriented gradients; SVM: support vector machine.



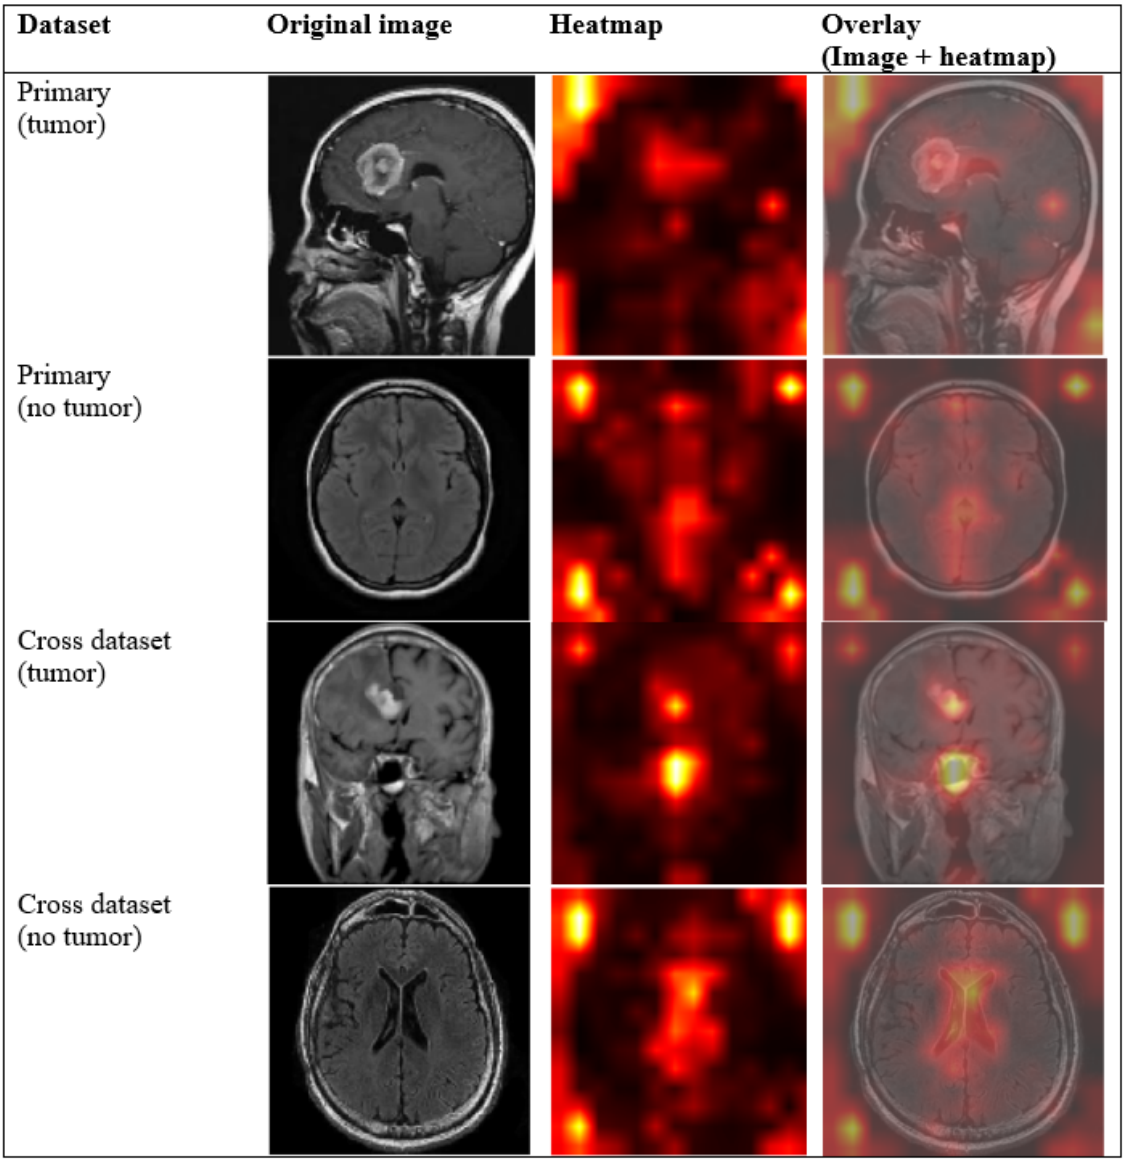
XSL•FO
RenderX

For the tumor in the overlay image, on the primary dataset, we observed bright activations inside the brain area on the top left range, which partially coincided with visible anomalies in the original image. However, we also observed activations along the skull and outside of the brain area, which are unlikely to have clinical meaning and may reflect spurious features learned from the noise. On the cross dataset, we observed that there were localized bright spots in the top middle region inside of brain, indicating that the model may have partially identified a relevant region; however, there was still considerable noise presented along the skull and outside the brain part. Given the simplicity and limits of SVM+HOG features, such alignments may not be accurate and reliable.

For the nontumor images, both on the primary and cross datasets, the red or yellow regions were dispersed across the images, indicating that the model is less confident and possibly focusing on nondiagnostic features.

Figure 5 shows the gradient-based saliency maps for ResNet18 [15]. This method calculated the gradient of the model's output score with respect to each input pixel, allowing us to identify regions that most influence the prediction. This approach aligns with the underlying mechanism of CNNs, which learns hierarchical feature representations through differential layers. In the saliency map, bright red areas indicate regions where small pixel changes impact the model's prediction.

Figure 5. Gradient-based saliency maps for ResNet18 model. Each row showed an example from the primary or cross dataset, categorized by tumor or nontumor class. The three columns displayed (1) the original magnetic resonance image, (2) the computed heatmap, and (3) the overlay of the heatmap on the original image.

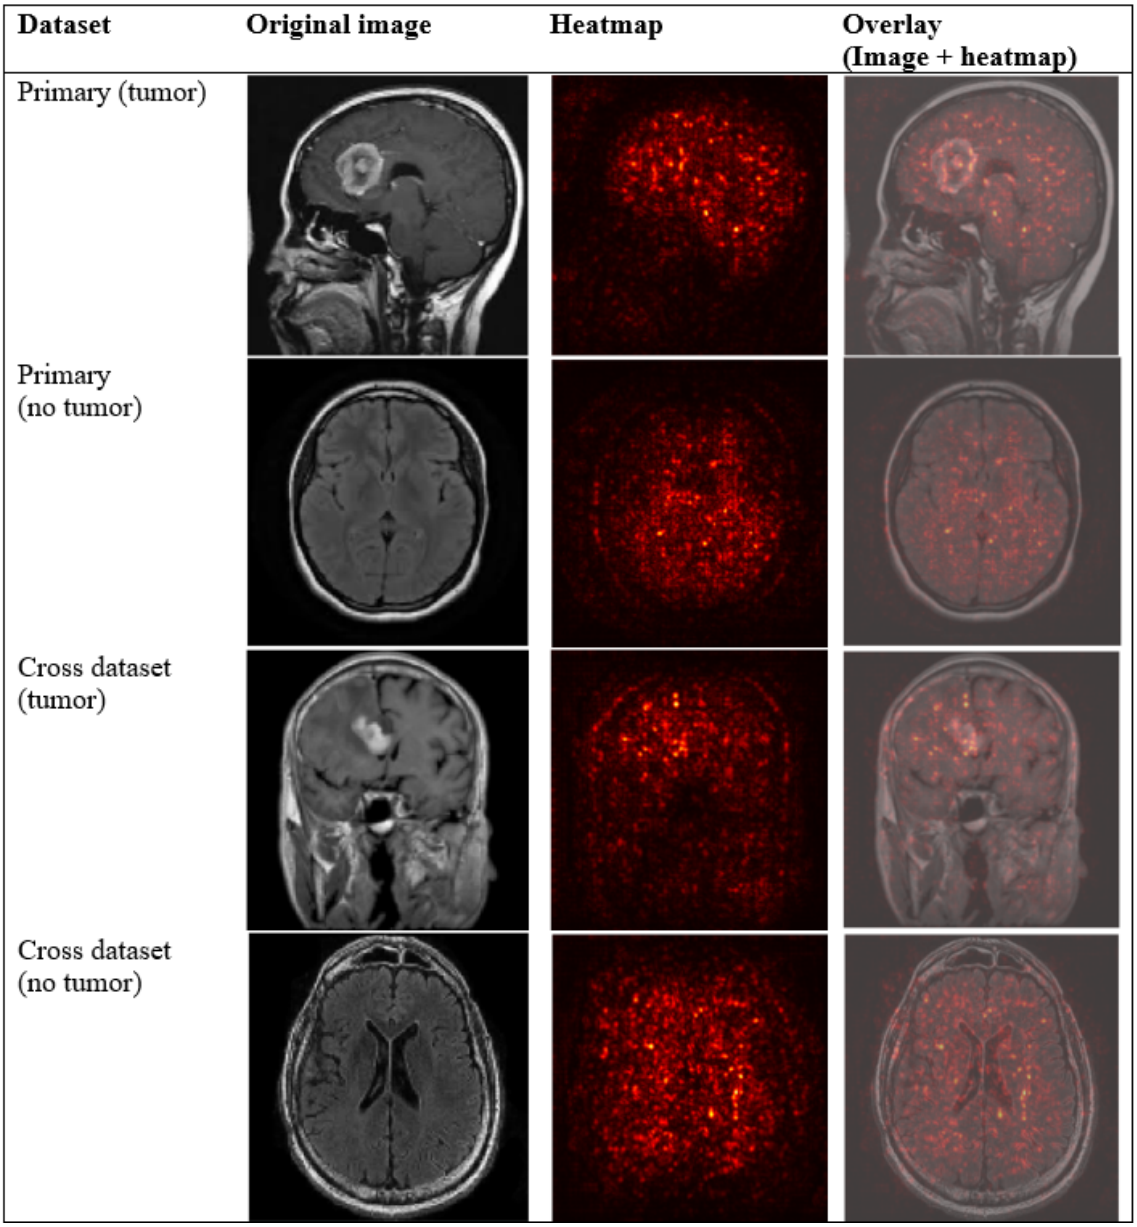


Notably, the gradient-based saliency maps do not directly identify tumor locations but instead highlight regions that are influential to the prediction. In the primary tumor image, we observed localized red regions on the back side of the brain; however, the anomalous region was more likely located at the front side of the brain based on the original image. Additionally, in the external brain tumor, the red regions were less localized and less prominent. For both nontumor images, the red activations were sparse and not strongly localized.

XSL•FO
RenderX

Figure 6 shows attention-rollout [31] saliency maps to the ViT-B/16 model. This method aggregates attention weights across all transformer layers, representing how information flows through the network by propagating attention scores recursively. Specifically, it multiplies the attention matrices from different layers, effectively rolling out the attention signal to show which patches most influence the model classification prediction.

Figure 6. Attention-rollout saliency maps for ViT-B/16 model. Each row showed an example from the primary or cross dataset, categorized by tumor or nontumor class. The three columns displayed (1) the original magnetic resonance image, (2) the computed heatmap, and (3) the overlay of the heatmap on the original image. ViT: vision transformer.



In the primary tumor image, red patches were concentrated in the front region of the brain, which well aligned with the visible anomaly in the original image, indicating that the model accurately identified the tumor location. In the external tumor image, the model also highlighted the central bright patches inside the brain, overlapping with the visible tumor, indicating a reasonable prediction. For both nontumor images, the patches were more diffusely spread, with no dominant hotspots; however, in the external nontumor image, slight attention near the ventricle area may reflect mild overattention to anatomical structure.

Compared to Figure 5 (ResNet18), the heatmaps from Figure 6 (ViT-B/16) appeared smoother and more globally distributed, reflecting the global attention mechanism to transformer models, in contrast to the more localized sensitivity observed in CNN-based saliency maps.

Figure 7 shows the gradient-based saliency maps [15], which visualize the regions that are most influential in SimCLR's downstream classification. In the heatmaps, brighter red areas indicate pixels where small changes significantly influence the model's prediction.

XSL•FO
RenderX

Figure 7. Gradient-based saliency maps for SimCLR model. Each row showed an example from the primary or cross dataset, categorized by tumor or nontumor class. The three columns displayed (1) the original magnetic resonance image, (2) the computed heatmap, and (3) the overlay of the heatmap on the original image. SimCLR: Simple Contrastive Learning of Visual Representations.

In both tumor and nontumor images, the saliency patterns were generally similar to those we observed in Figure 5 (ResNet18), though SimCLR's saliency patterns appeared sharp and more diffuse. This is likely because SimCLR pretrained encoder learns from many augmented views without label annotation, which encourages the model to capture more global structure consistency rather than relying solely on highly localized features.

In the primary tumor image, we observed that there were bright red spots on the frontal region and the lower back region of the brain, partially aligning with the visible anomaly in the original image. In the external image, red spots were concentrated around the middle-left brain region, overlapping with the tumor area.

In both nontumor images, the saliency maps appeared as uniformly distributed, with no dominant regions. Notably, in both primary and cross-domain tumor images, SimCLR's saliency maps displayed brighter and smoother red regions, with greater focus on the anomalous areas compared to those in Figure 5 (ResNet18), potentially making tumor regions more distinguishable in the saliency visualization.

Among the 4 saliency methods, attention rollout [31] from the ViT-B/16 model provided the most biologically meaningful explanations, with smoother and more globally coherent maps that aligned well with tumor regions in both the primary and cross datasets. SimCLR's gradient-based [15] saliency showed better results, with clearer and more generalizable tumor region activations than ResNet18, likely due to its global feature learning through self-supervised contrastive pretraining. In contrast, SVM+HOG's occlusion maps [14] were limited, interpretable, and often included spurious activations.

The interpretability of saliency maps does not always correlate with model performance. Gradient-based saliency maps from

XSL•FO
RenderX

ResNet18 were less reliable and may not reflect biological meaningful reasoning, aligning with recent findings that question their trustworthiness in medical imaging [32]. Future work could explore more robust interpretability techniques to better uncover model behavior and support clinical decision-making.

Real-World Cost, Complexity, and Deployment Feasibility

The SVM+HOG model is lightweight among these 4 models. It requires no GPU and has minimal memory use. It also requires grayscale images and simple feature extraction (HOG), making it ideal for low-resource settings. For instance, SVM+HOG could be deployed in community clinics or rural hospitals where computational infrastructure is limited, enabling rapid preliminary screening without the need for GPU resources.

The ResNet18 model balances moderate performance with reasonable efficiency, and it requires a GPU for fast training. It benefits from transfer learning by fine-tuning only the last few layers, making it more adaptable to small datasets. It is relatively compact in size and easily deployable on standard medical AI pipelines.

ViT-B/16, while achieving competitive accuracy, is the most computationally expensive, and it requires more memory, longer convergence, and benefits from larger datasets to reach optimal performance. These requirements may limit their feasibility in real time or low-resource clinical deployments.

SimCLR, with its 2-phase training, including pretraining and linear evaluation, is the most resource-intensive. Its deployment may be more complex due to the need for pretrained encoders and additional infrastructure for self-supervised pretraining. Despite the high initial cost, it shows strong generalization and can be highly effective when unlabeled data are abundant, but annotation resources are limited. For instance, SimCLR may be especially suitable for large medical centers with access to vast unlabeled image repositories but limited clinician time for annotation, allowing for scalable representation learning before fine-tuning.

While models like ViT-B/16 and SimCLR are more computationally demanding, their saliency visualizations provided more biologically meaningful explanations, which may support clinical trust and decision-making. In contrast, the simpler SVM+HOG model, although lightweight and suitable for low-resource settings, occasionally relied on spurious features, as reflected in its occlusion maps. The gradient-based saliency map on ResNet18 showed less reliability on medical imaging data.

Discussion

Principal Findings

The study presented a comparative trade-off analysis of 4 models, including SVM+HOG, ResNet18, ViT-B/16, and SimCLR, on 2 small-scale brain tumor MRI datasets. The evaluation spans multiple dimensions, including classification accuracy, robustness on the distribution shifts, generalization within- and cross-domains, training stability, and real-world deployment feasibility. Notably, the models demonstrated strong transferability and true generalization when tested on unseen data from an external independent dataset.

For a machine learning research perspective, model performance is typically prioritized. The results showed that ResNet18 delivered a strong balance between performance and training efficiency, making it suitable for settings where moderate resources are available. SimCLR offers compelling generalization with the advantage of requiring no labeled data during pretraining, making it well-suited for real-world conditions with annotation limitations [11]. ViT-B/16 shows potential, particularly due to its global attention mechanism, but may be more sensitive to overfitting under a small number of medical image datasets. SVM+HOG, although simpler, performs reliably with low computational cost and without relying on data augmentation [7].

For a clinical or radiologist perspective, model interpretability plays a critical role. In this regard, ViT-B/16 demonstrates the most coherent and biologically meaningful saliency maps through its attention-rollout mechanism, highlighting abnormal regions with greater reliability. SimCLR, despite its 2-stage training phases, produced saliency maps; these were smoother and more focused than those from ResNet18, likely due to its global feature learning through self-supervised contrastive training. Moreover, SimCLR requires no labeled data during pretraining, significantly reducing annotation effort for clinicians [24]. SVM+HOG, while occasionally producing spurious saliency activations under noise conditions, is an extremely lightweight and easy to deploy model. It does not require GPUs or deep learning architectures and can serve as a practical tool in resource-limited clinical environments or as a fast, interpretable baseline [33]. ResNet18 saliency map, relying on gradient-based method only, showing less reliable interpretability compared to ViT-B/16 and SimCLR, aligning with prior literature questioning the trustworthiness of gradient-based explanations in medical imaging [32].

Hyperparameter Selection and System Setup

To ensure reproducibility and model optimization, we systematically tuned key hyperparameters across all models. The details tested ranges and final selected hyperparameters are provided in Multimedia Appendix 8, while a summary of the overall system configurations across the 4 models is provided in Multimedia Appendix 9.

Multimedia Appendix 8 summarizes the model optimization strategies. For ResNet18 and ViT-B/16, lower learning rates combined with weight decay were selected to stabilize training and prevent overfitting. CosineAnnealing LR was adopted for ViT-B/16 to handle its slower convergence, which ReduceLROnPlateau performed better for ResNet18. Data augmentation strategies, such as random rotations and affine transformations, improved robustness to geometric variations. For SimCLR, we optimized the projection head dimensions and augmentations to enhance representation learning. For SVM+HOG, a linear kernel and default regularization parameter provided the best trade-off between simplicity and performance.

Multimedia Appendix 9 summarizes the complete experiment environmental settings to ensure reproducibility. It detailed the

XSL•FO
RenderX

hardware (NVIDIA RTX A6000 GPU, Intel Core i7 central processing unit, 251 GB RAM), operating system (Windows 11), and software frameworks (PyTorch 2.6.0+cu118 and torchvision 0.21.0+cu118). We also listed the Python (version 3.9.21; Python Software Foundation) and the key Python packages with their current versions, such as scikit-learn 1.6.1 and numpy 2.0.2. Finally, we set the random seed configuration used in the experiments; variable seeds were applied during training (42+run) to enhance model generalizability, while a fixed seed (42) was used during test runs to ensure deterministic evaluation results.

Comparison With Previous Studies

Previous studies have explored various strategies for brain tumor classification, ranging from traditional machine learning models to deep learning approaches. One study [34] demonstrates that an SVM model alone as the baseline to attain the accuracy of 86.57% on unseen brain tumor data, incorporating principal component analysis improved the accuracy to 94.20%. While the combination of SVM with HOG and local binary pattern achieved a higher accuracy of 96.03%. Another study [35] applied ResNet18 for brain tumor detection and reported superior performance over models such as GoogLeNet and CapsNet, with their ResNet18 achieving an accuracy of 88.33%.

While previous studies primarily focused on classification accuracy, our research explored 4 distinct model mechanisms and interpreted how each identified image classification predictions based on learned features and internal decision processes. Our models demonstrated strong and consistent performance across multiple evaluation criteria.

Specifically, for the SVM+HOG model, the HOG method is used to extract edge and shape features from image data, which are then fed into an SVM for binary classification. ResNet18, a CNN model, predicts by attending to localized pixel patterns and patch movements. ViT-B/16, a transformer-based model, aggregates attention weights across all image patches and their spatial relationship, capturing global context for classification. SimCLR uses a pretrained ResNet18 as a backbone to learn localized feature representations through self-supervised contrastive learning, followed by a linear classifier for downstream prediction.

Additionally, we extended our evaluation to assess the robustness and generalization both within-domain and cross-domain. We analyzed training convergence patterns and included the practical feasibility metrics such as training time, annotation cost, and interpretability via saliency map. This comparative trade-off analysis is for offering a broader and practical evaluation framework for deploying AI in real-world medical imaging tasks.

Limitations

This study has several limitations. First, the relatively small training images in the primary dataset contained 2008 images, and the cross-domain test data contained 3351 images. These dataset sizes were relatively small, particularly for deep learning models, which typically required large amounts of data to generalize better [3]. Second, we selected ResNet18, ViT-B/16, and SimCLR to enable fair baseline comparisons, but larger models such as ResNet50 or ViT-L may yield better performance. Third, we focused exclusively on image-level classification rather than voxel-level tumor localization. Finally, the interpretability of saliency maps does not always correlate with model performance and may potentially highlight spurious features.

Future Work

For future work, larger and more diverse datasets are needed to validate model generalization and enhance clinical relevance. Extending this work to segmentation and 3D modeling could offer more precise tumor localization and enhance voxel-level clinical interpretation [36]. Moreover, exploring more robust interpretability techniques such as concept-based methods or counterfactual explanations may strengthen clinician trust in model decisions. Finally, close collaboration between machine learning researchers and clinicians will be critical to translating models into trustworthy, deployable tools for health care.

Conclusions

This study aimed to evaluate trade-offs between classical machine learning and deep learning, including SSL approaches for brain tumor classification under small-scale medical imaging conditions. To achieve this, we compared 4 representative models, including SVM+HOG, ResNet18, ViT-B/16, and SimCLR, with consistent training pipelines and evaluated their performance across both within- and cross-domain settings, without retraining on cross dataset to simulate real-world deployment.

Our analysis revealed that no single model is universally optimal. ResNet18 achieved a strong balance of accuracy and computational efficiency, SimCLR demonstrated superior generalization under limited annotations, ViT-B/16 provided the most coherent visual interpretability through attention mechanisms, and SVM+HOG showed a lightweight, resource-efficient alternative. Importantly, the results highlighted that model choice depended on perspective: from a machine learning researcher standpoint, efficiency and accuracy dominate, whereas from a clinical perspective, interpretability through saliency maps can be important.

Abstract

Background: Electronic patient records are a valuable yet underused data source; they have been explored in research using natural language processing, but not yet within a third-sector organization.

Objective: This study aimed to apply natural language processing to develop a risk identification tool capable of discerning high and low suicide risk among veterans, using electronic patient records from a United Kingdom–based veteran mental health charity.

Methods: A total of 20,342 notes were extracted for this purpose. To develop the risk tool, 70% of the records formed the training dataset, while the remaining 30% were allocated for testing and evaluation. The classification framework was devised and trained to categorize risk as a binary outcome: 1 indicating high risk and 0 indicating low risk.

Results: The efficacy of each classifier model was assessed by comparing its results with those from clinical risk assessments. A logistic regression classifier was found to perform best and was used to develop the final model. This comparison allowed for the calculation of the positive predictive value (mean 0.74, SD 0.059; 95% CI 0.70-0.77), negative predictive value (mean 0.73, SD 0.024; 95% CI 0.72-0.75), sensitivity (mean 0.75, SD 0.017; 95% CI 0.74-0.76), F_1-score (mean 0.74, SD 0.033; 95% CI 0.72-0.76), and accuracy, which was measured using the Youden index (mean 0.73, SD 0.035; 95% CI 0.71-0.76).

Conclusions: The risk identification tool successfully determined the correct risk category of veterans from a large sample of clinical notes. Future studies should investigate whether this tool can detect more nuanced differences in risk and be generalizable across data sources.

natural language processing; risk; veterans; electronic patient records; self-harm

Introduction

Background

It is important to identify and manage risk in clinical populations [1]. In the United Kingdom, guidelines from the National Institute for Care Excellence require clinical mental health services to have a risk management plan in place. Individualized risk assessments must address risks to the patient—including self-harm and vulnerability to exploitation—as well as risks to others associated with the patient's mental health condition, such as aggression and violence, and include a plan for the ongoing management of identified risks [2].

Assessing Risk

In clinical settings, risk is typically assessed using psychometric methods and clinical interviews and patients are dichotomized into high- and low-risk groups [3,4]. However, assessing and identifying risk in clinical populations remains subjective and difficult [5]. Accurate risk assessment may be hampered by the complexity of biological, psychological, and environmental risk factors and the interplay between them. Meta-analyses have

XSL•FO
RenderX

indicated that no single factor [6] or set of factors [7] is sufficiently predictive of risk to be useful in clinical risk assessments. In addition, a systematic review of 19 studies indicated that while current methods for assessing risk in veterans are sensitive to identifying risk, they also yield a high rate of false positives, which undermines the clinical utility of these methods [8].

Novel Methods to Identify Risk

Electronic patient records (EPRs), including free-text clinical notes that document patient contact and sessions, are an underused yet rich source of data. Secondary research using natural language processing (NLP) has increasingly been used to make use of data contained in EPRs, informing clinical service planning and improving safety management [9]. NLP encompasses a range of techniques used to train algorithms to make meaning from natural speech or text, such as in speech recognition technology and can be used with large samples. Military research has also made use of these techniques to identify veterans from a clinical research database [10], as well as to categorize patients with probable posttraumatic stress disorder [11]. NLP has previously been used to identify suicide risk from EPRs of a large United Kingdom mental health service [12].

Risks in Veterans

Veteran services may be one clinical population that could benefit from such novel risk management methods. While suicide rates are no higher than the United Kingdom general population in serving military personnel, some veteran groups, such as those below the age of 25 years, face an increased risk relative to the general public [13]. Veterans experiencing mental health difficulties may delay seeking help compared to nonveteran clinical groups [14], often waiting until they are in crisis before doing so [15]. Once in treatment, veterans may be more likely to drop out and respond less effectively to treatment [16]. In addition, high levels of comorbidity and complexity in mental health presentations are observed in treatment-seeking veterans [17], particularly those who have reached a crisis point [18]. These considerations highlight the importance of monitoring risk in veteran services and evaluating the efficacy of methods for doing so.

This Study

This study aimed to develop an NLP framework to identify high and low risk of suicide from clinical notes of a United Kingdom veteran mental health charity. A machine learning classification framework is used to test and evaluate a range of classifiers to develop a risk identification tool.

Methods

Ethical Considerations

Approval for this project was granted by Combat Stress Research Committee (ref.pn2020). The study was conducted in alignment with the 2024 Declaration of Helsinki for medical research with human participants.

Participants

The deidentified data used in this study were extracted from an EPR system managed by a third-sector charitable organization that provides mental health services to United Kingdom veterans. The charity EPR system has supported a range of research projects [19-21]. Many of these studies have aimed to answer specific clinical or population-based research questions such as the demographic profile of referrals to the charity and to develop a mobile phone app to reduce alcohol consumption.

The data used in this study were extracted from the patient EPRs, which were created by clinical staff each time they interacted with a patient or updated the patient's file. These records provide an overview of patient interactions, treatment, risk profiles, and patient-reported concerns. Clinical risk is determined by individual clinicians, who assess and document it based on the charity's guidelines and their professional judgment. Risk is recorded as either low or high according to these criteria.

Procedure

There are approximately 650,000 records from 33,000 patients in the charity's EPR. Owing to the large number of records and time constraints, we extracted a subset for the development of our risk tool. This subset (hereafter termed *risk database*) was extracted from the EPR system for patients who had a modification in their record between July 2020 and July 2022, had a clinical risk indicator and free-text summary (see quote 1 as an example), and had provided consent for their anonymized data to be used for research purposes. The extraction time frame was selected because patients must have their consent reviewed after 2 years, and due to an EPR outage that commenced in late July 2022:

> *Full meeting minutes can be observed in the meetings tab. Patient appears happy and consent with life, but has indicated low mood, and bouts of manic depression with some suicidal thoughts. Recommend further follow-up in two weeks.* [Quote 1: synthetically generated free-text statement as an example of the type of note provided in the charity's EPR]

How Clinical Risk Category Is Computed in the Service the Sample Is Drawn From

Every veteran referred to the charity is offered a screening call during which the frequency of suicidal ideation is assessed using item 9 of the Patient Health Questionnaire [22]. Risk status is determined by this question, along with further questions regarding intent, previous suicide attempts, current plans, and the presence of high levels of shame, guilt, impulsivity, or risk-taking behaviors. Referrals for veterans who are assessed as high risk in this regard are not accepted for a full assessment and are instead offered information about more appropriate services. During treatment, risk status is determined by subjective clinician judgment and considering the following factors: historical attempts, vague or contemplative plans, evidence of elevated alcohol or drug use, previous involvement with acute mental health services, isolation and withdrawal, evidence of frequent anger or physical aggression, impulsivity, reduction in meaningful activities, and protective factors

XSL•FO
RenderX

(employment status, support network, motivation to engage in treatment, future orientation, evidence of external locus of control and self-efficacy, hope in treatment success, and triggers to mental health deterioration). A high-risk rating is assigned when the Patient Health Questionnaire-9 items 3 "feeling down depressed or hopeless" and 9 "thoughts that you would be better off dead or of hurting yourself in some way" are rated as "more than half the days" in the previous 2 weeks, as well as presence of the aforementioned risk factors.

A total of 20,342 records were retained for analysis, which are hereafter referred to as the gold standard dataset. These records included assigned clinical risk scores for 582 patients (low risk: 10,984; high risk: 9358). The clinical risk score serves as the benchmark for assessing the performance of machine learning models. Each patient may have multiple records, reflecting different points in their care. The decision to include only 582 patients was driven by resource constraints, such as limited staff time for annotating each record and the need to maintain patient privacy by processing the fewest possible number of records. Due to these considerations, a sample size calculation was not conducted.

For the development and evaluation of the risk tool, we allocated 70% of the dataset (14,239 out of 20,342 records) for training, while the remaining 30% (6103 records out of 20,342) were used for testing and evaluation. To ensure the integrity of the evaluation, patients were assigned to either the training or testing group, with no patient's records appearing in both groups. It is important to note that there is no universally recognized method for determining the size of the training and testing groups. Therefore, our approach was guided by methodologies reported in similar studies [10,23,24].

Generating an Annotated Word Features Dataset

In this phase, 5000 records from the training dataset, evenly divided between low risk (2500) and high risk (2500) and representing 105 patients, were annotated. To ensure balanced representation of both classes and to mitigate class imbalance during model training, we explicitly selected an equal number of records from each risk category. DL and NB developed a set of classification rules for annotating each record using an annotation protocol. This method involved categorizing words and phrases into three groups: (1) those indicating any kind of clinical risk, such as self-harm, suicidal thoughts, or suicidal intent; (2) descriptions of suicidal behavior or thoughts pertaining to individuals other than the patient; and (3) expressions that might cause confusion, such as "he was angry" or "the TV show had death." As the researcher team analyzed each record, terms relevant terms were highlighted by the annotation software based on the aforementioned groupings. These groupings were used to extract the different feature sets used for modeling. If differences occurred, these were discussed until an agreement was reached regarding inclusion or exclusion. This systematic categorization yielded a set of word features that were used in developing and training the risk identification tool. Details of the annotation protocol and classification rules are available upon request from the corresponding author.

Developing the Risk Identification Tool

In this study, we developed a machine learning classification framework to test and evaluate a range of machine learning classifiers.

The training dataset (defined earlier) was preprocessed to remove (1) punctuations (using regular expressions algorithm), (2) words or phrases related to another individual's clinical risk (these were required to exactly match those in the annotated feature dataset), (3) stop words and frequently occurring terms (except words related to harm and risk), and (4) word or phrases that may cause confusion with correctly identifying self-harm and risk. The remaining features were then converted into term frequency–inverse document frequency (TF-IDF) features. The risk terms and phrases identified in the annotation phase were used for the TF-IDF features. Mutual information scores were calculated for each annotation using the mutual_info_classif function to quantify the dependency between terms and risk class. The top 500 features with the highest scores were retained for model training and incorporated into the TF-IDF features. This approach was undertaken to ensure that key phrases and terms associated with risk were given a higher prominence, whereas terms related to confusion were penalized. This approach follows a similar framework reported elsewhere [10].

The classification framework was developed and trained to identify risk with the outcome being a binary value (1=high risk and 0=low risk). A training set of 9966 records was used within the framework to select the best performing machine learning classifier to use the on the test set defined earlier. As mentioned earlier, there is no standardized approach in the literature for determining the training and testing size cutoff. This is also the case when selecting the most suitable machine learning algorithms for specific analyses, not only in the field of NLP but also in areas such as health care, agriculture, and security [12,25,26].

Therefore, in this study, a comparison was made based on 10-fold cross-validation accuracy using TF-IDF features as an input of the following machine learning classifiers (which are part of the *scikit-learn* package): support vector machines, random forest, artificial neural network, k-nearest neighbor, logistic regression, and XGBoost. It is important to note that there is sparse literature on which machine learning algorithms are best suited for specific tasks such as clinical risk detection using NLP. Therefore, algorithms have been selected based on prior use in this domain. During this initial phase, each machine learning classifier used default parameters as specified by *scikit-learn* package. The 10-fold cross-validation randomly samples the 9966 records at each "fold" to identify which parameters are suitable for the best performance. Logistic regression yielded the best performance during the 10-fold cross-validation (see Table 1 for full results).

XSL•FO
RenderX

Table 1. Machine learning classifier 10-fold cross-validation performance based on the training dataset of 9966 records.

Classifier	Accuracy, mean (SD)	Negative predictive value, mean (SD)	Precision (PPV[a]), mean (SD)	Sensitivity, mean (SD)	F_1-score, mean (SD)
Support vector machines	0.922 (0.026)	0.898 (0.020)	0.948 (0.043)	0.900 (0.018)	0.923 (0.024)
Random forest	0.889 (0.025)	0.874 (0.043)	0.906 (0.015)	0.867 (0.043)	0.886 (0.026)
Artificial neural network	0.851 (0.014)	0.826 (0.035)	0.877 (0.017)	0.822 (0.028)	0.848 (0.012)
k-nearest neighbor	0.798 (0.031)	0.817 (0.044)	0.782 (0.031)	0.815 (0.042)	0.797 (0.028)
Logistic regression	0.977 (0.014)	0.972 (0.016)	0.983 (0.014)	0.972 (0.016)	0.977 (0.014)

[a]PPV: positive predictive value.

In addition to comparing multiple classifiers, we also considered dimensionality reduction and feature selection techniques, including SelectKBest and truncated singular value decomposition, to evaluate whether reducing the dimensionality of the feature space improved model performance. However, while these methods modestly reduced computational complexity, they did not significantly enhance classification accuracy or F_1-score when compared with other approaches. Furthermore, the records were relatively short in length, resulting in low computational complexity.

Data Analysis

All analyses were performed using Python version 3.5 with standard mathematical packages and *scikit-learn* (version 0.20.3) [26]. Machine learning classifier 10-fold cross-validation was selected as the highest accuracy with consideration of the negative predictive value, precision, sensitivity, and F_1-score with each reported with SD and 95% CI with SD and 95% CI reported to represent the n-fold result.

Record characteristics were reported as the average frequency in which words, sentences, whitespaces, stop words, and nonalphanumeric across records were stratified by risk status. For evaluating the risk tool, each classifier model was tested by measuring its results against the results from the clinical risk assessment status (the gold standard testing dataset), allowing for computation of positive predictive value, negative predictive value, sensitivity, F_1-score, and accuracy at a record level. In this study, positive predictive value was defined as the proportion of correctly identified true high-risk cases over the total number of true high-risk cases identified by the classifier. Negative predictive value was defined as the proportion of correctly identified true low-risk cases over the total number of low-risk cases identified by the classifier. Sensitivity was defined as the proportion of true high-risk cases identified by the classifier over the total number of actual high-risk cases (identified by each record). F_1-score considers both positive predictive value and sensitivity and produces a harmonic mean, where the best value lies at 1 and the worst value lies at 0. Classifier performance was additionally assessed using the Youden index, which summarizes the trade-off between sensitivity and specificity. The Youden index is calculated as (sensitivity+specificity−1), with values ranging from 0, indicating no discriminatory power, to 1, representing perfect discrimination. Thus, it provides a useful metric for identifying the classifier threshold that maximizes both sensitivity and specificity.

Results

Record Characteristics

Descriptive characteristics of the gold standard dataset are reported in Table 2. These analyses indicate that high-risk records had more words (mean 472.98, SD 407.75), sentences (mean 158.88, SD: 222.47), white spaces (mean 62.80, SD 87.66) and stop words (mean 25.39, SD 50.12).

Table 2. Record characteristics including frequency and mean (SD) stratified by low risk and high risk.

Characteristics	Low risk (n=10,984), mean (SD)	High risk (n=9358), mean (SD)
Words	376.28 (309.17)	472.98 (407.75)
Sentences	147.17 (234.01)	158.88 (222.47)
White spaces	56.02 (85.67)	62.80 (87.66)
Stop words	25.57 (52.45)	25.39 (50.12)

Performance

The performance of the risk tool using logistic regression is reported in Table 3 and evaluated using the testing dataset producing a positive predictive value, negative predictive value, sensitivity, F_1-score, and accuracy statistics. The testing data contained 6103 records, which represented 3102 low-risk and 3001 high-risk records. Overall, the clinical risk tool had an accuracy of 0.734 (0.035; 0.712-0.756), a negative predictive value of 0.734 (0.024; 0.719-0.749), a precision of 0.737 (0.059; 0.7-0.774), a sensitivity of 0.748 (0.017; 0.738-0.758) and an F_1-score of 0.741 (0.033; 0.721-0.761).

Table 3. Performance results for the clinical risk identification tool using logistic regression.

Performance metric	Results, mean (SD; 95% CI)
Youden index	0.734 (0.035; 0.71-0.76)
Negative predictive value	0.734 (0.024; 0.72-0.75)
Precision	0.737 (0.059; 0.70-0.77)
Sensitivity	0.748 (0.017; 0.74-0.76)
F_1-score	0.741 (0.033; 0.71-0.76)

Discussion

Principal Findings

This study applied NLP to EPRs from a national veteran mental health charity to develop a risk identification tool and the findings demonstrate the feasibility of using a large electronic records database to classify patients into general risk categories (high or low). This is one of the growing number of studies using free-text clinical records to identify risk [12,27]. Our risk tool performed favorably in comparison to similar studies, achieving a precision of 74% in classifying risk category. One study using an NLP algorithm to identify risk reported a precision value of 60%, while another tool was able to correctly identify 92% of cases of suicide ideation and 83% suicide attempts [12]. Another machine learning algorithm was able to identify suicide attempts with a precision of between 93% and 97%.

Key to why the performance metrics of the current tool were in the middle of this range is likely the much smaller samples and more precise risk categories used in previous studies, potentially making these tools more accurate. For example, other algorithms used gold standard datasets of thousands of records rather than hundreds. Second, “suicide ideation” and “suicide attempt” are much clearer to define and dichotomize than the high and low general risk classifications in this study. Risk ratings in the EPRs encompass multiple areas of risk of harm to self and others, including substance use, homelessness, and safeguarding concerns, among other risk areas. As such the categories “high” and “low” risk are relatively general and depend on clinician interpretation of multiple factors.

Of interest in this work, we found that high-risk records contained a greater number of words compared to low-risk records and may indicate differences in documentation practices when clinicians identify increased risk. Specifically, clinicians may provide more detailed or extensive documentation when patients present higher levels of risk, reflecting more complex clinical considerations, a broader range of concerns, or increased efforts to record comprehensive management plans. This observation warrants further investigation to better understand how documentation practices may vary according to perceived risk, which in turn may inform future NLP-driven approaches for risk identification.

The relatively lower accuracy of the current tool compared to similar studies indicates that such tools should not replace clinical risk assessment by a qualified clinician. Given the importance of evaluating risk in clinical samples, only 100% accuracy would suffice. However, this study has demonstrated that risk categories can be captured by free-text clinical notes, suggesting that there may be a place for NLP algorithms in using large databases of clinical notes to find patterns in indicators of risk that may not have been considered by individual clinicians.

Interpretability and Clinical Reasoning

An important consideration in the development of clinical decision support tools is their interpretability. That is, the extent to which the output can be explained and justified to clinicians and service providers. This is important in a mental health setting, where risk decisions have significant consequences. In this study, interpretability was a key consideration. Unlike black-box models, logistic regression (for example) allows for the direct examination of model coefficients, facilitating the identification of the most predictive features and their relative contribution to risk classification. In addition, low-complexity models can be exploited within the resource-constrained environments typical of third-sector organizations or National Health Service, where advanced infrastructure required for complex models may not be available.

Our analysis revealed that the most predictive features associated with high-risk classification included terms such as “suicidal thoughts,” “self-harm,” “hopeless,” “impulsive,” “previous attempts,” and “risk to self.” These features align closely with the clinical criteria used within the service to define and assign high-risk ratings. Conversely, terms associated with protective factors, such as “supportive family,” “engaged in treatment,” “stable,” and “improvement” were associated with low-risk classifications and contributed negatively to the model’s decision boundary.

These findings are consistent with clinical reasoning and established suicide risk frameworks. For example, indicators such as prior suicide attempts, as well as psychological markers such as hopelessness and impulsivity, are well-established predictors of suicide risk in both the general population and in veteran groups [8,23]. Similarly, the presence of social support, treatment engagement, and expressions of psychological recovery are routinely considered protective factors by clinicians when assessing risk. The ability to identify and understand which features contribute to risk classification improves trust in the algorithm and enables a mechanism for validation against clinician judgment. However, future development should continue to emphasize transparency and clinical alignment, particularly if such tools are to be integrated into routine practice within veteran mental health services.

Uses of a Risk Tool in Veteran Services

However, the naturalistic data contained within a large EPR database was able to be exploited by this study. An advantage of developing a tool using this approach is that the methods used could transfer more easily to create similar tools on extracted EPR data from other services. Risk tools, such as the one developed in this study, may be particularly useful in improving effectiveness and efficiency of risk evaluation, which is often highly subjective and lengthy [5]. EPRs are a rich data source because they contain longitudinal, detailed information from large patient samples. Using such data could permit a more nuanced perspective of risk, which may be particularly valuable in population subgroups such as treatment-seeking veterans, who may exhibit different risk profiles compared to other groups. For example, treatment-seeking veterans face a high burden of comorbid difficulties [28] adding to the complexity of their mental health difficulties [17] and yet veterans may delay seeking support until they have reached a point of crisis [15]. Veteran groups may be more likely to underreport when asked about risk factors by clinicians [29], which highlights a potential need to use whatever data are available when identifying risk, including that contained within clinical notes.

Strengths and Limitations

While this study was able to use a large sample to identify risk category, several limitations should be noted. First, the sample is drawn from a service that as part of its eligibility criteria does not offer treatment to veterans who are in crisis or considered at very high risk of harm to self or others. Future research should seek to understand how to capture differences in risk categories in a more fine-grained way. Second, eligibility criteria for treatment and service provision varied throughout the extraction period, including through the COVID-19 pandemic and the beginning of an EPR outage. However, the time for extraction of clinical notes was carefully considered to minimize the variation in reporting linked to these factors. It was not possible to use advanced models such as transformer-based models in this study. However, our approach aimed to replicate prior work, particularly the development of the Military Service Identification Tool [12], which focused on simpler modeling techniques. The rationale for this decision is that many National Health Service trusts and health care systems lack the necessary computational infrastructure to support advanced transformer-based architectures. Given the requirement for our approach to run behind secure health system firewalls (“behind the wire”), we prioritized models that balance performance with feasibility in real-world clinical deployments. Finally, variability and cognitive biases in clinicians’ subjective categorizations of risk are inevitable. Any transferability of the algorithms used in the current dataset would need to be adjusted to reflect different services’ reporting systems. However, the codes used to develop the current tool are malleable and unstructured.

Abstract

Background: Cancer progression is an important outcome in cancer research. However, it is frequently documented only in electronic health records (EHRs) as unstructured text, which requires lengthy and costly chart reviews to extract for retrospective studies.

Objective: This study aimed to evaluate the performance of 3 deep learning language models in determining breast and colorectal cancer progression in EHRs.

Methods: EHRs for individuals diagnosed with stage 4 breast or colorectal cancer between 2004 and 2020 in Manitoba, Canada, were extracted. A chart review was conducted to identify cancer progression in each EHR. Data were analyzed with pretrained deep learning language models (Bio+ClinicalBERT, Clinical-BigBird, and Clinical-Longformer). Sensitivity, positive predictive value, area under the curve, and scaled Brier scores were used to evaluate performance. Influential tokens were identified by removing and adding tokens to EHRs and examining changes in predicted probabilities.

Results: Clinical-BigBird and Clinical-Longformer models for breast and colorectal cancer cohorts demonstrated higher accuracy than the Bio+ClinicalBERT models (scaled Brier scores for breast cancer models: 0.70-0.79 vs 0.49-0.71; scaled Brier scores for colorectal cancer models: 0.61-0.65 vs 0.49-0.61). The same models also demonstrated higher sensitivity (breast cancer models: 86.6%-94.3% vs 76.6%-87.1%; colorectal cancer models: 73.1%-78.9% vs 62.8%-77.0%) and positive predictive value (breast cancer models: 77.9%-92.3% vs 80.6%-85.5%; colorectal cancer models: 81.6%-86.3% vs 72.9%-82.9%) compared to Bio+ClinicalBERT models. All models could remove more than 84% of charts from the chart review process. The most influential token was the word *progression*, which was influenced by the presence of other tokens and its position within an EHR.

Conclusions: The deep learning language models could help identify breast and colorectal cancer progression in EHRs and remove most charts from the chart review process. A limited number of tokens may influence model predictions. Improvements in model performance could be obtained by increasing the training dataset size and analyzing EHRs at the sentence level rather than at the EHR level.

Introduction

Background

Cancer progression is an important intermediate prognostic and predictive marker of clinical outcomes among patients with cancer. It is defined as the growth or spread of an existing cancer. Progression is distinct from cancer recurrence, which is the diagnosis of a second episode of cancer after the first episode is considered cured. Unfortunately, cancer progression and its date of occurrence are frequently not available in cancer registries and are only documented in the electronic health record (EHR) as unstructured text. Reports such as pathology and radiology reports also contain text that can inform the diagnosis of cancer progression in clinical notes. Therefore, the inclusion of cancer progression in retrospective research requires a chart review, which can be lengthy and expensive. Consequently, researchers may not have been able to include progression as an outcome in retrospective studies.

Algorithms using administrative claims data (eg, diagnosis and procedure codes and pharmacy-dispensed medication) have been developed to identify cancer recurrence and progression [1-3]. However, these algorithms do not approximate case definitions obtained from chart reviews well. When algorithms demonstrated sensitivity values >90%, the positive predictive values (PPV) were only near or <50%. PPV can be low due to algorithms misclassifying changes in treatment as cancer progression or recurrence when the change was due to other reasons (eg, toxicity). In addition, most algorithms demonstrated sensitivity values <100%. Methods other than algorithms that use administrative claims data are needed to reduce misclassifications and improve accuracy.

One recent option is to use pretrained deep learning language models, which have the potential to improve model accuracy relative to claims-based algorithms while decreasing the need for lengthy and costly chart reviews. Bidirectional encoder representations from transformers (BERT) [4] is an example of such a model, which can be fine-tuned to datasets to perform tasks such as creating classification models. This approach has demonstrated higher accuracy in developing text classification models than previous deep learning language models (eg, long short-term memory models [4]). Rather than using proxy information for identifying cancer progression (eg, claims data), these language models can analyze data directly from EHRs.

Objectives

The objective of this study was to develop and compare models to identify cancer progression in EHRs for stage 4 breast and colorectal cancer cohorts using 3 pretrained deep learning language models.

Methods

Data

Stage 4 breast and colorectal cancer cohorts were identified from the Manitoba Cancer Registry. Individuals diagnosed between January 1, 2004, and December 31, 2020, were included. EHRs for physician visits on or after an individual's diagnosis date were extracted from the CancerCare Manitoba's ARIA system up to April 30, 2022. Only text from physician notes within EHRs was extracted because these records included notes such as physicals and histories, progression notes, and treatment plans that would discuss the suspicion, investigation, and diagnosis of progression. Notes from other professionals (eg, nutritionists, social workers, and nurses) were removed because the diagnosis of cancer progression is the responsibility of physicians. Radiology and pathology reports as source documents were excluded. Radiology and pathology reports were stored as PDF files, which had issues with extracting text and retaining proper format (eg, text from multiple columns would be read as a single line rather than separate lines from different columns). Training and validation breast cancer cohorts included EHRs from individuals diagnosed between January 1, 2004, and December 31, 2017. Training and validation colorectal cancer cohorts included EHRs from individuals diagnosed between January 1, 2011, and December 31, 2017. Training and validation cohorts consisted of weight-stratified datasets representing 80% and 20% of the EHRs, respectively. Test cohorts consisted of EHRs from individuals with breast or colorectal cancer diagnosed between January 1, 2018, and December 31, 2020. Temporal external validation was used because external validation is more rigorous than internal validation [5].

Cancer progression reported in clinical notes was defined as a requirement for treatment change due to tumor growth. Tumor growth could be determined radiologically, when new lesions appeared or had increased in size on imaging. Criteria such as the response evaluation criteria in solid tumors may or may not have been reported in clinical notes. Tumor growth could also be considered by rising blood marker values or pathologically (eg, new lesions). Progression could also be defined clinically when deterioration requires a change in treatment, such as enrollment in palliative care.

Labels were provided for each EHR to identify cancer progression. Three-class labels were considered: (1) cancer progression (reported by an oncologist in the clinical note using the previously mentioned factors); (2) mention of progression but not actual progression or suspicion of progression (which occurred for 1 of 3 reasons—tumor growth was reported in the clinical note as not having increased enough to justify a change in treatment; nononcological use, eg, "the patient's symptoms are progressing well"; or suspicion of progression without sufficient evidence to indicate a diagnosis); and (3) no mention of progression. Three-class labels were generated to potentially

XSL•FO
RenderX

reduce false-positive rates. Two trained research assistants reviewed EHRs for the breast cancer cohort, 2 other trained research assistants reviewed EHRs for the colorectal cancer cohort, and a third individual with prior training provided the final label when disagreements in labels occurred between chart reviewers.

Analysis

Preprocessing of data before analysis consisted of changing all text to lowercase and removing words that contained more than 50 characters. Some EHR notes had *PROGRESS NOTE* as the first header. This text was removed to prevent models from confusing this term with cancer progression. Three pretrained deep learning language models (Bio+ClinicalBERT [6], Clinical-BigBird [7], and Clinical-Longformer [7]) were used to analyze data. Bio+ClinicalBERT is limited to a maximum of 512 tokens, whereas Clinical-BigBird and Clinical-Longformer are limited to a maximum of 4096 tokens. Three approaches were used with Bio+ClinicalBERT to account for the 512-token maximum: analyzing the first 512 tokens (head), analyzing the last 512 tokens (tail), and analyzing the first 256 and last 256 tokens (head and tail). Five-fold cross-validation was used with a repeated weighted k-fold function. The following parameters were used to optimize the results on the validation dataset: batch size (16 and 32 for Bio+ClinicalBERT; 4 for Clinical-BigBird and Clinical-Longformer), learning rate (1e-2 and 1e-5), and weight decay (0 and 0.25). Up to 10 epochs were considered with a stopping rule (a patience of 3 for Bio+ClinicalBERT and a patience of 1 for Clinical-BigBird and Clinical-Longformer). When the parameters were determined, the analysis was completed by combining the training and validation cohorts. The developed models were then applied to the test datasets. The models were analyzed with 2-class labels (cancer progression vs other labels combined) and 3-class labels. The models were run using a workstation with 2 GPUs of 24 GB RAM each.

Model Performance

Accuracy (ie, correct classification) was used to compare model performance by epoch. After the epoch numbers were selected, the model performance was evaluated on the validation and test cohorts. Performance measures for evaluating the 3-class models were based on the predicted probabilities of the "cancer progression" category versus the other 2 categories combined. Reported measures included sensitivity, PPV, area under the curve (AUC; a measure of discrimination), scaled Brier score (a measure of predictive accuracy), and the percentage of charts reduced (ie, true negatives plus false negatives divided by the total number of EHRs). The probability threshold used for sensitivity and PPV was 0.50. Models generated with breast cancer data were applied to the colorectal cancer test dataset, and vice versa, to evaluate generalizability.

Additional output was generated when evaluating the test datasets. The rate of progression over time was calculated for the observed data using the Kaplan-Meier (KM) approach. The predicted rate of progression over time was generated by assuming that the models would be used as a screening tool to reduce the number of charts that need to be reviewed or to replace the need for a chart review. When evaluating the model as a screening tool to reduce the number of charts required to review, the time to first progression predicted by the model on or after the first observed EHR identifying cancer progression was used to calculate time to progression. This was done because when used as a screening tool, users should not identify cancer progression before the observed date. In contrast, when evaluating the model to replace the need for a chart review, the time to the first EHR predicted by the model to mention progression was used to indicate time to progression. The hazard ratio (HR) from a Cox regression model with age at diagnosis (≥65 years vs <65 years) as a predictor was also run using the observed data. Similar to the KM analysis, Cox regression models were run, assuming that the models were used as a screening tool or to replace a chart review. Predicted values close to both observed KM rates and HRs indicate that a model approximated the observed data well.

Model Interpretability

The detection of influential tokens was determined by selecting samples of EHRs identified as true positive, true negative, false positive, and false negative from the test cohorts. EHRs with predicted probabilities near 0.00, 0.50, and 1.00 were sampled. EHRs were modified by replacing individual words or partial sentences with nonsensical terms (eg, XXXXXX) or by adding words or partial sentences that were assumed to be influential. Common terms that describe cancer progression (eg, progression) were added or removed from EHRs. Partial sentences such as *no evidence of progression* and *has not progressed yet* were also added. The predicted probabilities of the original and modified EHRs were compared. If an EHR had a predicted probability near 1.00, individual words and partial sentences were removed until the predicted probability was decreased to near 0.

Ethical Considerations

The study was conducted according to the guidelines of the Declaration of Helsinki and was approved by the University of Manitoba's Health Research Ethics Board (HS21379 [HS2017:422]; approval date March 28, 2022), the University of Waterloo's Ethics Board (44261; approval date April 29, 2022), the Manitoba Health's Provincial Health Research Privacy Committee, and the CancerCare Manitoba's Research and Resource Impact Committee. Because data were retrospectively collected and analyzed, informed consent was not required, and compensation was not provided. No identifiable information was included in the manuscript to further maintain and ensure privacy and confidentiality.

Results

Breast Cancer

In the breast cancer training (19,031 EHRs) and validation (4758 EHRs) datasets, 3884 (16.33%) EHRs indicated cancer progression, and 4324 (18.18%) indicated progression mentioned but not present (ie, ratios of 0.24 and 0.27 relative to the *no cancer progression* class). In the breast cancer test dataset (4486 EHRs), 582 (12.97%) EHRs indicated cancer progression, and 817 (18.21%) indicated progression mentioned

XSL•FO
RenderX

but not present (ie, ratios of 0.19 and 0.26 relative to the *no cancer progression* class). The number of tokens per chart differed by the model tokenizer (Table 1). All 3 tokenizers reported that more than 30% (breast cancer training and validation data: 8860/23,789, 7719/23,789, and 7775/23,789; breast cancer test data: 1955/4758, 1724/4758, and 1737/4758) of EHRs had more than 512 tokens and that no EHRs had more than 4096 tokens.

[a]EHR: electronic health record.

Only 1 epoch was required for the breast cancer models. Bio+ClinicalBERT reached 99% to 100% accuracy in the training dataset by the fourth or fifth epoch, but accuracy for the validation dataset was highest at the first epoch. Clinical-BigBird and Clinical-Longformer reached 99% to 100% accuracy in the training dataset by the second epoch, but accuracy for the validation dataset was highest at the first epoch.

The larger token models (Clinical-BigBird and Clinical-Longformer) demonstrated higher predictive accuracy (ie, scaled Brier scores) than the Bio+ClinicalBERT models in both validation and test datasets (Table 2). The highest sensitivity, PPV, and AUC were also achieved by the larger token models in the test datasets.

[c]AUC: area under the curve.

The test dataset included 140 individuals, of whom 77 (55%) had at least 1 EHR indicating cancer progression. Because the larger token models indicated higher accuracy than the Bio+ClinicalBERT models, an additional output was generated to evaluate their performance. Model predictions were used to identify the first EHR after diagnosis that predicted cancer progression (to represent a model replacing a chart review) and the first EHR on or after the first EHR identifying cancer progression (to represent a model being used as a screening tool). The resulting data were then analyzed using KM curves. All 4 larger token models (Clinical-BigBird and Clinical-Longformer, each with 2- and 3-class outcomes) demonstrated good performance as a screening tool (Figure 1), where KM estimates derived were good approximations of observed cancer progression rates. In total, 3 of the 4 models demonstrated an overestimation of cancer progression when used to replace a chart review. The Clinical-BigBird 2-class model reported the highest PPV (92.3%) among the 4 models and demonstrated estimates very close to the observed data when used to replace a chart review. Similarly, when the data generated were included in Cox regression models with age at diagnosis as a predictor, all larger token models provided results similar to the observed data when used as a screening tool, and all larger token models, except the Clinical-Longformer 3-class model, provided results similar to the observed data when used to replace a chart review (Table 3).

Colorectal Cancer

In the colorectal cancer training (19,182 EHRs) and validation (4795 EHRs) datasets, 2980 (12.42%) EHRs indicated cancer progression, and 3035 (12.66%) indicated progression mentioned but not present (ie, ratios of 0.16 and 0.17 relative to the *no cancer progression* class). In the colorectal test dataset (6405 EHRs), 683 (10.66%) EHRs indicated cancer progression and 807 (12.60%) indicated progression mentioned but not present (ie, ratios of 0.14 and 0.17 relative to the *no cancer progression* class). The number of tokens per chart differed by model tokenizer (Table 1). All 3 tokenizers reported that more than 30% (colorectal cancer training and validation data: 9186/23,977, 7866/23,977, and 7966/23,977; colorectal cancer test data: 2744/4975, 2368/4975, and 2401/4975) of EHRs had more than 512 tokens and that no EHRs had more than 4096 tokens.

Only 1 epoch was required for the colorectal cancer models. Bio+ClinicalBERT reached 99% to 100% accuracy in the training dataset by the fourth or fifth epoch, but accuracy for the validation dataset was highest at the first epoch. Clinical-BigBird and Clinical-Longformer reached 99% to 100% accuracy in the training dataset by the second epoch, but accuracy for the validation dataset was highest at the first epoch.

The Clinical-Longformer models reported the highest sensitivity and PPV for the validation dataset (Table 4). The Clinical-BigBird 3-class model reported the highest AUC and scaled Brier score for the validation dataset. The Bio+ClinicalBERT 2-class head and tail model reported the highest PPV and percentage of charts reduced. The highest sensitivity, PPV, AUC, and scaled Brier score for the test dataset were found with the larger token models, whereas the highest percentage of charts reduced was found with the Bio+ClinicalBERT 3-class tail model.

Application of Models to Different Cancer Sites

When models developed by analyzing colorectal cancer data were applied to the breast cancer test datasets, the results were slightly lower than those obtained from the models developed using breast cancer data (Table 6). For example, the scaled Brier scores ranged from 0.58 to 0.69 when a model developed using colorectal cancer data was applied, but were 0.66 to 0.79 when a model developed using breast cancer data was applied.

Table 6. Results by model and outcome class for the model applied to different cancer sites.

When models developed by analyzing breast cancer data were applied to the colorectal cancer test datasets, the results were also slightly lower than those obtained from the models developed using colorectal cancer data (Table 6). For example, the scaled Brier scores ranged from 0.52 to 0.61 when a model developed using breast cancer data was applied but were 0.49 to 0.65 when a model developed using colorectal cancer data was applied.

Identifying Influential Words in EHRs

Using the Clinical-Longformer 2-class model, influential words were identified by modifying EHRs and reporting differences in predicted probabilities (Multimedia Appendix 1). In addition, all EHRs sampled were provided with ID values for reference (B_1-B_6 for breast cancer and C_1-C_6 for colorectal cancer). The most common influential word identified from the sample EHRs was *progression*. In both the breast and colorectal models, the presence of the word *progression* early in the chart had a larger impact. For example, the predicted probability of sample B_2 decreased from >0.99 to <0.01 when the word *progression* was removed early in the chart. The predicted probability of sample C_2 decreased from 0.99 to 0.08 when the first 2 occurrences of *progression* were removed, despite having 4 additional occurrences of *progression* later in the EHR. The effect of adding the word *progression* to EHRs was inconsistent. When it was added to the first sentence of samples B_1, B_3, B_5, B_6, C_1, C_3, C_5, and C_6, the predicted probabilities increased to 0.70, 0.60, 0.99, 0.98, 0.86, 0.59, 0.88, and 0.57, respectively.

Predicted probabilities were also influenced by the frequency of tokens within an EHR. Adding *progression* twice to EHRs that did not mention *progression* had an inconsistent impact. Although *progression* was added twice in B_3 and C_1, the predicted probabilities were only 0.21 and <0.01, respectively. In contrast, adding *progression* twice to B_1 and C_3 increased predicted probabilities to 0.79 and 0.96, respectively. Brain metastases were mentioned twice in a false-negative sample (B_5). By removing the first occurrence of *brain*, the predicted probability decreased from 0.49 to 0.04. When *brain* was added to the first sentence, the predicted probability increased to 0.63.

Word combinations were also influential. The expression *disease is progressing* increased the predicted probabilities more than adding only the words *disease* or *progression* separately. For example, when this expression was added to the first sentences of samples B_1, B_3, and C_1, the predicted probabilities were 0.91, 0.92, and 0.98 versus 0.70, 0.60, and 0.86 when only *progression* was added. However, the predicted probability remained 0.59 for sample C_3 when either the term *progression* or the phrase *disease is progressing* was added to the first sentence. Despite the inclusion of *progression*, the addition of *no evidence of progression* and *has not progressed yet* was associated with limited increases in predicted probabilities for

XSL•FO
RenderX

true-negative and false-negative EHRs (values ranging <0.01-0.22 for samples B_1, B_3, C_1, and C_3).

Although none of the sample EHRs contained the words *relapse* or *recurrence*, these terms were sometimes used interchangeably with cancer progression (ie, tumor growth occurring without remission) in the physician notes reviewed. When *relapse* was added to the first sentence of true-negative and false-negative samples, the effect on predicted probabilities was inconsistent: 0.07 for B_1, 0.94 for B_3, 0.33 for C_1, and <0.01 for C_3. When *recurrence* was added to the first sentence of true-negative and false-negative samples, the effect on predicted probabilities was also inconsistent: 0.17 for B_1, 0.89 for B_3, 0.91 for C_1, and 0.39 for C_3.

Similarly, the false-negative B_3 sample described an individual with breast cancer who had worsened disease and was subsequently enrolled in the palliative care program (predicted probability of 0.04). The false-negative C_3 sample described an individual with colorectal cancer who had a substantial increase in carcinoembryonic antigen test values that required a change in chemotherapy regimen (predicted probability of <0.01). Although these EHRs included text describing cancer progression, the predicted probabilities generated were near 0. These terms may have been too infrequent in the training data for the language models to recognize them.

Discussion

Principal Findings

The larger token models (Clinical-BigBird and Clinical-Longformer, which can include up to 4096 tokens) demonstrated higher accuracy in capturing cancer progression in EHRs than the Bio+ClinicalBERT models (which can include up to 512 tokens). All larger token models trained on breast cancer data provided good approximations of the observed data when used as a screening tool (ie, provided good approximations for both KM estimates and HRs from a Cox regression model) and could remove approximately 85% of EHRs from the chart review process. The Clinical-BigBird 2-class model also provided good approximations for the observed data when used to replace a chart review. In contrast, the only model trained on colorectal cancer data that provided good approximations for both KM estimates and HRs from a Cox regression model was the Clinical-BigBird 3-class model to replace a chart review.

The models that were generated were not strongly influenced by cancer-site–specific terms (eg, site of cancer progression, site for radiation therapy, and chemotherapy regimen). Breast cancer models applied to colorectal cancer data were only slightly less accurate than colorectal cancer models, and colorectal models applied to breast cancer data were only slightly less accurate than breast cancer models. In addition, cancer-specific terms were not influential when removing or adding words from sample EHRs and generating predicted probabilities. The results from identifying influential words in EHRs suggest that the appearance of the word *progression* earlier in a chart led to higher accuracy compared to when it appeared later in a chart. This could explain why the Bio+ClinicalBERT model that analyzed the tail of EHRs had the lowest scaled Brier scores among the models. This may be because cancer progression more commonly appeared at the beginning of EHRs and allowed better pattern recognition for models that included this information. The lack of cancer-site–specific information could increase the applicability of the current models to a variety of cancer sites. However, larger datasets may be required to identify tokens missed by the current models that would be needed to distinguish the use of *progression* to describe cancer progression (eg, tumor growth and associated change in treatment) from other uses of progression (eg, a patient is progressing well in their treatment), such as terms indicating diagnostic uncertainty and diagnostic procedures. In this situation, the 3-class model would be advantageous in distinguishing between these 2 classes of terms. The results also indicated that models included relationships between tokens where sometimes combinations of words could increase accuracy more than individual words (eg, *disease is progressing* vs only *progression* or *no evidence of progression*). Sometimes the words *relapse* and *recurrence* were used to describe cancer progression (ie, tumor growth without remission), and their less frequent use may explain why they were less influential than the more commonly used word *progression*. In addition, the inconsistent impact of tokens could be due to the absence or presence of other tokens found in an EHR.

Although larger token models demonstrated higher accuracy relative to the Bio+ClinicalBERT models, a limited number of tokens appeared to be strongly captured by the models evaluated for influential tokens. If limited tokens are required to identify cancer progression, providing outcome labels for individual sentences rather than individual EHRs could increase accuracy by limiting the number of tokens that need to be considered, which would facilitate a model's ability to recognize patterns in the analyzed text. In addition, analyzing data at the sentence level would remove the impact of token location within EHRs. However, if limited tokens related to cancer progression are found to be influential because of inadequate examples of less commonly used terminology, larger datasets may be required.

All models demonstrated near-perfect AUC scores (ie, 0.95-0.99). However, AUC only reports whether predicted probabilities are higher for cases than for controls [8,9]. This ignores how close predictions are to outcome labels, as well as the rate of the outcome [10]. Due to these limitations, AUC lacks sensitivity when comparing different models [8]. In contrast, the scaled Brier score is a metric that accounts for the difference between predicted probabilities and outcome labels, while also accounting for the outcome rate [11]. This increases the sensitivity to detect differences between the models. For example, AUC values ranged from 0.95 to 0.99, but scaled Brier scores ranged from 0.49 to 0.79. Although a scaled Brier score of 0.79 may indicate near-perfect prediction, it does not indicate the impact of error (eg, the level of overestimation or underestimation). Because the purpose of the models is to simplify the chart review process, the ideal evaluation would be to compare the data generated from a model with the data generated from a chart review (eg, KM curves and Cox regression estimates compared with the observed data).

XSL•FO
RenderX

Limitations

Comparisons between generated data and chart review data could be biased (ie, KM curves and Cox regression HRs). The test dataset for breast cancer included 77 individuals with a cancer progression event, and the test dataset for colorectal cancer included 127 individuals with a cancer progression event. It has been suggested that external datasets should have at least 100 or 200 events [12-14] (and potentially more [15]) to effectively evaluate model performance. Although the other output reported (eg, sensitivity and PPV) was based on more than 200 events of cancer progression, this output may still be misleading. The previously mentioned recommendations were based on the performance of statistical models, which require substantially less data to achieve the same performance as machine learning models [16] or the same variability in performance [17].

Results generated for the test datasets substantially improved for some models, were relatively unchanged, or were worse in comparison with the validation dataset. Some of the improvement can be expected from generating models that analyze data by combining the training and validation datasets (ie, increased sample size). However, different results could have been obtained from selecting different seeds. Reporting the average and variation of performance metrics across models with different seeds (eg, dozens) would provide more reliable evaluations. This has previously been demonstrated in statistical models when comparing results from split-sampling to bootstrapping [18,19], where split-sampling (ie, reporting the performance of 1 model) required substantially more data than bootstrapping (ie, average across multiple models) to achieve the same level of accuracy. However, the feasibility of averaging model performance metrics depends on computational resources, model complexity, and dataset sizes. For example, the processing time for the training datasets of Clinical-BigBird or Clinical-Longformer models in this study was more than 6 hours using a workstation with 2 NVIDIA RTX A5000 GPUs with 24 GB RAM each. Calculated floating-point operations per second (FLOPS) in single-precision (FP32) operations varied from approximately 750 GigaFLOPS with 2-class Bio+ClinicalBERT models to 13 TeraFLOPS with 3-class larger token models. A larger dataset would be required to generate more accurate models, which would also increase the processing time.

The cancer cohort consisted of Manitoba residents and only included breast and colorectal cancer cases. The results may not be generalizable to other geographic locations where clinical notes and terminology may differ. Model generalizability would need to be evaluated with additional cancer sites.

Conclusions

In conclusion, the Clinical-BigBird and Clinical-Longformer models were able to generate tools to aid in screening EHRs from Manitoba, Canada, to identify breast and colorectal cancer progression. They could potentially remove at least 84% of EHRs from the chart review process to generate data for future retrospective research studies using breast and colorectal cancer EHRs. The colorectal models demonstrated more errors than the breast cancer models. In addition, the models appeared to include limited tokens to generate predictions. Additional research may be required to improve model performance. For example, improvements could be obtained by increasing the training dataset size and by analyzing EHRs at the sentence level rather than at the chart level. Both factors could increase the number of relevant tokens captured by the models for identifying cancer progression.

Acknowledgments

The authors gratefully thank Caroline Nguyen, Gulnaaz Dhillon, Jadon Khouv, and Raju Majumdar for conducting the chart review; Gary Annable for the study coordination; and Alex Zhuang for preliminary analyses. This work was supported by a research grant from the Canadian Cancer Society, Data Transformation Grants 2022 (grant 707584). Abstract

Background: Health care chatbots are rapidly proliferating, while generative artificial intelligence (AI) outpaces existing evaluation standards.

Objective: We aimed to develop a structured, stakeholder-informed framework to standardize evaluation of health care chatbots.

Methods: PRISMA (Preferred Reporting Items for Systematic reviews and Meta-Analyses)–guided searches across multiple databases identified 266 records; 152 were screened, 21 full texts were assessed, and 11 frameworks were included. We extracted 356 questions (refined to 271 by deduplication and relevance review), mapped items to Coalition for Health AI constructs, and organized them with iterative input from clinicians, patients, developers, epidemiologists, and policymakers.

Results: We developed the Health Care AI Chatbot Evaluation Framework (HAICEF), a hierarchical framework with 3 priority domains (safety, privacy, and fairness; trustworthiness and usefulness; and design and operational effectiveness) and 18 second-level and 60 third-level constructs covering 271 questions. Emphasis includes data provenance and harm control; Health Insurance Portability and Accountability Act/General Data Protection Regulation–aligned privacy and security; bias management; and reliability, transparency, and workflow integration. Question distribution across domains is as follows: design and operational effectiveness, 40%; trustworthiness and usefulness, 39%; and safety, privacy and fairness, 21%. The framework accommodates both patient-facing and back-office use cases.

Conclusions: HAICEF provides an adaptable scaffold for standardized evaluation and responsible implementation of health care chatbots. Planned next steps include prospective validation across settings and a Delphi consensus to extend accountability and accessibility assurances.

Introduction

The rapid rise of chatbots, also known as conversational agents, has garnered substantial interest in the health care market. Valued at $787.1 million in 2022, the global health care chatbot market is expected to grow at an annual rate of 23.9% from 2023 to 2030 [1]. This expansion is driven by the increasing demand for virtual health assistance, growing collaborations between health care providers and industry players, and the acceleration prompted by the COVID-19 pandemic. For example, over 1000 health care organizations worldwide developed COVID-19-specific chatbots using Microsoft's Health care Bot service to manage patient inquiries and reduce the burden on medical staff [2]. Entering the age of generative artificial intelligence (AI), health care chatbots have received even more attention since they enable human-level fluent conversations, have reached physician-level performance on board residency examinations [3] and comparable performance on other medical examinations and questions [4-6], and offer easy ways to train and adapt.

However, despite their popularity and potential, evaluating health care chatbots poses many challenges [7-9]. A lack of standardized evaluation approaches has led to diverse and inconsistent methods, making comparing chatbot performance difficult. Rapid technological advancements, particularly in generative AI, outpace existing regulatory frameworks [10], complicating the establishment of evaluation standards. These new chatbots using generative AI are not constrained by decision trees and are often built on top of larger models, meaning both the output and foundation are not stable. With such a moving target for evaluation, there is no widely accepted guideline or framework for evaluating health care chatbots. Developers lack a guide for assessment [11], and users often rely on company advertisements or marketing claims.

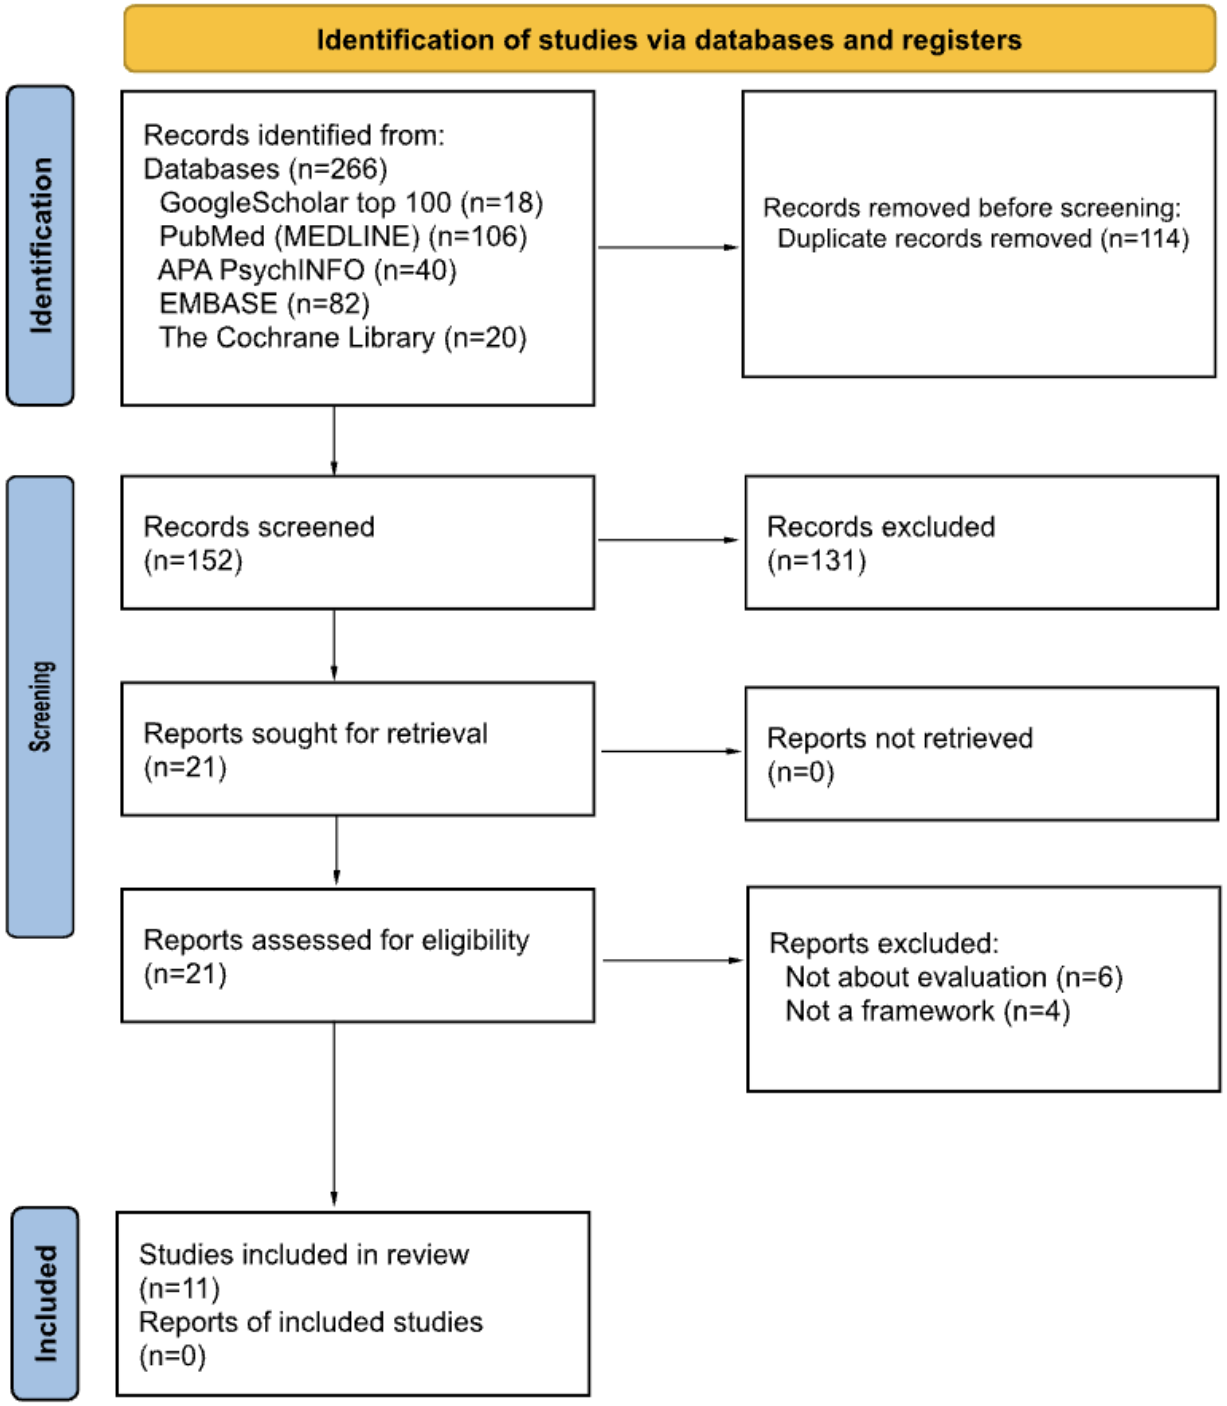
Several evaluation frameworks [12-22] have emerged in response to these challenges over the last few years, particularly following the popularity of generative AI. These frameworks vary—some review existing works and regroup metrics into a new structure, others adapt non–health care evaluation frameworks for this field, and some focus on narrow subdirections such as specific specialties or chatbot types. Given the need for a general guiding evaluation framework, a novel approach is necessary. Inspired by a framework for evaluating health apps [23], which has now been adopted by the American Psychiatric Association, we crafted a general evaluation framework integrating a literature review and broad stakeholder analyses. This approach involves the perspectives of developers, clinicians, patients, and policymakers to create a comprehensive evaluation structure.

Methods

As health care chatbots face a variety of users, there is no single way to evaluate a chatbot. Factors such as safety and privacy, user preferences, technology literacy, accessibility, and treatment goals are crucial in determining the most suitable evaluation method. In addressing these issues, organizations like the Coalition for Health AI (CHAI) have been working on designing guidelines for trustworthy AI. In April 2023, a group of experts representing diverse stakeholders crafted a blueprint for trustworthy AI implementation guidance [24]. This blueprint includes 7 aspects of trustworthy AI in health care: usefulness, safety, accountability and transparency, explainability and interpretability, fairness, security and resilience, and enhanced privacy. But this framework serves more as a theoretical foundation rather than an empirical evaluation framework, and its similarity or overlap with other frameworks remains unclear.

Building on the construct definitions in this blueprint and existing evaluation frameworks, we (1) identified a total of 11 evaluation frameworks; (2) extracted all individual questions from these frameworks; (3) removed redundant and nonrelevant questions; (4) mapped the remaining questions to CHAI constructs, their subcategories, and constructs not covered by CHAI's blueprint; (5) improved the evaluation framework structure with stakeholders, including health care providers, patients, technology developers, epidemiologists, and policymakers; and (6) further merged and rephrased questions based on assigned constructs.

To identify and evaluate existing frameworks for health care conversational agents, we followed the PRISMA (Preferred Reporting Items for Systematic reviews and Meta-Analyses) guidelines to conduct a systematic review (Figure 1). The literature search was performed across multiple databases to ensure comprehensive coverage of relevant studies. The databases and corresponding search terms are shown in Table 1.



The initial search results were screened based on titles and abstracts. Two authors (YH and WX) independently reviewed the titles and abstracts for full-text retrieval, with any discrepancies resolved by discussion with a third reviewer (JT). Full-text articles were then retrieved for further assessment against the inclusion criteria. From the initial 266 records, 152 were screened, and 21 reports were sought for retrieval. After detailed assessment, 11 studies were included in the review, providing a comprehensive evaluation of frameworks for health care conversational agents.

We began by summarizing each framework's intended use to assess specific concepts within a particular domain. The sections detailing the evaluation framework's questions were then extracted and listed. If the study did not explicitly present evaluation criteria in the form of questions, these criteria were rephrased as questions for clarity. The following steps were taken:

1. Describe the use intention: the purpose and intended application of the framework were articulated, highlighting its relevance and scope.
2. Identify the concepts evaluated: the key concepts and dimensions the framework evaluates were identified and outlined.
3. List the evaluation questions: a thorough list of the questions evaluated by the framework was provided. In cases where the study did not present evaluation criteria as questions, these criteria were rephrased into question format for consistency and clarity.

Database	Query
PubMed (MEDLINE)	(“health”[Title/Abstract] OR “medical”[Title/Abstract] OR “medicine”[Title/Abstract] OR “clinical”[Title/Abstract]) AND (“conversational agent”[Title/Abstract] OR “conversational AI”[Title/Abstract] OR “chatbot”[Title/Abstract]) AND (“framework”[Title/Abstract] OR “evaluation method”[Title/Abstract] OR “assessment method”[Title/Abstract])
EMBASE	(‘health’:ti,ab OR ‘medical’:ti,ab OR ‘medicine’:ti,ab OR ‘clinical’:ti,ab) AND (‘conversational agent’:ti,ab OR ‘conversational ai’:ti,ab OR ‘chatbot’:ti,ab OR ‘virtual agent’:ti,ab OR ‘virtual assistant’:ti,ab) AND (‘framework’:ti,ab OR ‘evaluation method’:ti,ab OR ‘assessment method’:ti,ab)
APA PsychINFO	(“health” OR “medical” OR “medicine” OR “clinical”) AND (“conversational agent” OR “conversational AI” OR “chatbot” OR “virtual agent” OR “virtual assistant” OR “digital assistant”) AND (“framework” OR “evaluation method” OR “assessment method”)
The Cochrane Library	(“health” OR “medical” OR “medicine” OR “clinical”) AND (“conversational agent” OR “conversational AI” OR “chatbot” OR “virtual agent” OR “virtual assistant” OR “digital assistant”) AND (“framework” OR “evaluation method” OR “assessment method”)
Google Scholar[a]	(“health” OR “medical” OR “clinical”) AND (“conversational agent” OR “conversational AI” OR “chatbot” OR “virtual agent” OR “virtual assistant” OR “digital assistant”) AND (“framework” OR “evaluation method” OR “assessment method”)

[a]Because Google Scholar does not support advanced search queries, we performed all combinations of searches separately to ensure comprehensive coverage.

To improve the evaluation framework structure, we adopted a similar approach to the 2019 study on creating a taxonomy for smartphone app evaluation [23]. This process involved a form of qualitative factor analysis, where all 4 authors, including 1 clinician, independently reviewed and discussed how the evaluation questions aligned with specific factors or categories. Consensus was reached through iterative discussions to ensure accuracy and relevance, allowing us to systematically organize the questions into meaningful constructs.

Results

The reviewed frameworks are listed in Table 2 with details of their intended use, the concepts evaluated, and the terms used for conversational agents.

Initially, 275 questions were extracted from these frameworks (Multimedia Appendix 1). Questions that contained multiple subquestions were broken down for clarity. Broad questions that were too general to be useful were removed (eg, “Can strategies or solutions be developed to address problems of conversational agents?”). This iterative process led to a refined list of 271 questions, mapped across constructs outlined in the Coalition for Health AI blueprint and beyond (Multimedia Appendix 2).

The final structure of the Health Care AI Chatbot Evaluation Framework (HAICEF) represents 3 priority-level constructs, 18 second-level constructs, and 60 third-level constructs (the first 2 levels are shown in Figure 2 and the full framework is shown in Table 3). The 271 questions covered 56 third-level constructs. Among these questions, Design and Operational Effectiveness accounted for 108 (40%) questions. Trustworthiness and Usefulness accounted for a similar weight of 107 questions each (39%). The most fundamental level of Safety, Privacy, and Fairness included 56 questions (21%).

Figure 2. Pyramid visualization for the Health Care AI Chatbot Evaluation Framework (HAICEF; simplified, first 2 levels only). Priority-level constructs are displayed on the left, with second-level constructs within the pyramid.

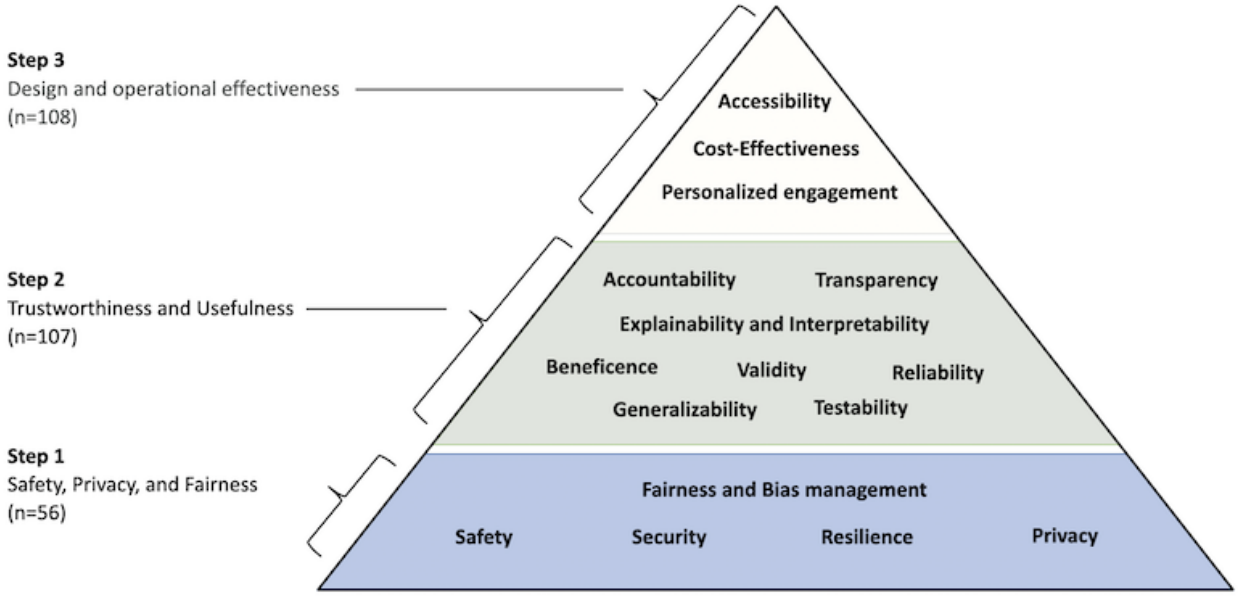

Table 3 presents the full structure of HAICEF, with definitions provided for each concept to enhance clarity. This review-based framework addresses multiple dimensions to ensure the effective, safe, and ethical operation of health care chatbots. For instance, safety considerations include measures such as data provenance, which ensures that the chatbot relies on credible data sources including hospital electronic health records and peer-reviewed studies, and harm control mechanisms to minimize risks, such as providing inaccurate advice that could lead to adverse outcomes. Privacy and security are critical pillars, with requirements for compliance with standards like the Health Insurance Portability and Accountability Act and the General Data Protection Regulation, robust data encryption practices, and clear privacy policies outlining how user data are handled. Fairness and bias management address systemic, computational, and population biases, ensuring that the chatbot provides equitable responses across diverse demographics. The emphasis on accountability and transparency mandates that chatbots clearly communicate their limitations, data usage, and performance metrics while adhering to ethical standards that prioritize patient safety and respect for autonomy. For example, questions such as “Is the chatbot compliant with data privacy regulations?” and “Does the chatbot avoid causing harm through incorrect information?” illustrate the necessity of rigorous evaluation to maintain trustworthiness and ethical integrity in health care applications (Multimedia Appendix 2).

XSL•FO
RenderX

Table 3. Framework for health care chatbot evaluation.

Constructs (levels 1, 2, and 3)	Description
Safety, privacy, and fairness	
Safety	Prevent worse outcomes for the patient, provider, or health system from occurring as a result of the use of an ML[a] algorithm.
Outcome proxies appropriateness	Use alternative measures or indicators that accurately reflect the desired health outcomes in the absence of direct measurements.
Data provenance	Track and document the origin and history of data, including where it came from and how it has been handled. • Data providers: assign roles and responsibilities to entities like hospital EHRsb and patient-generated health data for maintaining safe AIc. • Data sources: include various origins of data, such as social media and clinical settings.
Harm control	Reduce and manage potential risks and negative impacts associated with using a chatbot.
Automation bias reduction	The tendency to accept automated suggestions without critical evaluation or questioning.
Critical help	Provide necessary assistance and address negative and help-seeking information.
Ethics	Principles and standards that govern the conduct of individuals and organizations, ensuring fairness, privacy, and respect in using ML algorithms in health care.
Security	Maintain confidentiality, integrity, and availability through protection mechanisms that prevent unauthorized access and use
Protection method	Implement techniques and tools to safeguard data from unauthorized access and threats.
Security standard	Follow established guidelines and practices designed to protect data and systems from security breaches.
Third-party reliability	Ensure the trustworthiness of external partners or services in maintaining data security and integrity.
Resilience	Withstand unexpected adverse events or changes in their environment or use.
Privacy	Protect privacy according to standards like HIPAA[d] and GDPR[e], ensuring user autonomy and dignity.
Data exchange	Maintain privacy standards for accessing and sharing data with third-party tools, cloud platforms, and other external systems.
Data collection and storage	Maintain privacy standards for gathering and securely storing data for future use.
Data usage	Maintain privacy standards for using collected data for analysis, decision-making, and improving chatbot algorithms.
Privacy policy	Outline how an organization collects, uses, protects, and shares personal data.
Data protection	Implement methods to ensure privacy and prevent unauthorized access and breaches.
Fairness and bias management	Ensure the chatbots operate with minimized and acknowledged biases to ensure fair outcomes.
Systemic bias	Address biases originating from societal norms and institutional practices.
Computational and statistical bias	Manage biases arising from the way data is processed and algorithms are designed.
Human-cognitive biases	Recognize biases stemming from individual or group perceptions and attitudes.
Population bias	Address the issue where certain populations are underrepresented in data, leading to less accurate model performance for those groups.
Trustworthiness and usefulness	
Accountability	Ensure those involved in the chatbot's lifecycle uphold standards of auditability and harm minimization.
Transparency	Communicate clearly regarding the chatbot's characteristics and performance throughout its lifecycle.
Usage specification	Define how the chatbot should be used.
Model characteristics	Describe the specific features and behaviors of the chatbot**.**
Model availability	Ensure the chatbot is accessible as needed.
Model limitations	Identify and communicate the boundaries and constraints of the chatbot.
Data usage	Explain how data is used within the chatbot.
Explainability and interpretability	Described below.
Model explainability	Detail the internal mechanisms and decision-making processes of the chatbot.

XSL•FO
RenderX

Constructs (levels 1, 2, and 3)	Description
Model interpretability	Make the outputs of chatbots clear and meaningful to end-users.
Beneficence	Ensure the chatbot positively impacts its intended outcomes, emphasizing measurable benefits over potential risks.
Health outcomes	Focus on improving health results.
Clinical evidence	Use rigorous methods like A/B tests or randomized controlled trials to validate effectiveness.
Use behavior	Influence and improve user actions.
Intervention	Apply targeted measures to achieve desired outcomes.
Health care system	Integrate effectively within the broader health care environment
Validity	Ensure the chatbot performs as expected in real-world conditions.
Data relevance and credibility	Use high-quality, pertinent training data.
Language understanding	Ensure the chatbot's linguistic capabilities are robust.
Information retrieval accuracy	Accurately retrieve relevant information.
Outcome accuracy	Deliver precise and correct results.
Task completion	Effectively complete required functions.
Reliability	Ensure that the chatbot consistently performs as intended under various conditions and maintains dependable operation over time.
Failure prevention	Prevent system failures to maintain functionality.
Robustness	Handle unexpected inputs and diverse data without errors.
Workflow integration	Fit seamlessly into existing processes.
Reproducibility	Ensure consistent outcomes across different settings.
Monitoring	Continually check chatbots to ensure proper operation.
Up-to-dateness	Keep the system current with the latest information.
Generalizability	Apply learned patterns to new, unseen data.
Contextual adaptability	Function effectively in different environments or clinical contexts. • Age group adaptability: cater to different age groups. • Scenario adaptability: adapt to various situations.
Novel data performance	Perform well with new, unseen data.
Testability	Verify and meet standards for robustness, safety, bias mitigation, fairness, and equity.
Verifiability	Ensure different attributes can be tested. • Quantifiability: measure attributes precisely.
Regular auditing	Measure attributes regularly.
Design and operational effectiveness	
Accessibility	Ensure the chatbot is usable by the intended users regardless of their abilities, devices, or technical skills, promoting inclusivity and ease of use.
Versatile access	Provide multiple interaction methods to accommodate user preferences and needs. • Multilanguage: enable interaction in multiple languages to cater to a diverse user base. • Different input and output modes: accommodate various input and output methods, such as text, voice, and visual. • Multiplatform: ensure functionality across different platforms, such as web, mobile, and desktop applications. • Multidevice: provide compatibility with various devices, including smartphones, tablets, laptops, and desktop computers.
User literacy	Ensure the system is usable by individuals with varying levels of technical knowledge and literacy.

XSL•FO
RenderX

Constructs (levels 1, 2, and 3)	Description
User experience	Create a pleasant and effective interaction for users. • Likability: design the system to be appealing and enjoyable to use. • Understood by the conversational agent: ensure clear communication between the user and the chatbot. • User engagement: maintain user interest and active participation. • Respectfulness: interact with users in a polite and respectful manner. • Response appropriateness: provide suitable and contextually relevant responses. • Credibility: ensure the chatbot's reliability and trustworthiness.
User interface design	Create an intuitive and easy-to-use interface for users.
Simplicity and ease of use	Make the system straightforward and user-friendly, minimizing complexity and effort required from users.
Personalized engagement	Tailor responses based on patient data and preferences.
Personalization	Customized responses based on patient data and preferences.
Anthropomorphism and relationship	Build a human-like relationship with users. • Relationship building: develop a rapport with users. • Empathy: show understanding and compassion. • Humor: use appropriate humor to engage users. • Identity: establish a clear and consistent chatbot persona.
User adherence	Track and analyze how well users follow recommendations and adjust the chatbot's strategies based on this data to improve compliance and outcomes.
Feedback incorporation	Use user feedback to improve the system.
Progress awareness	Monitor and respond to the conversation's context and progress. • Memory: support multiturn or multisession conversations. • Strategy adjustment: adapt the conversation strategy as needed.
Cost-effectiveness	Assess whether the chatbot delivers beneficial outcomes at a reasonable cost, providing a better or more economical solution compared to existing methods.
Comparative effectiveness	Demonstrate that the chatbot is a better solution than previous methods.
Economical viability	Ensure the system is cost-effective.
Environmental viability	Minimize environmental impact.
Task efficiency	Perform tasks quickly and effectively. • Appropriate response time: provide timely responses. • Response conciseness: give clear and succinct information. • Response relevance: ensure responses are pertinent to the query. • Response practicality: offer practical and actionable information.
Workflow considerations	Integrate smoothly into existing systems.

[c]AI: artificial intelligence.

[d]HIPAA: Health Insurance Portability and Accountability Act.

[e]GDPR: General Data Protection Regulation.

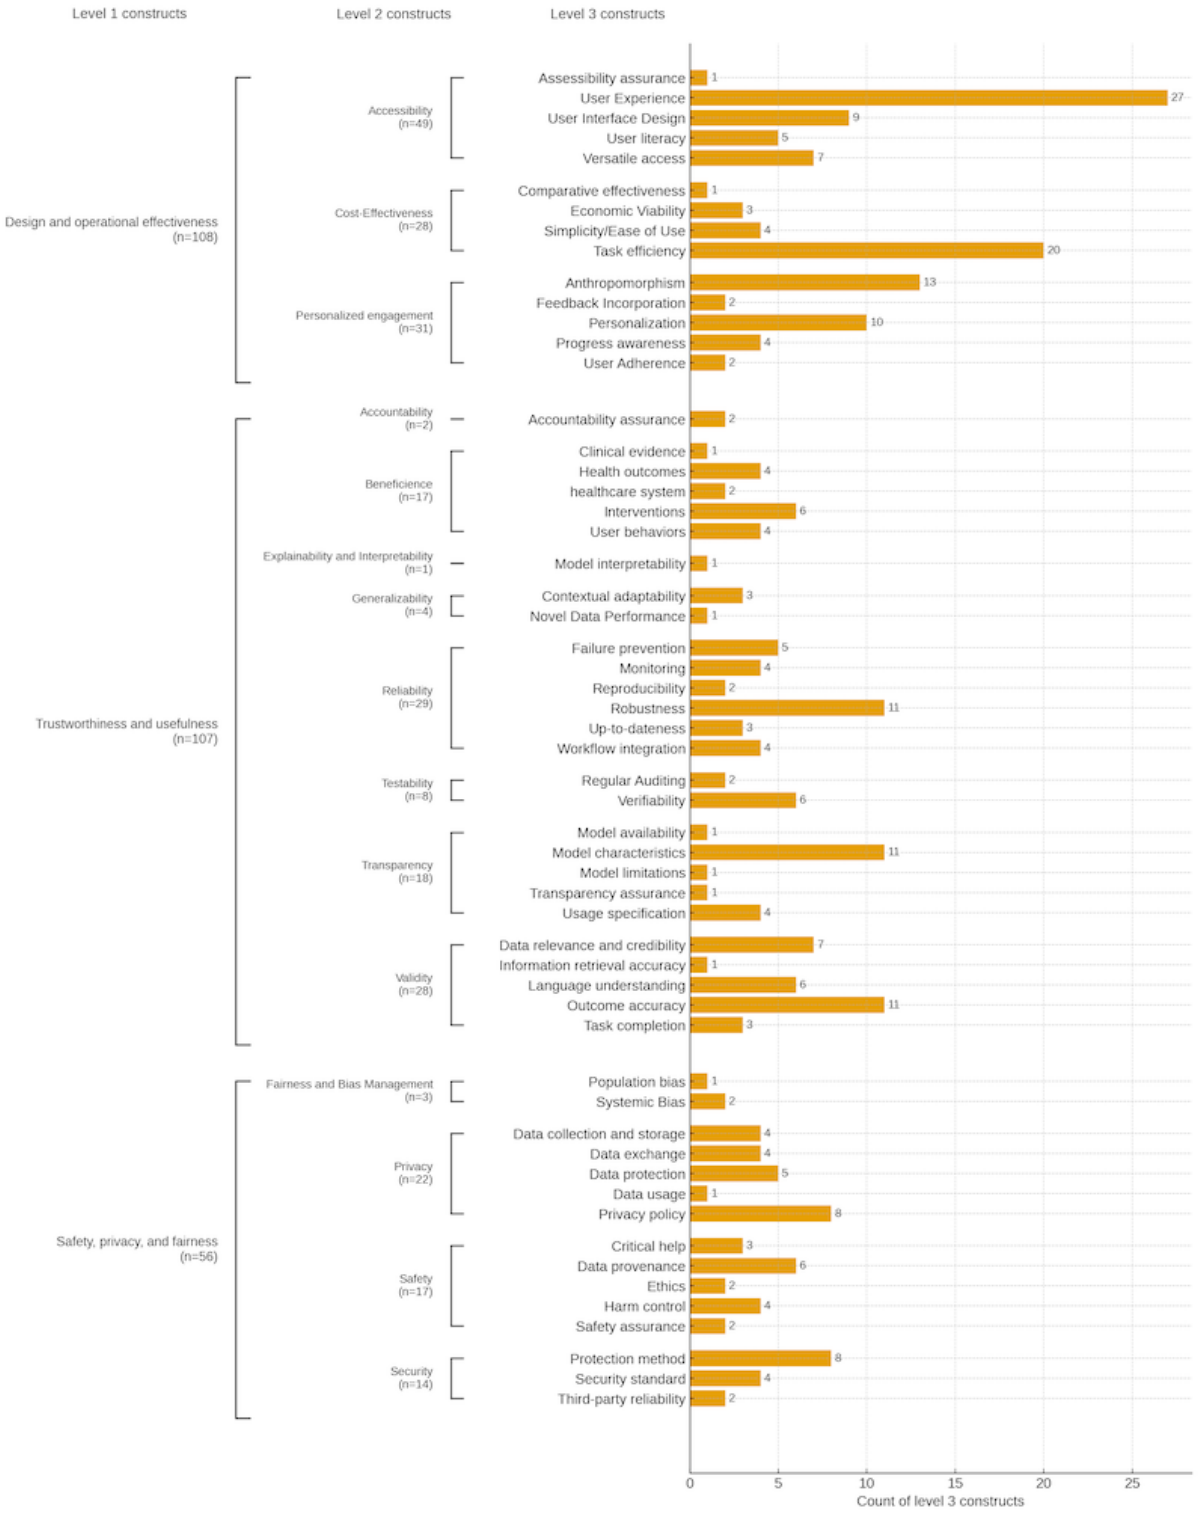

Figure 3 shows the distribution of constructs in the HAICEF framework, which shows a strong emphasis of current framework studies on "design and operational effectiveness," accounting for 108 level 3 constructs, making it the most densely populated level 1 category. Within this, "accessibility" and "personalized engagement" dominate, with 27 and 20 level 3 constructs, respectively, reflecting the importance of inclusivity and tailored user interactions in chatbot evaluation. Conversely, "trustworthiness and usefulness" exhibits a balanced distribution across its level 2 constructs, such as "reliability" (11 constructs) and "transparency" (7 constructs), emphasizing the need for dependable and comprehensible chatbot systems. The "safety, privacy, and fairness" category, though less populous with 56 level 3 constructs, prioritizes critical areas like "privacy" (11 constructs) and "safety" (9 constructs), underscoring foundational principles necessary for secure and equitable operation.

In Table 4, we compare all reviewed frameworks across key evaluation dimensions, including safety, privacy, fairness, trustworthiness, and operational effectiveness. Each prior framework contributes valuable insights but remains partial,

XSL•FO
RenderX

often focusing on isolated aspects rather than providing a comprehensive evaluation structure. HAICEF integrates these fragmented approaches, deduplicating and synthesizing 356 questions into a unified, adaptable framework that addresses the full spectrum of chatbot evaluation needs. By incorporating elements from all existing frameworks, HAICEF establishes the first standardized guidance for a holistic and comprehensive assessment across diverse health care applications.

Figure 3. Distribution of constructs in the Health Care AI Chatbot Evaluation Framework (HAICEF) by level. This figure visualizes the distribution of level 3 constructs within HAICEF across its 3 hierarchical levels. The figure is organized by level 1 constructs (design and operational effectiveness, trustworthiness and usefulness, and safety, privacy, and fairness), with subdivisions showing their level 2 and level 3 components. The lengths of the bars represents the density of constructs within each dimension.

Discussion

Principal Findings

Chatbots are increasingly widely used in health care, but no comprehensive framework for evaluating their performance has been available. We surveyed the existing frameworks and developed a new framework using PRISMA guidelines, which we hope will facilitate future comparisons. The new proposed framework, HAICEF, is designed to meet the myriad users, use cases, and advances around health AI chatbots by providing a flexible scaffolding to support informed decision making.

HAICEF's foundation in safety, privacy, and fairness is well aligned with recent research raising concerns about these aspects of chatbots. A 2024 review of AI apps concluded these apps may cause harm associated with bias [25], and the 2023 real-world case of an AI chatbot for eating disorders giving dangerous information to users [26] highlights the importance of step 1 in our framework (see Figure 2). Not all AI chatbots are patient-facing, and the framework is relevant to scaffolding conversations about clinical documentation chatbots, differential diagnosis chatbots, and even scheduling chatbots given the core aspects of the framework are relevant. For example, while efforts are underway to identify and address bias in conversational agents [27], checking for and identifying bias in any chatbot is a productive first step in considering any conversational agent and is a foundational step for avoiding harm.

Likewise, HAICEF's second step, trustworthiness and usefulness, is grounded in recent research. From concerning trends of conversational agents drawing schizophrenia in a stigmatizing manner [28] to some chatbots providing details on self-harm and how to die by suicide [29], it is critical to assess the trustworthiness and usefulness of conversational agents. Given most conversational agents today are trained on social media, not health data [30], there is justified concern about the utility of the information provided. Additionally, subtle errors can be mixed with correct responses that are difficult for even experts to detect [31]. While there are many approaches to determine trustworthiness and usefulness, and our framework does not dictate which should be used, the structure ensures a focus on this critical issue.

HAICEF also celebrates the success of conversational agents with step 3 considering factors like their often-high degree of accessibility and efforts to personalize content. In placing step 3 after the prior 2, our framework reminds the user to first consider the potential risks and appropriateness of the conversational agent. The majority of frameworks we assessed (Table 4) focused on the questions included here in step 3. Our approach provides a complimentary means to consider these same questions but in the broader context of steps 1 and 2.

XSL•FO
RenderX

The framework offers several advantages by synthesizing insights from previous efforts into a new, synergistic model applicable across diverse health conditions and stakeholder groups. Unlike traditional methods that report isolated metrics, HAICEF re-evaluates existing frameworks to distill and integrate them into a comprehensive general guiding framework. It is not designed to challenge or replace any framework and is flexible enough to incorporate new ones that will likely be developed.

A distinctive feature of the framework is its multilevel tree structure, mapping questions into granular constructs without assigning scores to individual questions. This approach facilitates future development of more detailed, domain-specific evaluation methods, using our framework as a reference or guide. Additionally, we aimed to maintain a consistent level of granularity across all levels of the framework, ensuring that each aspect of evaluation is addressed with equal thoroughness.

The pyramid structure, similar to Maslow's Hierarchy of Needs [32], serves as a visual reminder that evaluation may begin at the base, and progression is likely unnecessary if any level fails to meet the required standards. Still, the user may opt to approach the constructs and questions in any manner that suits their needs. The process of going through these questions will likely facilitate productive dialogue and reveal tensions that must be addressed by the user to make the optimal selection. Thus, this structure does not itself perform an evaluation but rather serves as a scaffold for evaluation. The same chatbot will be evaluated differently depending on the user and their intent for use, reflecting the flexible nature of this framing. The detailed questions, summarized in Multimedia Appendix 1, are designed to encourage and facilitate dialogue among stakeholders, with responses contextualized within each stakeholder's unique situation. For instance, some chatbots may collect user conversation histories for training purposes by default. Some patients may find this unacceptable, while others may be comfortable with it. Similarly, developers focused on improving chatbot validity and reliability should not be compelled to conduct user feedback field studies if their research scope explicitly excludes user experience.

The rise of generative AI, such as ChatGPT [33], has expanded interest in health care chatbots, placing a pressing need for robust evaluation guidance. Yet the emergence of so many frameworks may create more uncertainty. By assessing the details of numerous frameworks, we were able to simplify and unify different approaches to help inform decision-making. The current framework is designed to be flexible and serve various decision makers—from a designer seeking to create a new chatbot to a patient selecting one from the marketplace. Depending on the user and use case, a different weighting to each construct will be necessary, in the same manner that ethical principles offer a scaffold to guide diverse decision making. Our analysis (see Figure 3) suggests that while most frameworks emphasize factors like user experience and task efficiency, stakeholder feedback indicates that focusing on safety and usefulness (see Figure 2) may better match user needs and concerns. Furthermore, we hope these findings will help guide policymakers to design effective evaluation regulations for health care chatbots, safeguarding the quality of information and providing a clear roadmap for businesses worldwide to further develop tools that improve care.

Finally, certain constructs, such as accessibility assurance and accountability assurance, remain placeholders due to limited coverage in the literature. These elements underscore the need for further investigation to develop more specific evaluation questions and classifications. As research on these areas grows, we anticipate integrating new findings into an expanded framework that remains both comprehensive and adaptable.

This approach has several limitations. The framework should be validated prospectively in different contexts to ensure that it is comprehensive and captures important dimensions. There may be additional dimensions that need to be added as the underlying technology quickly evolves, uncovering new issues. Another limitation pertains to the selection and appraisal of source articles. We did not perform a formal quality assessment of each included framework beyond ensuring they met the inclusion and exclusion criteria (eg, scope and relevance to health care chatbots). All frameworks that aligned with these criteria were deemed acceptable. We justified this approach in order to cast a broad net and capture the wide diversity of existing evaluation tools. However, future iterations of this review and framework could benefit from a standardized critical appraisal of each source to more rigorously assess the quality of the evidence guiding HAICEF.

Given the absence of a universal standard for evaluating health care chatbots, many parallel review tools have emerged, often failing to capture the full range of important considerations. Our framework addresses this gap, offering a comprehensive, adaptable tool for the evaluation of health care chatbots, which we hope will lead to responsible integration of chatbots into health care settings. Furthermore, we hope that this review will help guide policymakers to design effective evaluation regulations for health care chatbots, both to safeguard the quality of information and provide a clear roadmap for businesses worldwide to further develop tools that improve the quality, efficiency, and effectiveness of care.

HAICEF presents a starting point that will evolve. Next steps include fully exploring the needs of different users of health AI chatbots and their most common intents and goals. Exploring chatbots beyond the classical medical domains (eg, nephrology and radiology) and understanding functions across the health care ecosystems (from scheduling to crisis support) will help ensure the framework is responsive to real-world needs. Further work to expand the granularity of individual questions and their focus on users (eg, developers versus clinicians) will help improve usability. Additionally, we plan to engage a broader range of stakeholders through a Delphi consensus process to ensure the framework's inclusivity and adoption. These efforts aim to establish HAICEF as a rigorous and widely adopted standard, enabling consistent and comparable evaluations across the health care sector. Through these efforts, we hope to establish a more rigorous, inclusive, and widely adopted evaluation framework for health care chatbots and enable "apples to apples" comparisons between them.

Conclusions

This is the first work to develop a structured and adaptable framework for evaluating health care AI chatbots, addressing the urgent need for standardized assessment criteria. By synthesizing insights from existing frameworks and diverse stakeholders, we developed a structured approach that prioritizes safety, privacy, trustworthiness, and usefulness. This framework is intended to guide the responsible evaluation and implementation of chatbots in health care, helping to ensure their safe and effective use. Future work will focus on validating and refining this framework in different contexts.

Acknowledgments

During the preparation of this work the authors used ChatGPT-4o (web version, OpenAI; (accessed June 26, 2024, to July 2, 2024) to rephrase some of the framework questions into binary questions (Multimedia Appendix 2). After using this tool, the authors reviewed and edited the content as needed and take full responsibility for the content of the publication.

Conflicts of Interest

Abstract

Background: Artificial intelligence (AI) and machine learning models are frequently developed in medical research to optimize patient care, yet they remain rarely used in clinical practice.

Objective: This study aims to understand the disconnect between model development and implementation by surveying physicians of all specialties across the United States.

Methods: The present survey was distributed to residency coordinators at Accreditation Council for Graduate Medical Education–accredited residency programs to disseminate among attending physicians and resident physicians affiliated with their academic institution. Respondents were asked to identify and quantify the extent of their training and specialization, as well as the type and location of their practice. Physicians were then asked follow-up questions regarding AI in their practice, including whether its use is permitted, whether they would use it if made available, primary reasons for using or not using AI, elements that would encourage its use, and ethical concerns.

Results: Of the 941 physicians who responded to the survey, 384 (40.8%) were attending physicians and 557 (59.2%) were resident physicians. The majority of the physicians (651/795, 81.9%) indicated that they would adopt AI in clinical practice if given the opportunity. The most cited intended uses for AI were risk stratification, image analysis or segmentation, and disease prognosis. The most common reservations were concerns about clinical errors made by AI and the potential to replicate human biases.

Conclusions: To date, this study comprises the largest and most diverse dataset of physician perspectives on AI. Our results emphasize that most academic physicians in the United States are open to adopting AI in their clinical practice. However, for AI to become clinically relevant, developers and physicians must work synergistically to design models that are accurate, accessible, and intuitive while thoroughly addressing ethical concerns associated with the implementation of AI in medicine.

Introduction

Background

Artificial intelligence (AI) is a topic of significant interest in recent literature. It has garnered considerable attention as a potential tool to aid in detecting, diagnosing, and managing diseases and demonstrated efficacy in detecting diabetic retinopathy, diagnosing skin cancers, and even predicting patients' surgical candidacy [1-5]. As artificial intelligence grows increasingly capable, one might expect an associated increase in the clinical uses of such programs; however, AI models are rarely harnessed in medicine today outside the realm of research [6,7].

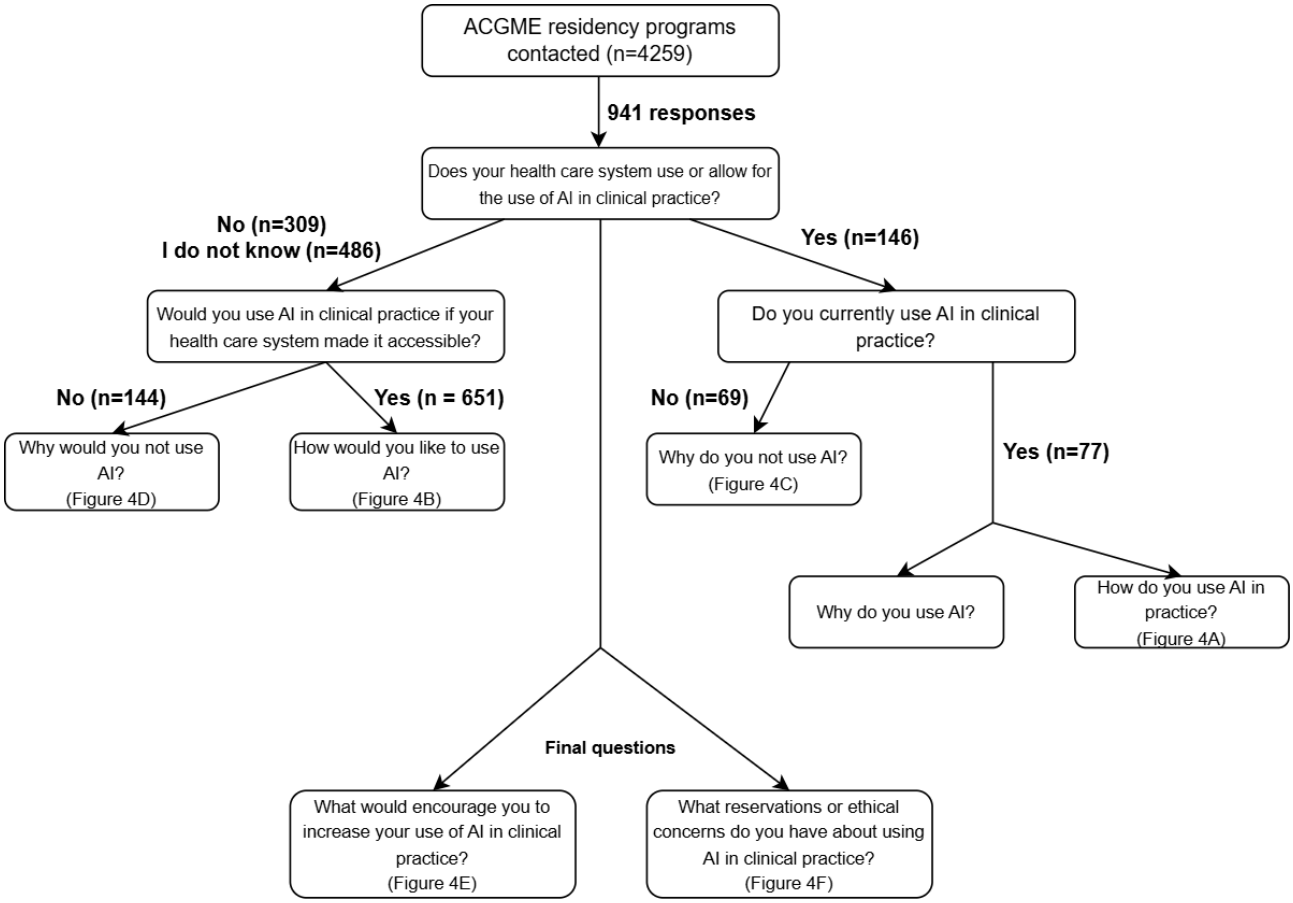
The disconnect between model development and deployment has been examined previously [8-10]. The lack of clinical implementation of AI and machine learning techniques often stems from a lack of physician trust in model accuracy and the difficulties associated with integrating models into existing clinical paradigms, such as electronic health record platforms [11]. Current articles on the topic are often authored by field experts and frequently present subjective or anecdotal findings rather than a systematic exploration of sentiments toward AI in medicine at large. For AI to realize its potential and become a clinically relevant tool, it is essential to understand how physicians foresee its use and integration.

Objectives

This study aims to quantify key factors relevant to integrating AI into clinical medicine, including physician adoption and use, incentivization strategies, and ethical considerations. To achieve this, we developed and distributed an anonymous survey using the Qualtrics platform (Qualtrics International Inc, Provo, UT) to resident and attending physicians associated with academic institutions across all medical specialties throughout the United States. The diversity and volume of responses to this survey yielded, to our knowledge, the largest and most comprehensive dataset to date of physician perspectives on the implementation of AI. In doing this, we aim to analyze use patterns across a broad range of physicians to better understand the gap between AI model development and clinical implementation.

Methods

Ethical Considerations



This study was conducted according to the Declaration of Helsinki, which sets ethical principles for medical research involving human participants [12]. As the present study involved a minimal-risk, de-identified survey, formal Institutional Review Board (IRB) review was not required.

Survey Instrument

The survey was initially conceptualized and developed by 2 authors. It was subsequently reviewed independently by 5 senior coauthors; after a group discussion, relevant modifications were incorporated, and all contributing authors approved the final version of the survey. The survey was piloted at our home institution before being distributed nationally. The final 14-item survey included 7 demographic questions (eg, training status, specialty, years in practice, and practice setting), followed by 7 AI-related questions assessing awareness, intent to use, perceived use cases, incentives, and ethical concerns. Conditional branching logic was used to display specific follow-up questions based on prior responses (Figure 1) to obtain a deeper understanding of the rationale behind response selections. The complete survey is provided in Multimedia Appendix 1. The survey was designed and distributed in accordance with the CHERRIES (Checklist for Reporting Results of Internet E-Surveys) checklist [13].

XSL•FO
RenderX

Figure 1. Flowchart of survey format. Participants were displayed subquestions depending on their selection of the questions shown here, presented as branches. ACGME: Accreditation Council for Graduate Medical Education; AI: artificial intelligence.

Study Design and Distribution

The survey was distributed to residency program coordinators representing 18 medical and surgical specialties in the United States: anesthesiology, dermatology, emergency medicine, family medicine, general surgery, internal medicine, neurology, neurosurgery, obstetrics and gynecology, ophthalmology, orthopedic surgery, otolaryngology, pediatrics, plastic surgery, psychiatry, radiation oncology, diagnostic radiology, and urology. These specialties were chosen to represent a diverse cross-section of core disciplines in US residency training.

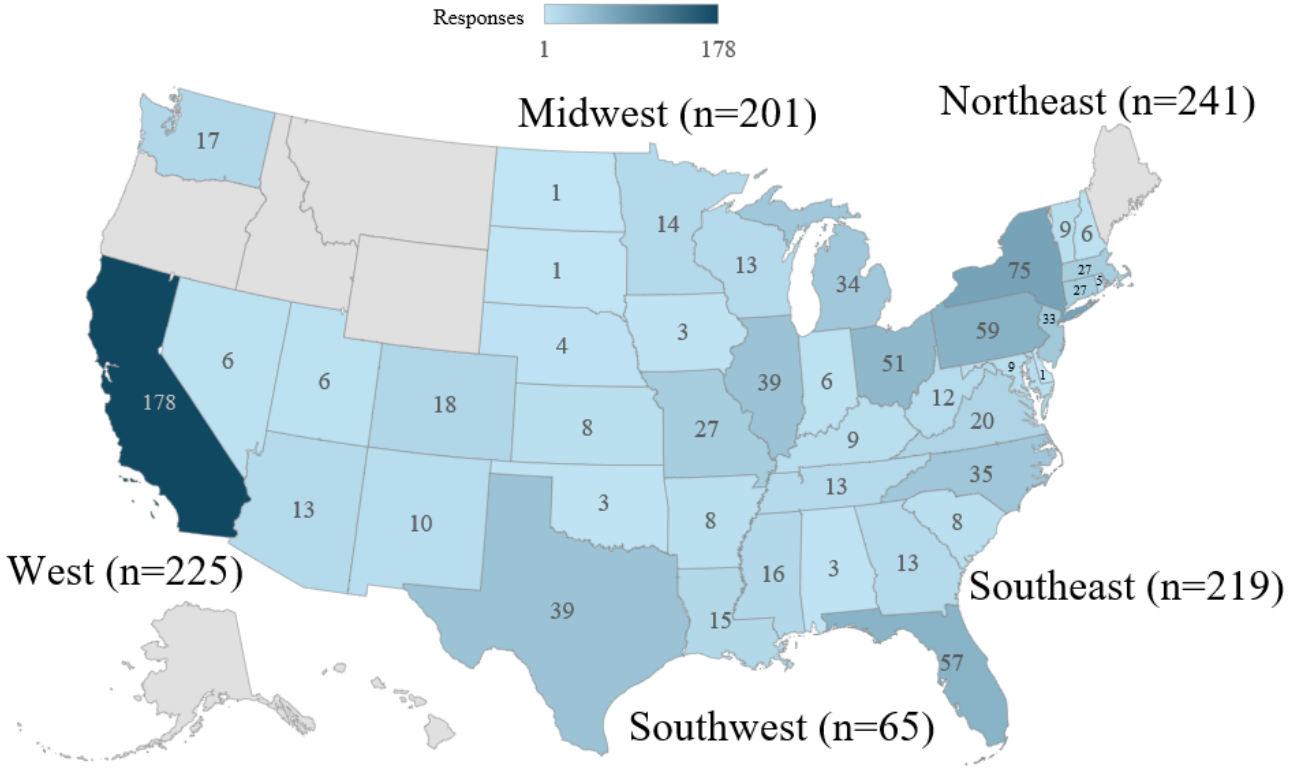
This open survey used a nonprobability referral sampling design, relying on program coordinators from Accreditation Council for Graduate Medical Education (ACGME)–accredited residency programs to distribute it to associated resident physicians and attending physicians. Program coordinators' contact information was manually obtained from the publicly accessible ACGME program search website. If an email address was invalid, the residency program's website was queried to obtain an updated email address. Correspondence containing the Qualtrics survey was first sent to program coordinators on January 11, 2023, by 1 author. The same author sent follow-up correspondence at 1-month and 2-month intervals after the initial outreach. Program coordinators who confirmed survey distribution were excluded from follow-up communications. The survey remained open for responses until November 3, 2023, allowing for an 11-month data collection period.

Survey participation was voluntary, anonymous, and without incentives. However, cookies, approximate location, and IP address were automatically collected using the Qualtrics platform to identify and remove duplicate submissions. Only complete responses were included in this analysis. As surveys were distributed to program coordinators, who subsequently disseminated them, the true survey response rate was not documented.

Statistical Analysis

Statistical analyses were conducted using the *SciPy* (version 1.11.4) and *Statsmodels* Python libraries. For group comparisons, chi-square tests of independence were used to evaluate differences in categorical variables. Phi coefficients were calculated as a measure of effect size for 2x2 contingency tables, and Cramér V was reported for larger contingency tables. A P value of <.05 was considered statistically significant. For proportion comparisons, 95% CIs were calculated using the Wilson score method. All tests were 2-tailed and conducted on complete-case data.

Results



Survey Respondents and Demographics

Of the 4405 programs contacted, coordinators from 645 programs (14.6%) confirmed by email that they had distributed the survey. Figure 1 summarizes the number of responses to the questions and responses within conditional branch points. Table 1 presents participant demographics. A total of 941

XSL•FO
RenderX

physicians completed the survey, including 384 (40.8%) attending physicians and 557 (59.2%) resident physicians. Among attending physicians, the mean time in practice was 15.43 (SD 11.49) years. Responses were received from 43 US states and Washington, DC. Among respondents, 23.7% (225/951) practiced in the West, 21.1% (201/951) in the Midwest, 6.8% (65/951) in the Southwest, 22.9% (219/951) in the Southeast, and 25.3% (241/951) in the Northeast (Figure 2). Of the 941 participants, 10 (1.1%) reported practicing in more than 1 state; in these instances, 1 point was assigned to each state listed. No responses were recorded from Alaska, Hawaii, Idaho, Maine, Montana, Oregon, or Wyoming. Regarding practice setting, 83.2% (768/923) practiced in an urban setting, 11.8% (109/923) in a rural setting, and 5% (46/923) in a suburban setting (Table 1). Of the 923 respondents, 22 (2.4%) used the *other* free-response option. On manual review of these responses, none could be definitively classified into the aforementioned practice-setting categories; therefore, these were excluded from setting comparisons. Concerning the type of practice, 51.8% (494/954) worked in a university practice, 7% (67/954) in a government practice, 35% (334/954) in a hospital-owned practice, and 6.2% (59/954) in a physician-owned practice (Table 1). Of the 954 respondents, 67 (7%) chose *other* and were therefore excluded from type-of-practice comparisons because they did not align with the other 4 categories.

Figure 2. Geographic heat map of locations where physician survey participants practiced. Geographic regions were divided based on National Geographic Education outline maps. Physician submissions from California represented the largest group (n=178), while those from Delaware, Nebraska, North Dakota, and South Dakota represented the smallest group (n=1 each). Other responses not shown on the heat map include Washington DC (n=4). No responses were recorded from Alaska, Hawaii, Idaho, Maine, Montana, Oregon, or Wyoming.

The Use of AI in Clinical Medicine

Most of the participants (795/941, 84.5%) were either unaware whether using AI was permissible in their practice or could not use AI in their health care setting. Figure 3 summarizes the responses to this survey question by physician specialty. Of the 795 respondents, 651 (81.9%) stated that they would use AI if their health care setting permitted it. Table 2 shows comparisons in responses to this question stratified by training status (resident physician vs attending physician), practice setting, and type of practice. Significantly more resident physicians (407/481, 84.6%, 95% CI 81.1%-87.6%) were open to using AI than attending physicians (244/314, 77.7%, 95% CI 72.8%-82%; χ^2=5.7; ϕ=0.08; *P*=.02). Similarly, a significantly higher proportion of urban practitioners (538/646, 83.3%) were open to using AI than rural practitioners (68/94, 72.3%, 95% CI 62.6%-80.4%; χ^2=5.9; ϕ=0.09; *P*=.03). There was no statistically significant difference in willingness to use AI between types of practice (χ^2=0.2; Cramér V=0.02; *P*=.97).

Figure 3. Artificial intelligence (AI) use in clinical practice by specialty. A total of 941 physicians from 18 specialties indicated whether their health care system allowed AI use in clinical practice. This was the first survey question displayed to all participants, and they were required to select only from the 3 options shown.

University (n= 412)	338 (82.0)	74 (18)

[a]Physicians were able to select multiple options if they practiced in more than 1 state.

Data were also collected regarding how physicians would use AI if given the opportunity and explored factors influencing their present use or nonuse (Figure 4 A-C). Among the respondents who indicated that they would use AI if allowed, the most common applications were risk stratification (513/651,78.8%), image analysis or segmentation (352/651, 54.1%), and disease prognosis (295/651, 45.3%). When stratified by specialty, medicine respondents most often indicated interest in using AI for risk stratification (316/422, 74.9%), followed by image analysis or segmentation (197/422, 46.7%) and clinical decision-making (190/422, 45%), whereas surgical respondents more frequently selected risk stratification (197/229, 86%), followed by image analysis or segmentation (155/229, 67.7%) and disease prognosis (124/229, 54.1%) (Table 3). Although surgical decision-making was the least frequently selected use of AI overall (98/651, 15.1%), surgeons (66/229, 28.8%, 95% CI 23.3%-35%) were significantly more likely than nonsurgeons (32/422, 7.6%, 95% CI 5.4%-10.5%; χ^2=50.7; ϕ=0.28; *P*<.001) to indicate interest in this application.

RenderX

Opinions Regarding the Utility of and Reservations About AI

The most common incentives for wanting to use AI (Figure 4 A-C, E) were proof of utility or success of AI in clinical practice (763/941, 81.1%) and better integration into the clinical workflow (683/941, 72.6%). Among the stated reservations about using AI (Figure 4F), the most commonly listed was clinical errors made by AI (742/941, 78.9%), whereas the second most common was a concern about AI replicating and perpetuating human biases 583/941, 62%).

Discussion

Principal Findings

This study describes the perspectives of academic physicians on adopting AI in medicine, based on survey responses from 941 physicians across all 18 specialties accredited by the ACGME. Our results demonstrate that, broadly, physicians at academic institutions in the United States are interested in harnessing AI in their clinical practice, particularly for risk stratification, image analysis or segmentation, and disease prognosis. However, this eagerness to adopt AI is tempered by significant and pertinent ethical concerns regarding perpetuating human biases. To our knowledge, this study represents the largest and most diverse dataset to date of physician perspectives on AI.

Given the wide-ranging potential of AI, the term itself carries a high degree of ambiguity in interpretation, both in this study and society at large. [14]; for instance, the term artificial intelligence can be applied to several technologies, ranging from virtual assistants to robotic navigation systems [15]. Essentially, AI refers to the capability of an automated machine to replicate human intelligence, such as understanding and interpreting data to make decisions in ways that approximate human reasoning [16]. Our observation, that 51.6% (486/941) of the respondents were unsure about whether their health care system permitted the use of AI techniques, may be explained by this lack of a concrete definition or understanding of what the term *artificial intelligence* constitutes. Solidifying this consensus would address at least some of this observed discrepancy [17].

Despite our imperfect understanding of AI in medicine, this survey demonstrates that academic physicians are eager to adopt it in clinical practice. The majority of the physicians (651/795, 81.9%) indicated that they would use AI if given the opportunity. Among the options provided, risk stratification was cited as the most frequent intended use. Patients regularly want to know about their prognosis, how long they might live with a given disease, or their chances of experiencing a complication during a procedure [18]. The ability to input patient-specific data into an algorithm, integrate AI-derived insights, and receive individualized prognostic data would provide immense value for patients in terms of setting expectations and maintaining transparency [19].

The least frequently selected intended use of AI was surgical decision-making (98/651, 15.1%). This is partly a result of fewer surgeons comprising the cohort of respondents (324/941, 34.4%). Unsurprisingly, a significantly greater proportion of surgical respondents indicated that they might use AI to help with surgical decision-making (66/229, 28.8%; $P<.001$), but the overall proportion still remains relatively low. The results of this study suggest that surgeons foresee using AI in several areas of medicine more readily than in surgical decision-making (Table 3), including risk stratification (197/229, 86%) and image analysis or segmentation (155/229, 67.7%). This observation may in part be due to the phrase “surgical decision-making,” which could be interpreted to mean second-to-second decisions during an active procedure or surgery, in which case it might seem difficult to imagine a real-world application of AI that does not interfere with the pace or rhythm of surgery [20]. Moreover, it could be due to a lack of imagination as to what an AI model can process as input, as preoperative planning often involves synthesizing various information modalities. Without further insight into the respondents’ rationale, we can only speculate why only a few participants (98/651, 15.1%) expressed interest in using AI for surgical decision-making. Ongoing work aims to clarify why, among the options presented, surgical decision-making was perceived as the least applicable AI integration and how this perception might be addressed in future model development.

In our survey, 81.1% (763/941) of the physicians indicated that increased proof of the success of new models in clinical practice would encourage their adoption of AI techniques. This speaks to an important, whether real or perceived, drawback of AI adoption in the current health care system. Realizing the success of AI may not be sufficient for widespread adoption, as 72.6% (683/941) of that physicians felt that improving the integration between AI algorithms and clinical workflow was another important incentive for its use. This should come as no surprise; physicians are unlikely to engage with a technology that is neither trustworthy nor easy to use [21,22].

One concern about the use of AI in medicine expressed by all respondents involves the ethical considerations of using AI algorithms. Respondents seemed most concerned about the possibility of introducing nonhuman error. Such a concern is understandable but fails to appreciate the alternative status quo in which human errors abound [23]. Rather than holding AI models to the impossible standard of perfection, these models should be compared to the current paradigm in which human beings practice medicine and make errors, as the goal of AI should be to provide *improved* rather than *perfect* medical treatment [24].

Another focal concern regarding implementing AI in medical practice among respondents was the potential for replicating human biases (583/941, 62%). Several articles have cited bias as an issue that must be resolved before the clinical integration of AI [25,26]. A landmark paper by Obermeyer et al [27] found that racial bias was deeply embedded in a widely used medical algorithm for predicting health care costs. At a given risk level, Black patients were significantly sicker than White patients because the algorithm used health care costs rather than illness severity to assign risk, significantly reducing the likelihood that Black patients were identified as needing additional care. One may argue that health care expenses were—in retrospect—a poor and biased indication of health; however, such bias is well known to persist even in models trained on actual clinical

XSL•FO
RenderX

decision-making trends [28,29]. This is largely due to the lack of diversity in age, racial, ethnic, and geographic distributions in the datasets used to train medical machine learning models [30,31]. As it is unknown whether a model's prognostic accuracy applies equally—or at all—to populations that differ from the training dataset, applying models to populations that have not been validated can generate inaccurate results that mislead physicians [32]; for example, a study testing 5 most commonly used medical machine learning algorithms demonstrated significantly better performance in White patients than in other racial groups despite being trained on a large, publicly available database [33,34]. Models trained on homogeneous data—or those that fail to report the demographic data on which they were trained—are not appropriate for clinical practice, as physicians will be unable to ascertain how deploying such models in clinical practice may impact the care of the patient they are treating. This limits the application of AI in medicine and speaks to the need for both more diverse datasets and data transparency in medical machine learning. These concerns should be thoroughly addressed before widespread clinical adoption of all machine learning models.

To our knowledge, this study represents the largest and most diverse assessment to date of attitudes toward implementing AI in clinical practice. Overall, our results demonstrate that academic physicians are open to implementing AI in clinical practice, especially after specific concerns regarding model evaluation and integration are addressed. However, AI models are vulnerable to any bias present in the data on which they are trained, and thus, the success of AI in medicine will rely as much on the quality as the quantity of training data [35]. For AI to become truly beneficial, we must harness the breadth of objective patient-specific data that are becoming increasingly available, such as through wearable devices, digital phenotyping, and other objective metrics. Even for successful models, widespread adoption may be an uphill battle. We expect that as physicians become more familiar with AI and the general population grows accustomed to its use in other domains, the integration of AI into clinical practice is likely to follow.

Comparison With Prior Work

The scope and utility of AI in medicine continue to expand alongside advances in broader society. Nevertheless, large-scale research studies exploring physician perceptions of AI in medicine are scant and focus on a narrow subset of specialties. Doraiswamy et al [36] surveyed 791 psychiatrists from 22 countries, while Pecqueux et al [37] surveyed 147 German surgeons, and De Simone et al [38] surveyed 200 members of the World Society of Emergency Surgery. To our knowledge, our sample of 941 physicians spanning 18 discrete specialties is the first of its kind in both size and scope.

Implications for Implementation

Essential insight into strengthening the practical utility of AI may come from the two most frequent reasons cited by the minority of physicians (144/795, 18.1%) for not adopting it: (1) an insufficient understanding of AI (84/144, 58.3%) and (2) a distrust in the accuracy of AI models (81/144, 56.3%; Figure 4D). These findings suggest that AI developers still have work to do in explaining how their technology works and validating its efficacy. Some of this understanding may develop naturally over time as AI becomes more common in nonmedical settings, making it feel more familiar to physicians and the public alike. However, there are specific actions that developers could take now that might help them in this effort; for instance, the introduction of AI into medicine would benefit tremendously from explainable AI methods, which provide insight into how a model generates predictions and help counter the perception of AI as a "black box." In addition, explainable AI methods such as gradient-weighted class activation mapping, occlusion maps, and Shapley additive explanation values should be incorporated into research papers proposing new AI use cases in medicine [39]. Ultimately, for AI to be clinically relevant, models must not only demonstrate success in addressing risk-sensitive decisions but also be intuitive and adaptable to the demands of everyday clinical practice.

Limitations

Our study provides valuable insights into physician perspectives on AI in medicine, but several limitations should be acknowledged. First, the survey targeted only physicians affiliated with ACGME-accredited teaching institutions, which limits the generalizability of our results to the broader population of American physicians, including those in community-based settings; however, given the wide breadth of ACGME-accredited residency programs and the hospitals they serve—including many that cross-cover veterans' and community hospitals—we believe that the diversity of respondents across specialties and geographic regions is fairly representative of academic physicians overall. Future works are needed to identify whether a similar trend exists among physicians in community-based settings. Second, the survey was designed to be distributed via residency coordinators, making it impossible to determine the number of coordinators who actually forwarded the survey compared to the number of completed responses, limiting the validity of our study. We also cannot determine, therefore, whether certain institutions, for instance, those with an interest in AI, comprised a more significant percentage of the survey responses than other institutions. It is certainly possible that institutions with an interest in AI may have made up a large portion of our response rate, thus influencing the results of our study in favor of the use of AI. Due to the anonymous nature of this study, we are unable to determine whether this bias exists. In addition, only complete responses were included in this analysis, and view, participation, and completion rates were not recorded. Finally, while our survey was designed to explore physicians' perspectives on AI, we did not formally assess respondents' understanding of what constitutes AI. This introduces the potential for variation in interpretation, particularly for questions about AI-related clinical applications. Future studies should include a standardized definition of AI to ensure uniform understanding among respondents.

Overall, the success of this study design depended on three key factors: (1) the availability of reliable contact information for program coordinators, (2) the coordinators' willingness to distribute the survey, and (3) the intended respondents' willingness to complete it. Although this study does not capture the full spectrum of American physicians and trainees, to our knowledge, it represents one of the most extensive datasets of

XSL•FO
RenderX

physician perspectives on AI in medicine. We emphasize that these findings reflect the perspectives of this specific subset of respondents and are not intended to be generalized to the entire physician population.

Conclusions

AI represents an exciting, ever-evolving domain of opportunity for improving clinical practice. However, limited understanding of AI and its utility, uncertainty regarding its performance, and concerns about the perpetuation of human biases remain critical barriers that must be overcome in the process of gaining trust among clinicians who are considering using AI in their practice. This study reflects physicians' opinions and perceived use cases of AI across a variety of specialties and practice settings, quantifying both the reasons why they currently use or are eager to implement AI as well as the rationale for not using or preferring not to adopt AI in their practice. The most desired avenues for implementing AI in medicine were risk stratification, image analysis or segmentation, and disease prognosis, while the most cited reservations were concerns about clinical errors made by AI and the potential for replicating human biases.

Although this study does not fully represent American physicians and trainees, to our knowledge, it represents one of the largest and most diverse datasets of physician perspectives on AI in medicine. Ultimately, the data and insight provided in this work aim to lay the foundation for how AI may best be modified by scientists and harnessed by physicians to be optimally integrated into clinical practice.

Acknowledgments

The authors would like to dedicate this work in honor of Dr Bilwaj Gaonkar, PhD, a member of our lab who passed away prior to this study. This study would not have been possible without him.

Abstract

Background: ChatGPT-4o, Google Gemini, and Microsoft Copilot have shown potential in generating health care–related information. However, their accuracy, completeness, and safety for providing drug-related information in Thai contexts remain underexplored.

Objective: This study aims to evaluate the performance of artificial intelligence (AI) systems in responding to drug-related questions in Thai.

Methods: An analytical cross-sectional study was conducted using 76 public drug-related questions compiled from medical databases and social media between November 1, 2019, and December 31, 2024. All questions were categorized into 19 distinct categories, each comprising 4 questions. ChatGPT-4o, Google Gemini, and Microsoft Copilot were queried in a single session on March 1, 2025, by using input in Thai. All responses were evaluated for correctness, completeness, risk, and reproducibility independently by clinical pharmacists using standardized evaluation criteria.

Results: All 3 AI models provided generally complete responses (P=.08). ChatGPT-4o yielded the highest proportion of fully correct responses (P=.08). The overall risk levels of high-risk answers were not significantly different (P=.12). Response correctness was influenced by the category of the drug-related questions (P=.002) but not completeness (P=.23). The correctness of Google Gemini and Microsoft Copilot was higher than that of ChatGPT for pharmacology queries. The type of questions also statistically significantly affected the risk level of the answers (P=.04). In particular, the pregnancy and lactation category had the highest high-risk response rate (1/76, 1% per system). All 3 AI models demonstrated consistent response patterns when the same questions were re-queried after 1, 7, and 14 days.

Conclusions: The evaluated AI chatbots were able to answer the queries with generally complete content; however, we found limited accuracy and occasional high-risk errors in responding to drug-related questions in Thai. All models exhibited good reproducibility.

Introduction

Large language models such as ChatGPT, Google Gemini, and Microsoft Copilot have demonstrated potential in generating human-like responses, including for medication-related queries [1]. Traditionally, the public has relied on health care professionals for drug information; however, the growing accessibility of the internet and social media platforms has shifted this behavior. Generative artificial intelligence (AI) technologies are now playing a crucial role in facilitating prompt and efficient responses to health-related questions. A recent survey showed that more than 70% of the people expressed willingness to use AI applications such as ChatGPT for self-diagnosis and health-related queries [2]. Notably, GPT-4.0 has demonstrated marked improvements in both accuracy and safety over its earlier versions, including GPT-3.0 and 3.5 [3]. Because these AIs are primarily trained in English, they have reduced performance in non-English pharmaceutical contexts, such as in Chinese, Japanese, and Turkish [4-7]. In addition, the performance of generative AI varies across languages due to differences in the linguistic structure, question complexity, domain-specific content, cultural factors, and regulatory frameworks [8-10].

Launched in May 2024, ChatGPT-4o replaced ChatGPT-4.0. Advanced natural language processing features, including real-time interaction, multimodal input handling, and enhanced multilingual comprehension, provided by ChatGPT-4o, offer strong potential for communication enhancement between users and large language models in medical contexts [11]. Recent evaluations have shown that ChatGPT-4o significantly outperformed GPT-4.0 and GPT-3.5 in multiple-choice questions from the United States Medical Licensing Examination, with superior accuracy across overall, preclinical, and clinical domains [12]. A network meta-analysis confirmed that ChatGPT-4o showed better performance than GPT-4.0, Microsoft Copilot, and Google Gemini [13]. Despite these promising outcomes in structured assessments, there is insufficient evidence regarding the performance of ChatGPT-4o in open-ended medical and drug-related questions, especially in non-English contexts.

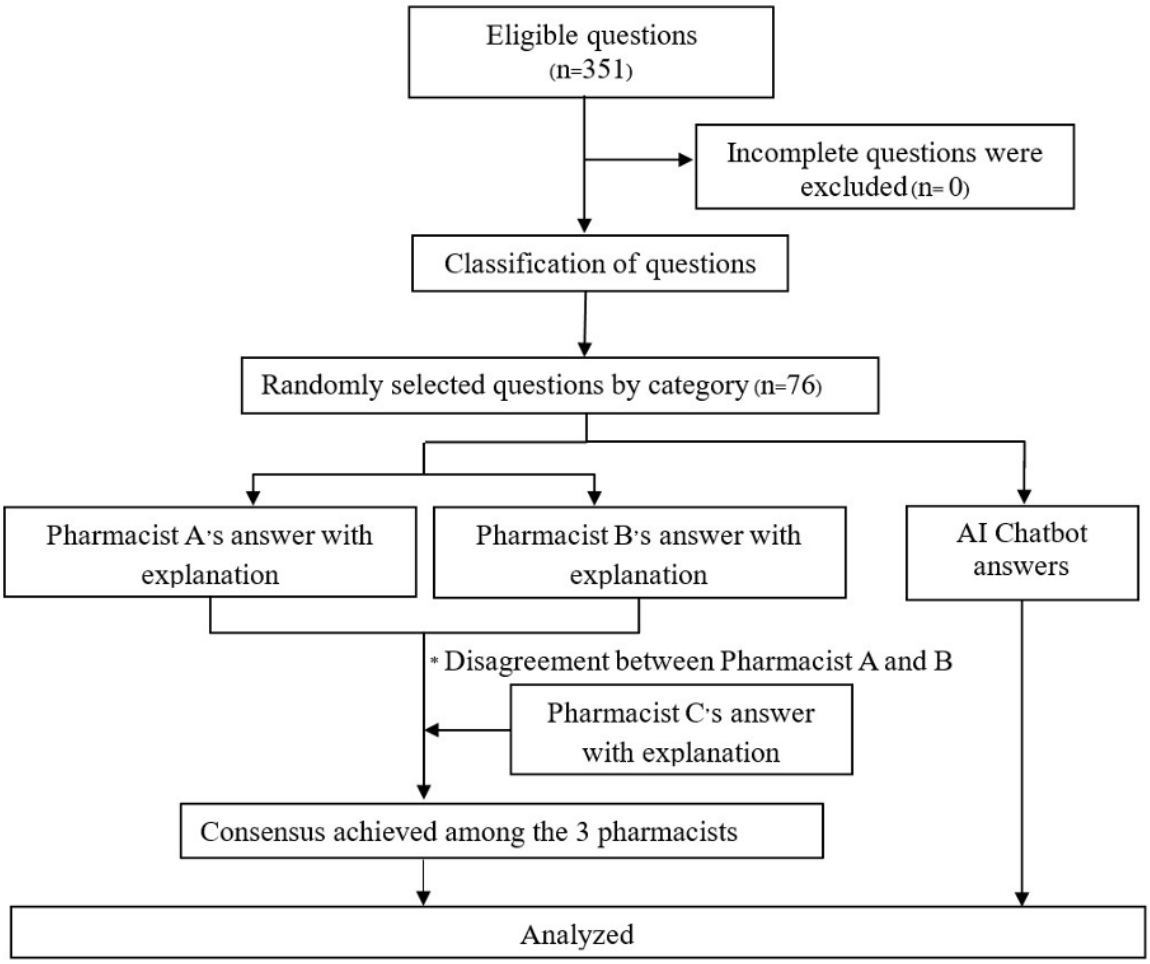
In Thailand, unique linguistic and contextual features, including the use of local trade names, Thai-language medical terminology, and region-specific clinical practices, may further affect the performance of large language models. ChatGPT-4o, Google Gemini, and Microsoft Copilot remain underrepresented in Thai-language applications, particularly within the pharmaceutical context, where empirical research is limited. To address this gap, this study aims to evaluate the performance of ChatGPT-4o, Google Gemini, and Microsoft Copilot in responding to drug-related queries in Thai language from the public.

Methods

Ethical Considerations

This study was approved by the Burapha University Ethical Committee (HS032/2567) with exemption from further review, as it involved publicly available data with no personal identifiers.

Study Design and Duration



This was an analytical cross-sectional study, where data sources included public medical forums, whose websites were hosted by academic institutions (eg, the Faculty of Pharmacy's websites) as well as social media. All questions were submitted freely by the public. The major data source was the Pantip website, the largest Thai online community since 1997. Although it is not a search engine, it offers a search function that enables the retrieval of relevant discussions across its forum categories. Its high traffic and diverse user demographic render it a valuable source for health-related queries. Additional data were obtained from public posts on Facebook and Twitter by using Thai hashtags such as #medicine, #herb, and #lab result (in Thai). Only publicly available content written in Thai was included. The data collection period referred to the posting dates of eligible questions, which spanned from November 1, 2019, through December 31, 2024.

Query Retrieval and Selection Criteria

The query selection process followed the CONSORT (Consolidated Standards of Reporting Trials) diagram (Figure 1). Three pharmacists independently retrieved drug-related questions from public databases in January 2025. The questions covered 18 predefined categories and an additional miscellaneous category for mixed-type questions. The 19 question categories and examples are presented in Multimedia Appendix 1. The drug-related question categories were classified based on systematic drug information response guidelines [14,15]. A minimum of 10 questions per category was selected, totaling at least 190 questions.

XSL•FO
RenderX

Figure 1. CONSORT (Consolidated Standards of Reporting Trials) diagram presenting the selection process of drug-related questions included in this study. AI: artificial intelligence.

Duplicate checks and proper categorization were independently verified. Four questions per category were randomly selected using Microsoft Excel 2006. The pharmacists retrieved the answers from predefined reference sources for all questions before querying the AI models, preventing AI responses from biasing their evaluation. The selected questions were then submitted without modification to ChatGPT-4o [16], Google Gemini [17], and Microsoft Copilot [18] on March 1, 2025. ChatGPT responses were generated using the GPT-4o model via the ChatGPT Plus platform, accessed on March 1, 2025. Each question was submitted in a separate chat and analyzed within a single session, with all AI queries conducted on the same day to minimize potential variability from prior context or system updates.

The correctness, completeness, risk, and reproducibility of the responses were assessed by clinical pharmacists using predefined criteria. To obtain the correct answers, drug information was systematically collected from tertiary resources, including Micromedex [19], Lexicomp, Drug Interaction Facts [20], Drugs in Pregnancy and Lactation [21], Handbook on Injectable Drugs [22], MIMS Thailand [23], The Thai Food and Drug Administration [24], Summary of Product Characteristics, DiPiro's Pharmacotherapy: A Pathophysiologic Approach, 12th edition [25], and both international and local clinical practice guidelines. Additionally, Thai herbal medicine databases, manufacturer catalogs, and distributor information were accessed to obtain local data. If data were incomplete, secondary resources (PubMed, ScienceDirect, Scopus) and primary resources were explored. Google Scholar was used as a supplementary tool with a reliability assessment. Examples of responses provided by the 3 AI systems compared with those of the pharmacists are presented in Multimedia Appendix 2.

Evaluation of Correctness, Completeness, Risk, and Reproducibility Domains

The evaluation focused on 3 key domains: correctness, completeness, and risk, as assessed by the pharmacists. Reproducibility was tested by re-querying 1 random question per category after 1, 7, and 14 days. Two of the 3 pharmacists independently handled question retrieval, answer searching, and response evaluation. Disagreements were resolved by consensus or third-party review, as shown in Table 1.

XSL•FO
RenderX

Table 1. Evaluation of the 3 domains.

Key domains, subdomains	Categories and definitions
Correctness	
Fully correct	The response is entirely accurate (2 points)
Partially correct	The response contains some inaccuracies (1 point)
Incorrect	The response is incorrect or does not address the core issue of the question (0 point)
Completeness	
Complete	The response addresses all aspects of the question comprehensively (2 points)
Partially complete	The response addresses some aspects of the question but omits others (1 point)
Incomplete	The response does not address the question and is irrelevant to the topic (0 point)
Risk	
No risk	The response is entirely accurate and complete, posing no harm to the patient if complied with as recommended (2 points)
Low risk	The response poses minimal harm but may contain inaccurate or incomplete information (1 point)
High risk	The response poses a significant risk to patient safety, such as the potential for adverse drug reactions, hospitalization, or delayed treatment if the advice is followed (0 point)

Statistical Analysis

The sample size was determined using α=.10 and power=.80. A prior study evaluating the suitability of ChatGPT for answering drug-related questions found that only 26% of the responses were satisfactory, while 74% were unsatisfactory due to inaccuracies, incomplete answers, or failure to address the question directly [26]. Therefore, at least 53 questions are required to achieve a 90% confidence level with an acceptable margin of error of 10% [27]. For content validity and balanced domain coverage, the final questions consisted of 76 items, which were structured into 19 prespecified categories with 4 items per category (19×4). The final item set was fixed before model evaluation. All statistical analyses were conducted using SPSS software (version 28.0; IBM Corp). The differences in the correctness, completeness, and risk were analyzed using a linear regression model with repeated measures. The analysis of reproducibility was performed using the coefficient of variation stated in the Association of Official Analytical Chemists Official Methods of Analysis [28].

Results

Overall Performance of ChatGPT-4o, Google Gemini, and Microsoft Copilot

This study retrieved 76 public questions from medical websites (36/76, 47%) and social media platforms, including Pantip (35/76, 46%), Facebook (1/76, 1%), and Twitter (4/76, 5%), posting from November 1, 2019, through December 31, 2024, and then submitted to ChatGPT-4o, Google Gemini, and Microsoft Copilot on March 1, 2025. The overall evaluation across all the question categories is illustrated in Table S1 of Multimedia Appendix 3.

Statistical analysis revealed that the type of AI chatbot did not significantly impact correctness, completeness, and risk (*P*=.08, .08, and .12, respectively). In contrast, the type of drug-related question significantly influenced the performance outcomes in correctness (*P*=.002) and risk (*P*=.04) but not in completeness (*P*=.23) (Multimedia Appendix 3). Although the differences in the correctness did not reach statistical significance (*P*=.08), a practical trend was observed. ChatGPT-4o demonstrated the highest tendency to provide fully correct responses and complete answers by addressing all the key points, followed by Google Gemini and Microsoft Copilot, respectively. For example, in adverse drug reaction–related questions on how to manage initial symptoms, ChatGPT-4o provided comprehensive and clinically useful answers that covered underlying causes, self-care strategies, symptom monitoring, and red-flag signs warranting medical attention. However, the other 2 systems offered only partially correct responses that lacked sufficient detail for practical application. Notably, Microsoft Copilot was the only AI system that provided entirely incomplete answers, primarily by generating content irrelevant to the question.

Performance Correctness, Completeness, Risk, and Reproducibility of the AI Chatbots by Question Category

The highest correctness ratings were observed in the general product information category, as shown in Figure 2. In this and the adverse effect category, ChatGPT provided fully correct responses to all the questions, while Google Gemini and Microsoft Copilot, respectively, yielded a lower rate of correctness. In contrast, Google Gemini and Microsoft Copilot demonstrated superior performance in pharmacology-related questions to ChatGPT. However, all 3 AI systems performed poorly in the following categories: pediatric pharmacotherapy, pharmacy law, availability of dosage forms, dietary and herbal supplements, drug identification, and mixed-type questions. Regarding online source citations, Microsoft Copilot used Drugs.com, NHS, WebMD, Medthai, Pantip, Mahidol University Faculty of Pharmacy, and PobPad websites as references, whereas ChatGPT and Google Gemini did not provide citations.

XSL•FO
RenderX

Figure 2. Performance of the artificial intelligence chatbots by question categories across the dimensions of correctness, completeness, and risk. One-fourth of the pie chart represents one question within each question category. Green, yellow, and red segments indicate a score of 2, 1, and 0, respectively.

For completeness, ChatGPT and Google Gemini did not produce any incomplete responses for all the questions. In contrast, Microsoft Copilot yielded the highest number of partially complete responses and produced incomplete responses in the laboratory tests and pharmacy law categories. In terms of risk, all 3 AI chatbots produced high-risk responses. ChatGPT produced the highest responses categorized as no risk, followed by Microsoft Copilot and Google Gemini. Additionally, ChatGPT yielded a lower frequency of responses with lower risk than the other AI systems. Responses to pregnancy and lactation-related questions posed high risks across all 3 AI chatbots, indicating potential safety concerns.

In addition, there were no significant differences in performance across the correctness, completeness, or risk dimensions between the responses on days 1, 7, and 14. The responses to all the questions were unchanged across all 3 AI systems, with the coefficient of variation of less than 2% in all questions, demonstrating the reproducibility of the AI chatbots' responses.

Discussion

Principal Findings

This study provides new evidence on the performance of ChatGPT-4o, Google Gemini, and Microsoft Copilot in responding to drug-related queries in Thai. Overall, ChatGPT-4o

XSL•FO
RenderX

achieved the highest proportion of fully correct and complete responses. This shows the improvement in the performance of ChatGPT since the 3.5 version provides incorrect answers in general [29]. In addition, the earlier version of ChatGPT provided inaccurate answers in the following domains: clinical guidelines, dosage adjustment, therapeutics, compounding and formulation, dosage regimens, compatibility and stability, adverse drug reactions, administration routes, drug-drug interactions, legal matters, foreign drug identification, toxicology, and multidomain queries [26,29-31]. A previous study also showed that the earlier version of ChatGPT had higher accuracy than Gemini [32]. However, the improved performance is not homogeneous across all question categories. We found that Gemini and Copilot performed better in specific areas such as pharmacology. Evidence availability may shape relative model performance because certain queries (eg, the combined use of central nervous system stimulants and antipsychotics) required theoretical reasoning in the absence of robust empirical evidence. This aligns with prior evidence showing that Gemini achieved higher concordance with clinical practice guidelines in evidence-based health advice than either Copilot or ChatGPT [33]. These limitations, particularly evident in Thai-language responses, indicate that despite advancements from version 3.5 to 4o, large language models still exhibit substantial limitations across various question categories.

Across all AIs, high-risk responses were rare but most evident in the pregnancy and lactation category. This highlights the limitations of generative AI models when responding to inquiries that rely on nuances. All 3 AI systems failed to recommend contraception during the use of medication, with clear evidence on the concurrent use of effective contraceptive methods. Such an omission could cause potential fetal harm. This observation is consistent with previous evidence [34], which found that ChatGPT-3.5 provided acceptable pregnancy-related responses in only 50% of the cases. Overall, our findings support the conclusion that the newer AI models, particularly ChatGPT-4o, have achieved improved accuracy and safety in responding to medication-related questions. Our study also shows that all 3 evaluated AI systems demonstrate a high degree of reproducibility. This shows that AIs have been improved since the previous versions of ChatGPT had reproducibility issues [29,30]. However, questions initially answered incorrectly continued to yield incorrect responses upon reassessment.

Regarding the language in evaluation, the earlier version of ChatGPT produces more accurate answers in response to English questions than other languages (eg, Turkish [5], Chinese [4]). The accuracy of ChatGPT in answering Chinese and Turkish medical questions was approximately 50% [4,5], agreeing with the accuracy of ChatGPT in answering Thai questions at 50%. The observed inaccuracies were attributed to several key factors. First, lexical and linguistic challenges such as informal vocabulary, abbreviations, slang, or transliterated English terms may lead to misinterpretation and incorrect responses [35], which could have serious consequences, particularly in patients with known drug allergies [36]. Second, variations in the underlying data sources used by each AI model influenced the quality of the responses. For instance, in this study, Microsoft Copilot often relied on nonmedical Thai sources, whereas ChatGPT and Google Gemini did not disclose their data sources. This raises concerns about transparency and source reliability. Third, the capacity of each AI system to handle complex cognitive tasks varied considerably. In this study, examples of such tasks included identifying locally manufactured drug products from text or image inputs, recognizing currently marketed dosage forms, interpreting legal implications of pharmacy-related scenarios, evaluating evidence levels between animal and human studies, and assessing the currency and clinical relevance of the information input. In addition, some of these domains (eg, pediatric pharmacotherapy, herbal and dietary supplements, locally marketed dosage forms) are particularly underrepresented in structured Thai resources such as Thai medical databases or drug labeling. This scarcity likely compounds the linguistic and contextual challenges described above, further limiting model accuracy in these categories.

This study offers valuable insights into the capabilities and limitations of AI chatbots in retrieving drug-related information in the Thai language. By evaluating responses from ChatGPT-4o, Google Gemini, and Microsoft Copilot across multiple question categories, we observed that AI systems were generally effective in addressing basic inquiries, particularly those involving general product information. These results support the potential utility of AI as a supplementary tool in routine information retrieval tasks, especially when queries are framed using clear formal language and include specific drug names. An additional strength of this study lies in the diversity of the question sources. All queries were collected from medical forums and social media platforms. This mix of sources introduced heterogeneity in terminology—from formal medical vocabulary to colloquial slang as well as variability in depth and clinical relevance. The diverse health literacy of the enquirers reflects the real-world patterns of medication information-seeking behavior [37]. However, the findings also underscore several critical limitations. The performance of all AI systems was markedly lower when addressing more complex or context-dependent domains such as pediatric pharmacotherapy, drug use in pregnancy and lactation, pharmacy law, and drug identification based on physical descriptions or images. In such cases, relying solely on AI systems may result in clinically significant inaccuracies, reinforcing the necessity for consultation with licensed health care professionals.

Limitations

From a methodological perspective, this study was underpowered by the limited number of questions per category, which may have limited the detection of subtle differences in chatbot performance across subdomains. Expanding the sample size in future research would likely yield more insights. Additionally, this study primarily evaluates AI responses to general questions. Future investigations should assess AI performance in handling more individualized clinical scenarios to evaluate practical applicability and safety in real-world decision-making contexts. Moreover, because the study focuses exclusively on Thai queries, the findings may not be directly generalizable to other languages. Replication across diverse linguistic and clinical settings will be necessary to confirm the accuracy and reliability of AI systems.

XSL•FO
RenderX

Conclusions

This study shows no statistically significant differences in correctness, completeness, or risk levels among ChatGPT-4o, Google Gemini, and Microsoft Copilot in responding to Thai-language drug-related questions. ChatGPT-4o yielded the highest number of fully correct and complete responses overall. However, Google Gemini and Microsoft Copilot performed relatively better for questions in pharmacology. All AI systems demonstrated notable limitations in addressing complex queries, including pediatric pharmacotherapy, pharmacy law, dosage form availability, dietary and herbal supplements, drug identification, pregnancy and lactation, and mixed-type drug inquiries. Although response risks were observed in all systems, ChatGPT-4o produced the highest proportion of no-risk responses. The reproducibility of the 3 AIs was consistent, though incorrect responses remained unchanged when reassessed.

Acknowledgments

The authors sincerely thank the Faculty of Pharmaceutical Sciences, Burapha University, for providing access to online databases and research resources that were essential to the successful completion of this study. We also acknowledge the use of publicly accessible medical forums and social media platforms as primary sources of health-related questions for this study. This study uses artificial intelligence tools—GPT-4o, Google Gemini, and Microsoft Copilot—for preliminary language refinement and content structuring. All substantive decisions regarding the study's design, data interpretation, and final conclusions were made independently and solely by the authors. This study did not receive any funding or grant.

Data Availability

All data generated or analyzed during this study are included in this manuscript and in the appendices.

Abstract

Background: Objective structured clinical examinations (OSCEs) are widely used for assessing medical student competency, but their evaluation is resource-intensive, requiring trained evaluators to review 15-minute videos. The physical examination (PE) component typically constitutes only a small portion of these recordings; yet, current automated approaches struggle with processing long medical videos due to computational constraints and difficulties maintaining temporal context.

Objective: This study aims to determine whether multimodal large language models (MM-LLMs) can effectively segment PE periods within OSCE videos without previous training, potentially reducing the evaluation burden on both human graders and automated assessment systems.

Methods: We analyzed 500 videos from 5 OSCE stations at University of Texas Southwestern Simulation Center, each 15 minutes long, by using hand-labeled PE periods as ground truth. Frames were sampled at 1, 2, or 3 seconds. A pose detection preprocessing step filtered frames without people. Six MM-LLMs performed frame-level classification into encounter states by using a standardized prompt. To enforce temporal consistency, we used a hidden Markov model with Viterbi decoding, merging states into 3 primary activities (consulting/notes, physical examination, and no doctor) and adding a brief edge buffer to avoid truncating true PE segments. Performance was computed per video and averaged across the dataset by using recall, precision, intersection over union (IOU), and predicted PE length with 95% CIs.

Results: At 1-second sampling, GPT-4o achieved recall of 0.998 (95% CI 0.994-1.000), IOU of 0.784 (95% CI 0.765-0.803), and precision of 0.792 (95% CI 0.774-0.811), identifying a mean of 175 (SD 83) seconds of content per video as PE versus a mean labeled PE of 126 (SD 61) seconds, yielding an 81% reduction in video needing review (from 900 to 175 seconds). Across stations, recall remained high, with expected IOU variability linked to examination format and camera geometry. Increasing the sampling interval modestly decreased recall while slightly improving IOU and precision. Comparative baselines (eg, Gemini 2.0 Flash, Gemma 3, and Qwen2.5-VL variants) demonstrated trade-offs between recall and overselection; GPT-4o offered the best balance among high-recall models. Error analysis highlighted false negatives during occluded or verbally guided maneuvers and false positives during preparatory actions, suggesting opportunities for camera placement optimization and multimodal fusion (eg, audio cues).

Conclusions: Integrating zero-shot MM-LLMs with minimal-supervision temporal modeling effectively segments PE periods in OSCE videos without requiring extensive training data. This approach significantly reduces review time while maintaining clinical assessment integrity, demonstrating that artificial intelligence methods combining zero-shot capabilities and light supervision can be optimized for medical education's specific requirements. This technique establishes a foundation for more efficient and scalable clinical skill assessment across diverse medical education settings.

Introduction

Background

Objective structured clinical examinations (OSCEs) have been integral to medical education assessment since their introduction in the 1970s, offering a standardized method to assess clinical competencies [1-3]. During these examinations, medical students rotate through multiple 15-minute stations, interacting with standardized patients to demonstrate skills in communication, physical examination (PE), and clinical reasoning. This controlled setting ensures consistent evaluation across diverse scenarios such as pediatric assessments or surgical consultations. Recent bibliometric mapping shows OSCE scholarship expanding with a sustained emphasis on performance, competence, and skills, underscoring the assessment focus of grading OSCE examinations [4].

Grading OSCE performance relies heavily on trained standardized patient evaluators who review video recordings, assessing students against rubrics that emphasize verbal communication, emotional intelligence, and PE proficiency. This manual process is labor intensive and resource demanding, creating a significant bottleneck as medical schools scale training for larger cohorts.

While automated assessment has progressed for written components of medical examinations, leveraging natural language processing for transcript analysis and written exams [5-7], video-based evaluations such as OSCEs remain challenging to automate [8,9]. The complexity stems from the dynamic, visual nature of clinical interactions, including subtle movements and gestures that require deep domain understanding.

Existing multimodal models struggle with 15-minute OSCE recordings due to computational constraints and challenges maintaining temporal context over extended durations as models must either truncate sequences or aggressively downsample, sacrificing critical details [10-12]. These limitations are particularly pronounced for PEs, where students' practical skills must be precisely evaluated. Therefore, PE assessment remains a critical gap in automated OSCE evaluation, and identifying and isolating these segments is a foundational step toward comprehensive automated assessment of clinical competencies. Moreover, emerging evidence that large language models can handle complex multimodal clinical cases further motivates our choice of multimodal large language models (MM-LLMs) for video understanding [13].

Significance

To address this gap, we propose a novel approach that fundamentally differs from general video classification methods. Unlike traditional approaches that assign a single label to entire recordings [14,15], our method performs temporal segmentation to isolate specific activities within OSCE videos precisely. This distinction is critical in educational contexts, where evaluators need to assess discrete skills demonstrated in brief segments, such as the PE portion, which typically constitutes only 15% to 20% of the total recording time.

Despite the critical importance of PE assessment in medical education, to our knowledge, this study represents the first attempt to automatically segment PE periods within OSCE videos. While temporal segmentation approaches have been used in other domains [16], the unique requirements of OSCE evaluation—particularly the need for near-perfect recall to capture even brief examination components—present distinct challenges that general methods were not designed to address.

Our approach integrates MM-LLMs with Viterbi decoding through hidden Markov models (HMMs), creating a solution specifically tailored to medical education's requirements. This combination leverages the contextual understanding capabilities of MM-LLMs for frame-level classification while applying Viterbi decoding to filter out spurious false positives and negatives, ensuring consistent segmentation of examination activities across the video timeline. Our primary research question was as follows: can MM-LLMs accurately identify PE activities in OSCE videos without specialized training across diverse examination scenarios?

We evaluated our approach across 500 recordings from 5 OSCE stations at University of Texas (UT) Southwestern Simulation Center: family medicine, surgery 1, surgery 2, internal medicine 1, and internal medicine 2. Each station presents unique challenges, from differing examination techniques to varied spatial configurations. Additionally, each station uses different camera angles due to variations in room setup, allowing us to test the robustness of our approach across diverse recording environments.

By streamlining video analysis, our method not only enhances grading efficiency but also establishes a foundation for fully automated OSCE assessment. This advancement aligns with the broader shift toward competency-based medical education frameworks, where efficient, objective assessment of clinical skills is increasingly vital. As medical education evolves to meet growing health care workforce demands, such technological innovations could significantly improve the scalability and consistency of clinical skill evaluation while alleviating institutional resource constraints.

Methods

Study Design and Dataset

This study analyzed OSCE videos from medical students at the UT Southwestern Simulation Center. We specifically focused on the comprehensive OSCE administered during clerkship. Of the 10 total OSCE stations administered in the fall of 2019, we selected the 5 that included PE components: family medicine, surgery 1, surgery 2, internal medicine 1, and internal medicine

XSL•FO
RenderX

2. For each station, we randomly selected 100 videos (500 videos in total), each approximately 15 minutes (900 seconds) in length.

The videos were recorded at 1920 × 1080 resolution with 2 fixed cameras: one facing the patient and one facing the medical student. For our analysis, we primarily used the camera angle facing the patient to best capture the medical student's movements during PE.

Ground Truth Labeling

To establish ground truth for model evaluation, a single rater with emergency medical technician–level expertise manually annotated the PE periods in all 500 videos. We defined the PE period using clear visual criteria: beginning when the medical student made direct physical contact with the patient for assessment purposes (such as when the otoscope light aligned with the patient's eye during an eye examination) and ending when all direct physical assessment activities concluded. This definition excluded preparatory activities such as retrieving examination tools, ensuring that only unambiguous examination activities were labeled. Given the straightforward nature of identifying direct physical contact beginning and end points, a single expert annotator was sufficient for this task. To establish ground truth for model evaluation, a single rater with emergency medical technician–level expertise manually annotated the PE periods in all 500 videos, as shown in Table 1.

Table 1. Video count and physical examination duration statistics by station.

	Videos, n	Physical examination time (s), mean (SD)
Overall	500	126 (61)
Family medicine	100	141 (70)
Surgery 2	100	163 (74)
Internal medicine 1	100	108 (54)
Surgery 1	100	119 (59)
Internal medicine 2	100	101 (47)

Automated PE Segmentation Workflow

Our approach used a streamlined pipeline for identifying PE periods within OSCE videos. This process consisted of human detection preprocessing, direct frame classification using MM-LLMs, and temporal consistency enforcement through Viterbi decoding. The complete workflow is illustrated in Figure 1.

XSL•FO
RenderX

Figure 1. Frame classification pipeline for physical examination detection. This streamlined approach classifies frames directly into states (taking notes, physical examination, no doctor, greeting, or preparing for examination) before applying Viterbi decoding. AI: artificial intelligence.

Preprocessing Using Human Pose Detection

We used YOLO11 (Ultralytics Inc) to detect human presence in each frame [17,18]. This preprocessing step allowed us to optimize computational efficiency by only having the MM-LLM process frames containing people. Frames without detected humans were automatically assigned to the "no doctor" state.

The model identified the bounding boxes of human skeletons and was configured to detect a maximum of 2 individuals per frame (the medical student and standardized patient), which aligned with the design of OSCE systems. We set a minimum confidence threshold of 0.5 for human detection, balancing detection sensitivity with computational efficiency.

For each frame containing humans, we created a square bounding box encompassing all detected individuals. As illustrated in Figure 1, these cropped frames were then resized to 512 × 512 pixels for MM-LLMs.

RenderX

Frame Classification Approach

We conducted frame analysis at 3 different sampling rates to evaluate computational efficiency versus accuracy trade-offs: 1 frame every second (1-second interval), 1 frame every 2 seconds (2-second interval), and 1 frame every 3 seconds (3-second interval). These specific sampling rates were selected to balance computational requirements with detection accuracy. The lower bound of 3-second intervals was particularly significant as PEs in OSCEs can sometimes be brief (2-3 seconds for specific techniques). Sampling less frequently would risk missing these short examination components entirely.

For frame classification, we evaluated 6 MM-LLMs: GPT-4o (November 6, 2024), GPT-4o-mini (July 18, 2024), Gemini 2.0 Flash (February 5, 2024), Gemma 3, Qwen2.5-VL-72B, and Qwen2.5-VL-7B. Open-source models were hosted on graphics processing unit nodes within BioHPC, UT Southwestern's shared high-performance computing infrastructure. Proprietary models were accessed via secure, HIPAA (Health Insurance Portability and Accountability Act)- and Family Educational Rights and Privacy Act (FERPA)–compliant application programming interfaces. These models analyzed each preprocessed frame using the structured prompt shown in Textbox 1.

Textbox 1. Prompts for frame classification task.

System message—prompt

- "You are an AI assistant designed to analyze images about medical scenarios and select the most appropriate interpretation from a set of multiple-choice options. Your responses must be in JSON format."

User message—prompt

"The patient is wearing a gown."

Choose from the following choices:

A. doctor is reviewing information, taking notes, or consulting with the patient

B. doctor is performing a physical examination

C. there is no doctor

D. the doctor is greeting the patient

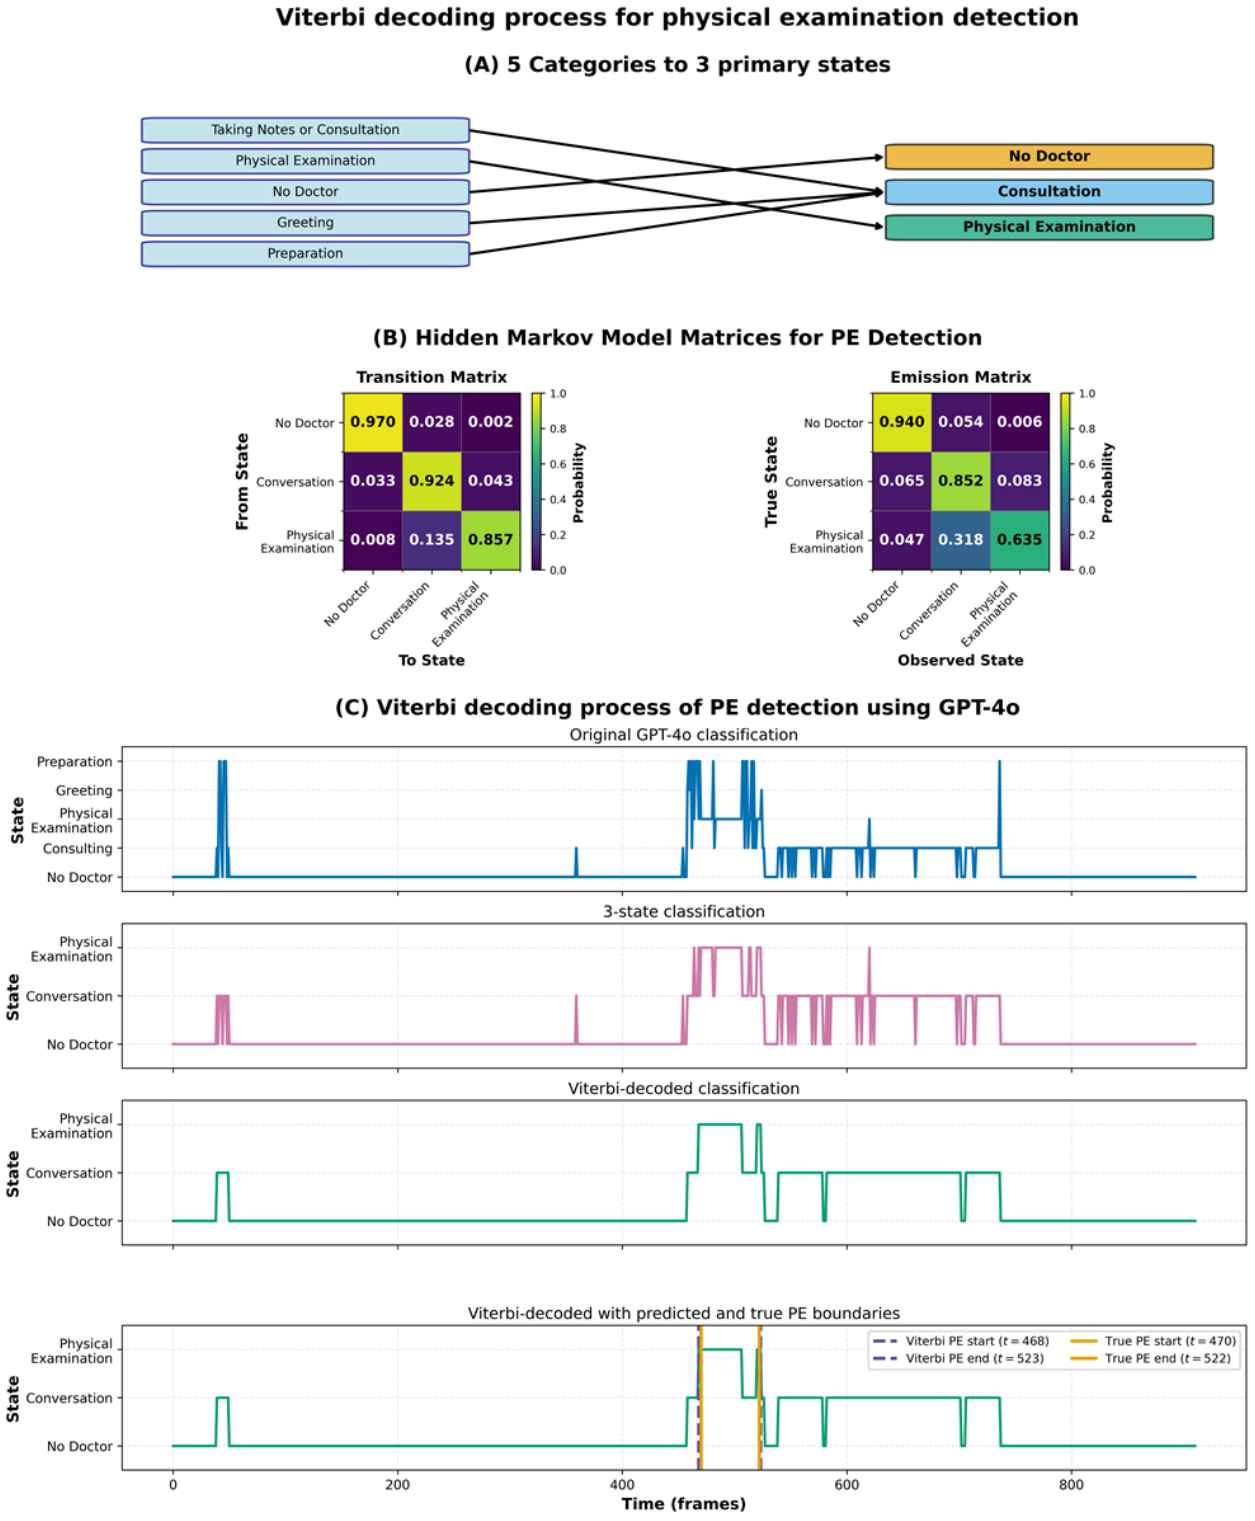
E. doctor is preparing for examination

Answer in JSON format ONLY:

{'Reasoning': 'a brief explanation of why this choice was selected based on what is observed in the image'

'Choice': 'letter,'}

Example: {'Reasoning': 'The doctor is using a stethoscope to listen to the patient's chest, actively performing a physical examination.'



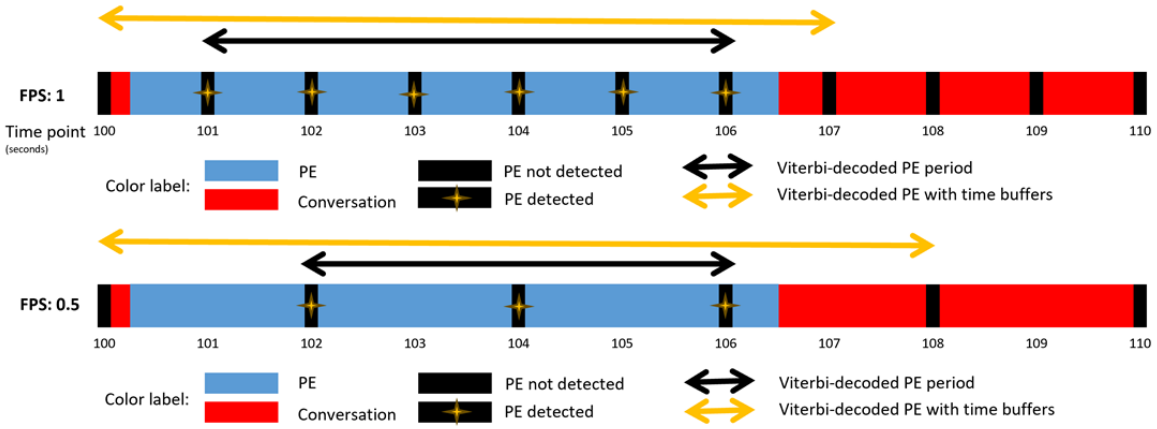
'Choice': 'B,'}"

Viterbi Decoding for State Prediction

After obtaining frame-level classifications, we implemented an HMM with Viterbi decoding to enforce temporal consistency and address the inherent noise in frame-level predictions. We simplified the analysis by merging the 5 initial categories into 3 primary states that reflect the fundamental activities in OSCE encounters (Figure 2A): taking notes/consulting, physical examination, and no doctor.

XSL•FO
RenderX

Figure 2. Viterbi decoding process: (A) 5 categories to 3 primary states, (B) hidden Markov model matrices—transition matrix showing probabilities between states and emission matrix showing a relationship between true and observed states, and (C) example of the Viterbi decoding process for finding a physical examination within a video. PE: physical examination.



We randomly selected 10 videos from each station (50 videos in total) to calculate the average transition and emission matrices for the HMM, shown in Figure 2B. In 500 bootstrap resamples (per video), elementwise mean absolute change was 0.008 for both matrices, and 95% CIs for self-transitions averaged approximately 0.046 (Multimedia Appendix 1). The transition matrix captured the probability of moving between states, whereas the emission matrix represented the probability of observing a particular state given the true underlying state.

On the basis of the OSCE protocol, we initialized the model with "no doctor" as the starting state as sessions begin with the patient alone in the examination room. We then applied the Viterbi algorithm through the PyHHMM library [19] to determine the most likely sequence of states and identify the PE period.

XSL•FO
RenderX

To ensure complete capture of PE periods despite discrete sampling, we added a buffer time at the edges of detected periods proportional to the frame sampling rate (Figure 3). This buffer compensated for transitions that might occur between sampled frames. Additional experiments examining the effect of different buffer times (0, 15, and 30 seconds) on performance metrics are shown in Multimedia Appendix 2, demonstrating how increased buffer sizes improve recall at the expense of precision and intersection over union (IOU).

Figure 3. Buffer time implementation to ensure complete transition capture between sampled frames. FPS: frames per second; PE: physical examination.

Evaluation Metrics

We assessed model performance using 4 primary metrics calculated per video and averaged across all videos.

The first metric was recall, which is the proportion of the labeled PE period correctly captured by the model. A high recall is critical as missing any PE segment compromises clinical skill assessment:

A recall of 1 constituted complete capture of the PE, whereas a recall of 0 indicated that no PEs captured.

The second metric was precision, which is the accuracy of the predicted PE segments, calculated as the ratio of correctly predicted PE duration to total predicted PE duration:

The third metric was IOU, which measures the overlap accuracy between predicted and actual PE periods:

The fourth metric was predicted PE length, which evaluates practical utility by quantifying the potential reduction in video review time:

We prioritized high-recall models, accepting slightly longer predictions to ensure that critical examination segments were not omitted. All metrics were calculated on a per-video basis and averaged across the dataset, with 95% CIs reported.

Ethical Considerations

This study was reviewed and approved by the UT Southwestern institutional review board (STU-2022-0908). The institutional review board granted a waiver of informed consent for the retrospective analysis of existing OSCE recordings, which are FERPA-protected educational records. Raw videos stayed on secure institutional servers, with access restricted to study staff; analyses were conducted on HIPAA- and FERPA-compliant systems, and only deidentified time stamps and summary metrics were used for reporting. Participants were not compensated. The manuscript and supplements do not include identifiable images or video frames, so masking was not required.

Results

Overall Model Performance Across Sampling Rates

Our evaluation compared hand-labeled PE periods against those identified through our approach across 5 OSCE stations (n=500 videos). We prioritized recall as our primary metric as missing examination components could lead to incomplete evaluation of clinical skills in high-stakes educational assessments. Table 2 shows the comprehensive findings across all models and sampling rates.

XSL•FO

[a]IOU: intersection over union.

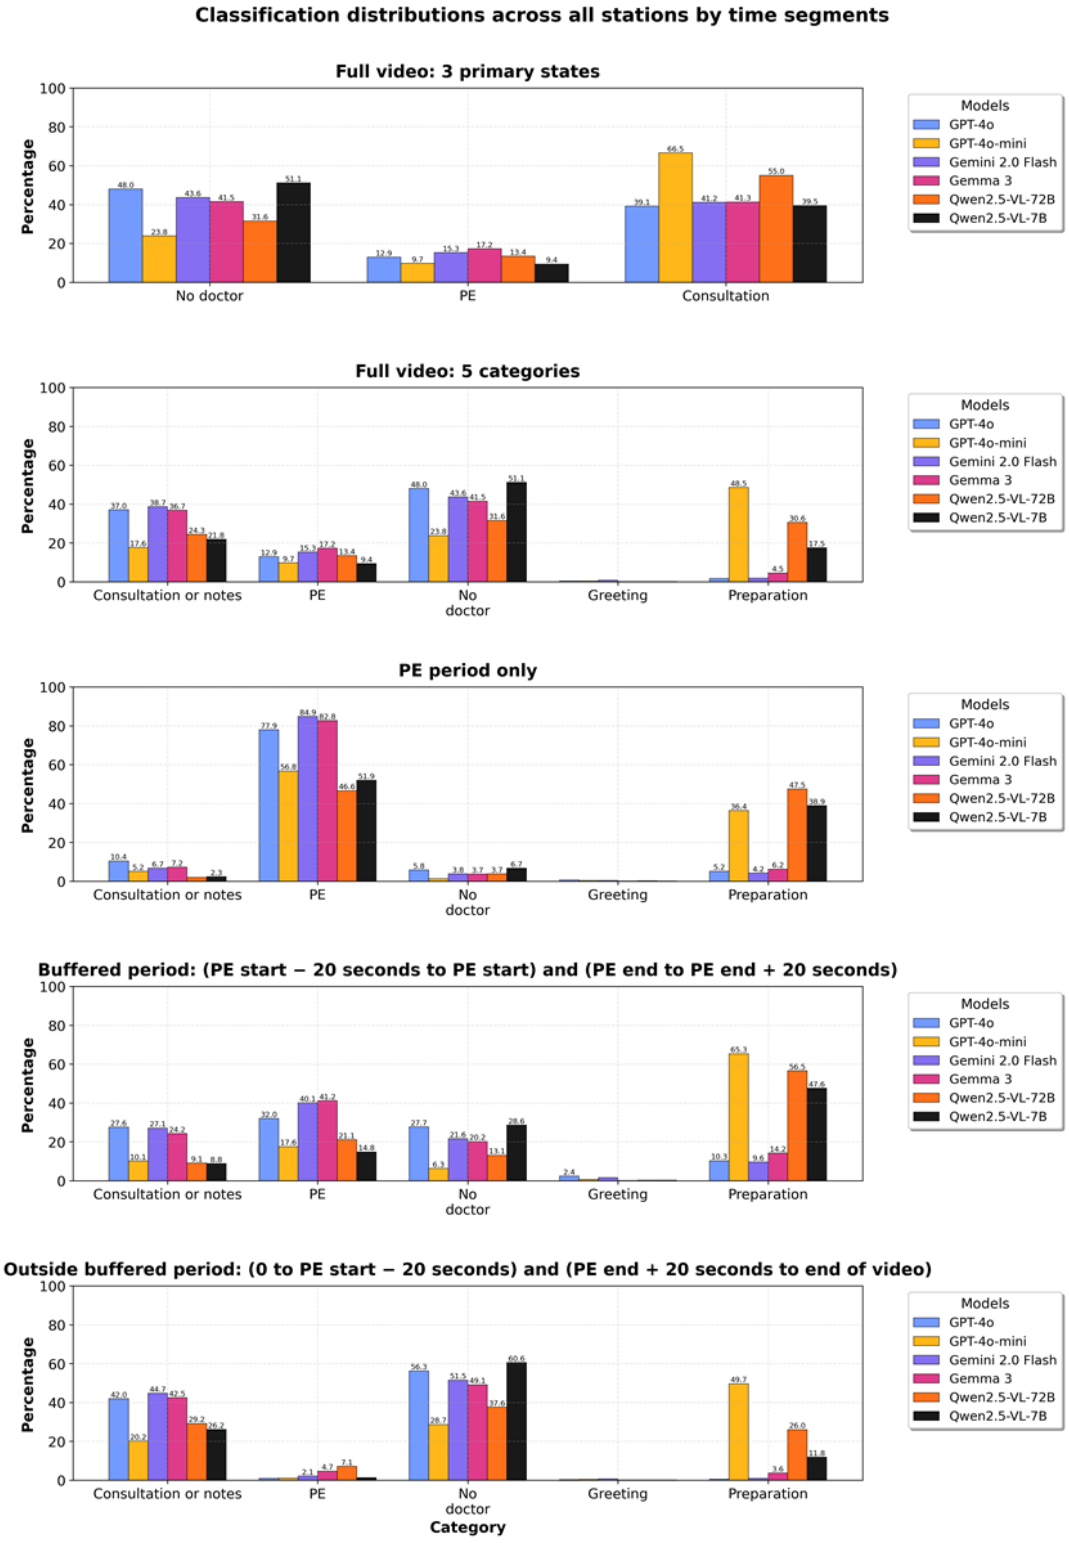
[b]PE: physical examination.

Of all models evaluated, GPT-4o, Gemini 2.0 Flash, and Gemma 3 achieved the highest recall (0.998, 0.999, and 0.995, respectively) at a sampling rate of 1. We selected GPT-4o as our optimal model due to its superior combination of high recall with the best IOU (0.784) and precision (0.792) and lowest predicted length (175 seconds) among high-recall performers.

At 1-second sampling, GPT-4o-mini showed significantly higher IOU than GPT-4o (mean 0.835, SD 0.180 vs mean 0.785, SD

XSL•FO
RenderX

0.220; mean difference 0.050, 95% CI 0.032-0.068; t_{486}=5.49; Cohen *dz*=0.25; *P*<.001). Conversely, GPT-4o achieved significantly higher recall (mean 0.998, SD 0.036) than GPT-4o-mini (mean 0.945, SD 0.138; mean difference −0.052, 95% CI −0.064 to −0.041; t_{488}=−8.66; Cohen *dz*=−0.39; *P*<.001), representing a precision-recall trade-off (Multimedia Appendix 3).



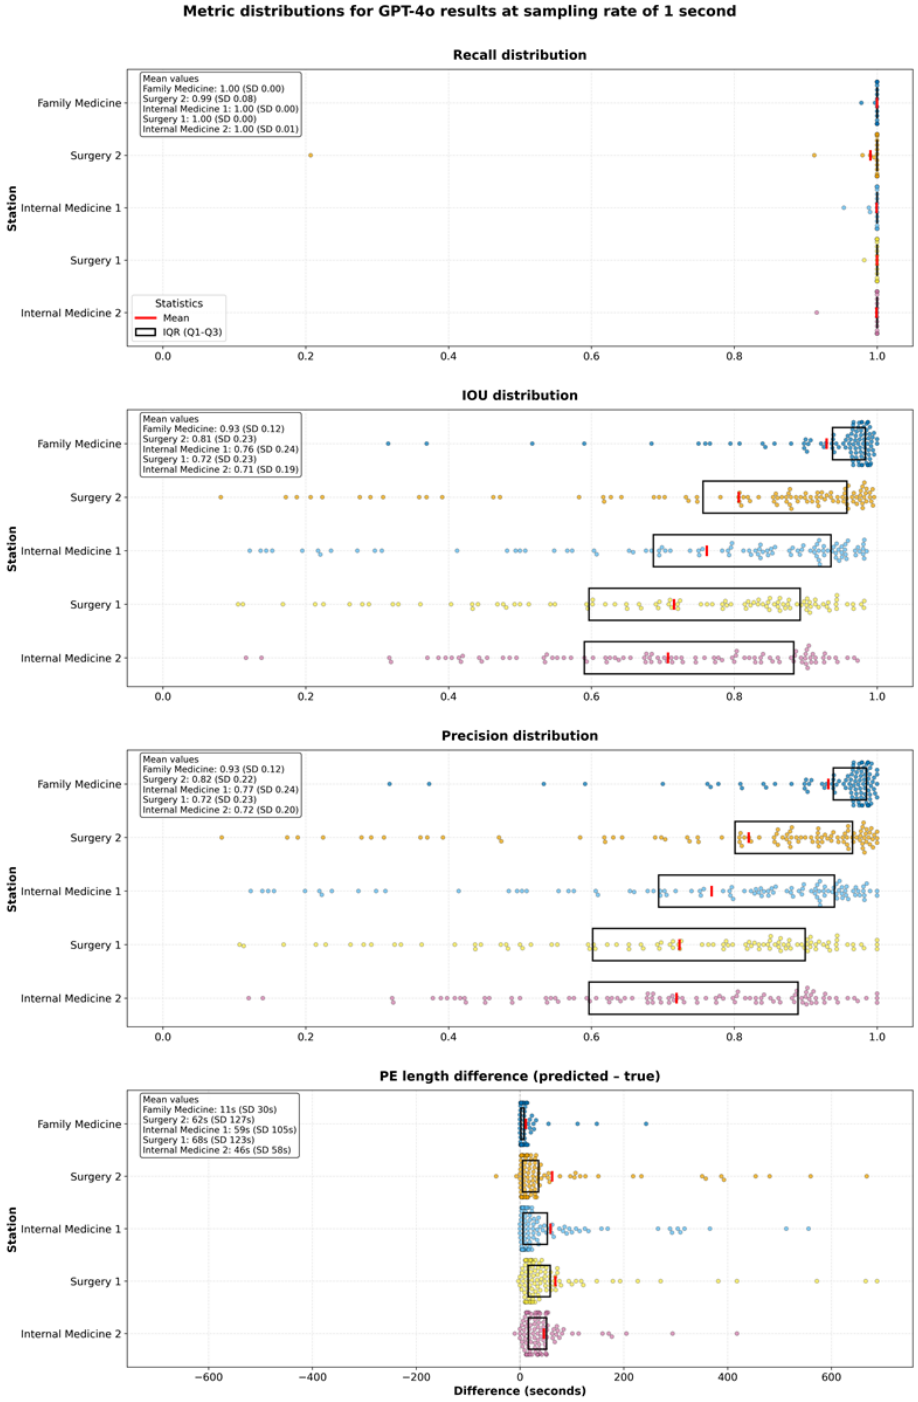
We observed that increasing sampling rates generally reduced recall while improving IOU and precision. This inverse relationship between sampling rate and recall demonstrates how sampling frequency affects detection performance, with more frequent sampling capturing more examination events but potentially introducing more false positives. Using bootstrap median HMM matrices did not materially change performance at 1-second sampling (Δrecall≤0.002; ΔIOU≤0.003; Multimedia Appendix 1).

Classification Distribution Analysis

Figure 4 illustrates classification distributions across different time segments, revealing distinct patterns among the models. In the analysis of the 3 primary states, all models showed relatively consistent classification patterns, with GPT-4o-mini and Qwen2.5-VL-72B notably classifying more “no doctor” segments as “preparation” compared to other models.

XSL•FO
RenderX

Figure 4. Classification distribution percentages by station: taking notes or consulting, physical examination (PE), no doctor, greeting, and preparation.



During PE periods, all models correctly identified a high percentage of frames as "physical examination." The buffer period analysis (–20 seconds to +20 seconds) showed a gradual transition between states, whereas classifications outside the buffered period correctly showed minimal "physical examination" identifications, confirming the models' spatial accuracy.

Station-Specific Performance at 1 Frame Per Second

We examined performance variations across the 5 different OSCE station types to evaluate our approach's adaptability to different clinical scenarios. Figure 5 shows that GPT-4o achieved high recall performance across all stations, with most cases achieving near-perfect recall (100%).

XSL•FO
RenderX

Figure 5. Recall, intersection over union (IOU), and physical examination (PE) length difference distributions with IQRs by station for GPT-4o.

The family medicine station exhibited the highest IOU (mean 0.93), likely because this station did not require medical students to place patients in a supine position for assessment, which reduced false positive PE classifications. The surgery 1 and internal medicine 2 stations showed the lowest IOU means (0.72 and 0.71, respectively), although they still maintained strong performance.

The PE length difference analysis in the bottom panel of Figure 5 indicates that GPT-4o generally predicted slightly longer examination periods than the ground truth across all stations, with mean differences ranging from 11 seconds (family medicine) to 68 seconds (surgery 1). These extended predictions ensure a comprehensive capture of examination activities while maintaining manageable review segments.

Classification Error Analysis

We identified 2 primary types of error cases that affected our models' performance: false negatives that reduced recall and false positives that reduced precision and IOU. Table 3 categorizes these errors into 5 distinct failure modes with representative examples.

XSL•FO
RenderX

Table 3. Classification failure mode analysis.

Case	Image	Model output and analysis
Out-of-frame examination • Error type: false negative • Model classification: "no doctor" • True classification: "physical examination"		• Model output: the patient is sitting on the chair. There is no doctor in the image. • Failure reasoning: the camera fails to capture the full examination that takes place around the legs of the patient.
Patient view occlusion • Error type: false negative • Model classification: "consulting" • True classification: "physical examination"		• Model output: the patient is sitting on the chair. The doctor is consulting the patient. • Failure reasoning: the medical student is obstructing the view of the patient, while the doctor is palpating the hands of the patient.
Verbal instruction examinations • Error type: false negative • Model classification: "consulting" • True classification: "physical examination"		• Model output: the doctor appears to be seated and observing the patient, possibly talking with the patient. • Failure reasoning: without the audio, it is very difficult to differentiate a patient walking to the medical chair and a patient being tested on their gait.
Preparation activity • Error type: false positive • Model classification: "physical examination" • True classification: "preparation"		• Model output: the doctor is standing up next to the patient, appearing to examine or interact with the patient's shoulders, indicating a physical examination is taking place. • Failure reasoning: while the doctor is lowering the chair for the patient, the model believes that the medical student is assessing the shoulders of the patient due to the student's hand position on the patient.
Bird's eye view • Error type: false positive • Model classification: "physical examination" • True classification: "consulting"		• Model output: the doctor is crouched in front of the patient, appearing to examine or interact with the patient's lower body, indicating a physical examination is taking place. • Failure reasoning: due to the camera being positioned higher than the eye level, if the medical student is close to the patient while taking notes with their hands hovering over the patient's legs while they explain something to the patient, the model thinks that the student is assessing the patient's legs from their hand position on the patient's legs.

All images used in the error analysis (Table 3) were generated by Grok 3 (xAI) to protect patient and student privacy while accurately representing the classification challenges observed in the actual OSCE videos.

These failure modes provide valuable insights for future system optimizations, particularly regarding camera placement and the potential integration of additional contextual information.

Discussion

Principal Findings

This study demonstrates that integrating MM-LLMs with temporal modeling provides an effective solution for automatically segmenting PE periods within OSCE videos. Our approach achieved 99.8% recall while reducing the video content requiring review by 81%, offering substantial benefits for both manual and automated assessment of medical student clinical skills. In the following sections, we discuss the implications, limitations, and future directions of this work.

The emission matrix (Figure 2B) showed 63.5% frame-level accuracy for "physical examination" states, with 31.8% misclassified as "conversation" due to similar visual features between these activities. However, high self-transition probabilities (0.857 for "physical examination") enabled Viterbi decoding to enforce temporal consistency and produce accurate segmentations despite frame-level noise, demonstrating the necessity of temporal modeling for this task.

Significance for Medical Education Assessment

The high recall rate (99.8%) achieved by our GPT-4o implementation represents a critical advancement for clinical skill assessment. In medical education, missing even brief examination components can lead to incomplete evaluations, potentially overlooking critical errors or skillful techniques that

XSL•FO
RenderX

determine pass or fail outcomes. Our approach ensures comprehensive capture of examination activities while substantially reducing the review burden.

By reducing a 15-minute (900-second) video to an average of 175 seconds of relevant content, our method creates significant efficiency gains for educational institutions. For programs conducting OSCEs with hundreds of students across multiple stations, this could translate to significant time savings, potentially thousands of hours saved annually. Beyond time savings, this approach enhances assessment quality by allowing evaluators to focus their attention on the most pertinent segments of student performance.

The station-specific performance analysis revealed important insights about contextual factors affecting detection accuracy. Family medicine stations achieved the highest precision (93.2%) and IOU (93.4%), likely due to their seated examination format with minimal patient repositioning. In contrast, the surgery stations showed more variability in precision (72.3%), reflecting the challenges posed by frequent patient repositioning and varying examination techniques. These findings highlight how PE contexts influence detection performance and suggest potential optimization strategies for different clinical scenarios.

Cost-Benefit Consideration

When comparing model configurations, GPT-4o achieved near-exhaustive capture of PE frames (recall=0.998) with lower IOU (0.784) at approximately US $1.25 per 15-minute video, whereas GPT-4o-mini yielded lower recall (0.945) but higher IOU (0.835) at approximately US $0.06 per video. Interpreted for deployment, GPT-4o minimizes the risk of missing examination content and is preferable when recall is paramount (eg, high-stakes evaluations), whereas GPT-4o-mini offers a near 20-fold cost reduction and yields more conservative segments that can streamline review. Selection of the operating point should reflect local tolerance for missed frames, desired review efficiency, and budget constraints.

Practical Implementation

Implementation in educational settings should begin with optimizing camera positioning. Our error analysis identified several failure modes directly attributable to suboptimal camera angles, including out-of-frame examinations and patient view occlusion. On the basis of these findings, we recommend positioning cameras at eye level with a side view that captures both the medical student and patient simultaneously.

Institutions must also consider data privacy regulations when implementing artificial intelligence–based video analysis systems. Our research used HIPAA- and FERPA-compliant application programming interfaces for proprietary models, whereas open-source alternatives were hosted on secure institutional infrastructure. These approaches demonstrate viable pathways for maintaining compliance while leveraging advanced artificial intelligence capabilities in educational settings.

Limitations

This study was conducted at a single institution with specific room layouts, camera positions, and station designs, which may limit generalizability to other educational settings and recording environments. Although this approach consistently identified PE segments, some dynamic or verbally cued maneuvers (eg, gait examination) remain challenging when relying on video frames alone; incorporating audio or transcripts may help resolve these issues. The current system detects the presence of a PE rather than classifying specific techniques, which constrains immediate use for fine-grained skill feedback. While annotations underwent quality checks, we did not conduct a formal interrater reliability study, so boundary uncertainty in the reference labels may persist.

With respect to human diversity and fairness, all recordings originated from a single site. Model behavior may vary across populations that differ in skin tone, body habitus, attire, assistive devices, or interaction styles, and we did not stratify performance by these attributes. Multisite validation with prespecified subgroup analyses will be necessary to quantify any performance differences and guide mitigation strategies before broad deployment.

Recommendations and Future Work

Future work should extend this PE and non-PE segmentation to finer-grained, technique-level labels that align with OSCE rubrics (eg, inspection, palpation, percussion, and auscultation). Moving beyond binary segmentation would make outputs immediately actionable for feedback and remediation. Methodologically, integrating audio or transcripts with video is a logical next step, particularly for dynamic or verbally cued maneuvers; multimodal fusion may reduce boundary errors and improve recognition of short, transient actions. In parallel, interface and workflow studies are needed to evaluate how predicted segments affect reviewer behavior, interrater reliability, and total review time in authentic grading settings.

External validation across multiple sites should quantify generalizability and fairness by reporting subgroup performance and CIs on prespecified attributes such as skin tone, body habitus, attire, and assistive devices. Where performance differences are observed, prompt design, postprocessing, or sampling strategies could be adapted to mitigate disparities. Prospective studies should also formalize decision criteria for selecting the model family and sampling rate using an explicit utility framework that balances recall (risk of missed PE content), precision and IOU (review efficiency), and monetary cost; these studies can incorporate paired statistical tests to determine whether observed differences between model configurations are significant in the target deployment context. Finally, releasing the code for the temporal postprocessing pipeline and standardized prompts, together with clear governance and consent procedures, would support reproducibility and accelerate comparative evaluations.

Conclusions

In a large corpus of OSCE recordings, a zero-shot MM-LLM paired with lightweight temporal decoding reliably isolated PE periods while substantially reducing the duration of video requiring human review. This approach meets the study aim of testing whether PE segments can be identified without previous task-specific training to lessen evaluation burden. Although this work is limited to a single site and targets PE presence rather

XSL•FO
RenderX

than specific techniques, sensitivity analyses support the robustness of the temporal model, and the results collectively indicate that selective review guided by model-predicted segments is a practical pathway for scaling assessment in medical education. Broader, multisite validation with attention to fairness, together with extensions to technique-level labeling and multimodal inputs, are appropriate next steps before routine implementation.

Acknowledgments

A generative artificial intelligence tool (eg, Grok 3; xAI) was used for portions of figure generation (synthetic exemplars) and editorial assistance. All authors verified the accuracy and accept responsibility for the content. The authors would like to thank the standardized patients and medical students who participated in the objective structured clinical examinations. They also thank the staff at the University of Texas Southwestern Simulation Center for their assistance in data collection and access to video recordings. Azure compute credits were provided to AJ by Microsoft as part of the Accelerating Foundation Models Research initiative.

Data Availability

The datasets generated or analyzed during this study are not publicly available because they comprise Family Educational Rights and Privacy Act–protected objective structured clinical examination recordings with identifiable audio and video but are available from the corresponding author on reasonable request.

Abstract

Background: The digitization of health care, facilitated by the adoption of electronic health records systems, has revolutionized data-driven medical research and patient care. While this digital transformation offers substantial benefits in health care efficiency and accessibility, it concurrently raises significant concerns over privacy and data security. Initially, the journey toward protecting patient data deidentification saw the transition from rule-based systems to more mixed approaches including machine learning for deidentifying patient data. Subsequently, the emergence of large language models has represented a further opportunity in this domain, offering unparalleled potential for enhancing the accuracy of context-sensitive deidentification. However, despite large language models offering significant potential, the deployment of the most advanced models in hospital environments is frequently hindered by data security issues and the extensive hardware resources required.

Objective: The objective of our study is to design, implement, and evaluate deidentification algorithms using fine-tuned moderate-sized open-source language models, ensuring their suitability for production inference tasks on personal computers.

Methods: We aimed to replace personal identifying information (PII) with generic placeholders or labeling non-PII texts as "ANONYMOUS," ensuring privacy while preserving textual integrity. Our dataset, derived from over 425,000 clinical notes from the adult emergency department of the Bordeaux University Hospital in France, underwent independent double annotation by 2 experts to create a reference for model validation with 3000 clinical notes randomly selected. Three open-source language models of manageable size were selected for their feasibility in hospital settings: Llama 2 (Meta) 7B, Mistral 7B, and Mixtral 8×7B (Mistral AI). Fine-tuning used the quantized low-rank adaptation technique. Evaluation focused on PII-level (recall, precision, and F_1-score) and clinical note-level metrics (recall and BLEU [bilingual evaluation understudy] metric), assessing deidentification effectiveness and content preservation.

Results: The generative model Mistral 7B performed the highest with an overall F_1-score of 0.9673 (vs 0.8750 for Llama 2 and 0.8686 for Mixtral 8×7B). At the clinical notes level, the model's overall recall was 0.9326 (vs 0.6888 for Llama 2 and 0.6417 for Mixtral 8×7B). This rate increased to 0.9915 when Mistral 7B only deleted names. Four notes of 3000 failed to be fully pseudonymized for names: in 1 case, the nondeleted name belonged to a patient, while in the others, it belonged to medical staff. Beyond the fifth epoch, the BLEU score consistently exceeded 0.9864, indicating no significant text alteration.

Conclusions: Our research underscores the significant capabilities of generative natural language processing models, with Mistral 7B standing out for its superior ability to deidentify clinical texts efficiently. Achieving notable performance metrics, Mistral 7B operates effectively without requiring high-end computational resources. These methods pave the way for a broader availability of pseudonymized clinical texts, enabling their use for research purposes and the optimization of the health care system.

Introduction

The digitization of medical data has profoundly transformed health care, facilitating the easy and efficient sharing of patient information [1]. This digital transition, embodied by electronic health records systems, offers promising opportunities for data-driven solutions, research, and surveillance on a pan-European scale [2]. Yet, alongside the many advantages of digitization come significant concerns about the privacy and security of sensitive patient data [3]. The European General Data Protection Regulation emphasizes the necessity of stringent data protection measures, particularly for health-related information [2]. Clinical notes, which often encompass identifiable patient details, must adhere to these standards to safeguard patient confidentiality [loi informatique et liberté], before any data sharing researchers face the critical task of developing and integrating methods that mask sensitive data, guaranteeing protection against any unauthorized access [4]. Our team was recently faced with this challenge in a project aimed at classifying clinical notes from emergency services to extract the necessary information for the establishment of a trauma observatory [5].

Manual deidentification of medical records is not feasible, as it is expensive in terms of personnel resources and the time required to accomplish the task. Alternatively, multiple strategies have been implemented for the automated deidentification of medical records [6,7]. These methods evolved from systems based on explicit rules, regular expressions or dictionaries [8-16], to techniques using machine learning [17-19].

In recent years, the evolution of language models, particularly those based on transformer architectures, has reshaped the landscape of natural language processing (NLP). Transformers, introduced by Vaswani et al [20] in 2017, provided a novel approach to handling sequential data using self-attention mechanisms, thereby obviating the need for recurrent layers and significantly augmenting training efficiency. This pivotal innovation paved the way for the advent of progressively sophisticated and expansive models. Transformer-based language models of a moderate scale, particularly through customized and fine-tuned versions of the architecture BERT [21], have demonstrated high capabilities in various health care applications. These models excel in understanding and processing complex clinical texts, enabling tasks such as predicting patient outcomes and identifying medical events. For instance, a recent study highlighted the effectiveness of fine-tuned BERT models in analyzing clinical notes to predict occurrences of falls, showcasing the model's ability to comprehend subtle nuances in medical language [22]. Additionally, BERT models offer significant benefits for tasks such as named entity recognition (NER). Those models offer notable benefits for deidentification, thanks to their capacity to discern patterns among words and phrases. They have the ability to learn from diverse text types means they can effectively tackle various pseudonymization challenges, as they can be trained to erase a wide range of identifiable details across different document types.

The burgeoning of computational resources and datasets has since kindled a shift toward the construction of massive models, embedded with trillions of parameters [23-25]. As they grew in size, their generalization aptitude and versatility witnessed substantial enhancement, optimizing tasks such as deidentification. In 2023, Liu et al [25] underscored the potential of leveraging the GPT-4's inherent capacity for 0-shot in-context learning. A salient highlight of their methodology was its ability to maintain the original structure and meaning of the text after the removal of confidential details. While the capabilities of GPT-4 are undeniable, its application in the realm of health care presents serious ethical and legal dilemmas, primarily concerning data privacy and patient confidentiality. On the one hand, due to the vastness of the model, local hosting of GPT-4 is not feasible, therefore, data should be transmitted to external servers, in this case OpenAI's infrastructure. On the other hand, considering the confidentiality of the weights, only locally hosted servers are regulatory compliant. Furthermore, considering that GPT-4 is a proprietary model, organizations cannot fully control or audit the underlying mechanics or data handling processes.

From a regulatory perspective, sending personal health information externally contravenes many data protection regulations, most notably the General Data Protection Regulation in Europe and the Health Insurance Portability and Accountability Act [26,27] in the United States. This raises not just data sovereignty issues but also infringes on patient rights, as they might not have explicitly consented for their data to be processed in external environments. Hence, while the technological feats of models such as GPT-4 are commendable, their real-world applications, especially in sensitive sectors such as health care, require careful consideration and possibly, significant adjustments to ensure full regulatory compliance and ethical integrity.

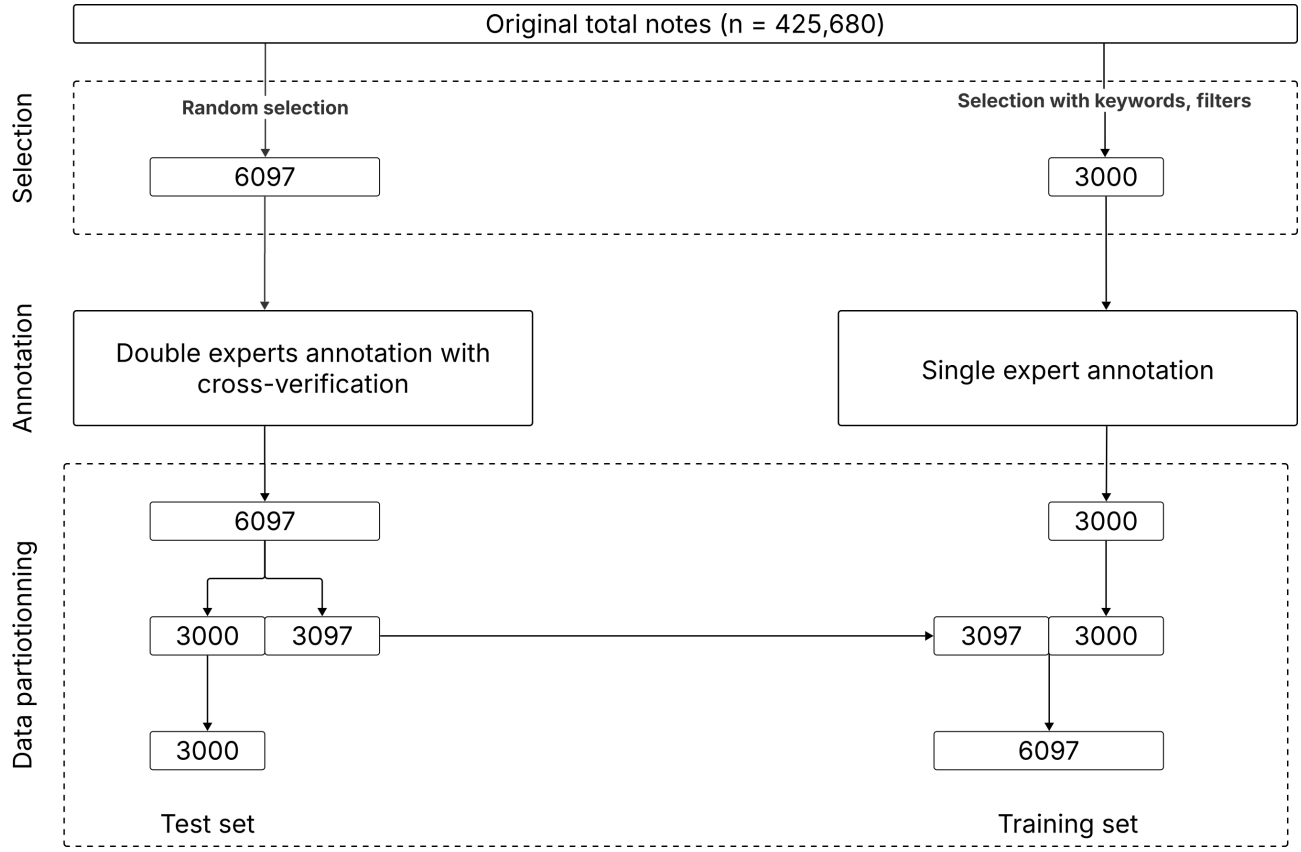
Generative language models significantly smaller in size (several billion parameters compared to over a trillion for GPT-4) have been recently developed and made available to the public under licenses that allow for almost unrestricted use (Llama 2 by Meta [28]) or even under open-source terms (Mistral [29]).

The objective of our study is to design, implement, and evaluate deidentification methods involving proper prompt engineering and fine-tuning of 3, open-source language models (Llama 2 7B, Mistral 7B, and Mixtral 8×7B [30]). These models were selected for their moderate size, making them suitable for deployment on personal computers for production inference tasks.

Methods

Study Design

We first attempted to perform the task using only prompt engineering and 0-shot inference. As we failed to achieve any significant results, we improved the selected models' capability to deidentify clinical texts using quantized low-rank adaptation [31] fine-tuning with a dataset of instruction or response pairs. In practice, the task consists in replacing personal identifying information (PII; name, location, dates, telephone number,



XSL•FO
RenderX

email, or identification numbers) with generic placeholders, represented as "[XXXXX]," or, when no PII is detected, by generating the text as "ANONYMOUS." The ultimate goal of this procedure is to preserve text content, ensuring adherence to privacy and confidentiality requirements.

Data Source, Datasets Allocations, and Annotation

Within the emergency department, triage is conducted by triage nurses. This process involves the collection of information on each patient, including medical history, current symptoms, vital signs, and personal details. It is these data that we have at our disposal in our study. For this investigation, we curated our dataset from a repository containing 425,680 clinical free-text notes (Multimedia Appendix 1), authored by a nurse during the initial reception and triage of individuals at the Bordeaux University Hospital's adult emergency department over the period spanning from January 2013 to December 2022. A subset of 6097 clinical notes was randomly selected and independently annotated by 2 experts. Any arising discrepancies were adjudicated by a third expert, thus establishing a reference database. From this curated sample of 6097 clinical notes, 3000 were delineated to constitute a test dataset, upon which accuracy metrics were evaluated (Figure 1). The residual 3097 clinical notes, alongside an additional sample of 3000 clinical notes designed using filters and keywords search to encompass a broad spectrum of identifying scenarios, comprised the validation dataset.

Figure 1. Data preparation: annotation and splitting into training and test sets.

In order to further assess whether the deidentification performances of the models varies with the type of PII, we classified identifying information within clinical notes into 6 distinct categories (Table 1). These categories were used by annotators to label such information in the test dataset. While we have taken care to remove obvious PII such as names, addresses, and identification numbers, it is important to note that deidentification cannot be considered as a strict anonymization process. For instance, in cases of rare diseases or very specific descriptions, reidentification could theoretically be possible. As every clinical history is unique, ensuring complete anonymity is unattainable. Our goal is to pseudonymize data, striking a balance between patient confidentiality and data utility for research, as removing all sensitive information will significantly diminish the data's usefulness.

Table . Personal identifying information categories description in medical records.

Type	Code	Description
Individual names	NAME	Includes both first and last names of individuals (including patients and medical staff) or of relatives, employers, or household members of the individuals, ensuring personal identification.
Dates	DATE	Pertains to specific dates related to medical events, appointments, or personal milestones, formatted as day, month, or year.
Geographic identifiers	LOC[a]	Covers names of geographic locations such as cities, medical facilities, or addresses, facilitating location-based identification.
Phone numbers	TEL[b]	Comprises all forms of telephone numbers for direct contact, including mobile and landline numbers.
Email addresses	MAIL	Encompasses electronic mail addresses, allowing for digital communication.
Miscellaneous identifiers	OTHER	A catch-all category for unique identifiers not covered by other categories, including social security numbers, medical analysis codes, and URLs for patient images.

[a]LOC: location.

[b]TEL: telephone.

Selected Models

We have selected 3 language models that share the following 2 characteristics: being open-source and of sufficiently small size for the production phase to be implemented on affordable PC-type systems. These are Llama 2 7B, Mistral 7B, and Mixtral. Llama 2 7B is developed by Meta. Launched in 2023, this is a 7-billion-parameter model, which is claimed to exhibit a good balance between performance and efficiency. We also selected the Mistral 7B model, introduced to the public in October 2023. It has demonstrated superior performance, either matching or surpassing that of Llama 2 13B in extensive benchmarks and showing comparable results to Llama 1 34B in specific domains such as reasoning, mathematics, and code generation. In December 2023, the Mixtral 8×7B model was released. It is described as a Sparse Mixture of Experts language model. Its key innovation lies in the routing of inference tasks through 1 selected expert out of 8, enabled by an additional routing layer. Consequently, despite its 8×7B size with respect to fine-tuning, Mixtral achieves a significant efficiency by requiring an eightfold reduction in parameters for inference task.

Fine-Tuning and Inference

Each model was subjected to the same prompt or response pairs of clinical notes. The fine-tuning process was uniformly standardized across all 3 models, albeit with variations in batch sizes and quantization rates to accommodate our hardware constraints. The fine-tuning configuration for Mistral 7B and Llama 2 7B involved a batch size of 24 records per GPU, while Mixtral used a batch size of 20. The models were fine-tuned over 15 epochs, using the AdamW optimizer [32] with a learning rate of 5e-5 and a weight decay of 0.01. We used the quantized low-rank adaptation technique, allowing for specific adjustments in selected parts of the model, such as query, key, value, output, and gates projection modules while preserving the overall architecture integrity. The low-rank adaptation configuration included a rank setting of 32, a learning rate multiplier (alpha) set to 64, with a dropout of 0.1, and without any bias setting. Additionally, to optimize computational efficiency and minimize memory consumption, the models were quantized to 8-bit precision for both 7B models, and 4-bit precision for Mixtral. At every fine-tuning epoch, the inference was induced for each model.

The computational undertakings of this research were performed on a server running Ubuntu (version 22.04; Canonical Ltd), outfitted with 4 A100 GPUs, collectively boasting 320GB of VRAM.

Evaluation

Overview

In evaluating the deidentification performance of personal data within clinical notes, our analysis is structured around 2 primary methodologies. The first methodology operates at the PII-level, enabling us to provide estimates of recall, precision, and F_1-scores that are comparable with previous work in the literature. The second methodology focuses on clinical notes as the statistical unit, enabling us to assess the variation in recall performance according to the category of PII. This latter approach needs to be complemented by the measurement of a BLEU (bilingual evaluation understudy) score to assess potential modifications in the text. The assessment of the number of successful deidentifications was conducted through a comparison with the manually annotated test dataset.

PII-Based Metrics

This approach centers on treating each PII as an independent statistical unit. This perspective allows us to gauge the precision

XSL•FO
RenderX

and recall of our deidentification efforts at the most granular level. Recall in this context is conceptualized as the proportion of PIIs accurately identified and removed from the clinical notes.

$$\text{Recall}_{\text{PII}} = \frac{\text{number of correctly identified PII in clinical notes}}{\text{total number of PII in clinical notes}}$$

Precision, meanwhile, reflects the accuracy of our model in identifying and eliminating actual PIIs, distinguishing between correct identifications and false positives.

$$\text{Precision}_{\text{PII}} = \frac{\text{number of correctly identified PII in clinical notes}}{\text{total number of PII tagged}}$$

The summary F_1-score measure is:

$$\text{F1-score} = \frac{2}{\frac{1}{\text{precision}} + \frac{1}{\text{recall}}}$$

Clinical Note–Based Metrics

The second approach adopts the entire clinical note as the statistical unit of analysis. Here we evaluate the success of deidentification on a document-wide scale, marking a "success" when every PII within a note has been successfully deidentified. Such a measure offers insight into the overall effectiveness of our deidentification protocols. Recall, in this instance, measures the ratio of fully deidentified notes to those containing any PII.

$$\text{Recall} = \frac{\text{number of correctly deidentified clinical notes containing PII}}{\text{total number of PII clinical notes}}$$

Because the clinical notes in the validation set are annotated by indicating the nature of the PII (according to the categories in Table 1), it is possible to detail the variations in recall by category. The relevance of precision is altered in this context, as it necessitates a different consideration of what constitutes a pseudonymization attempt, denoted by the presence of a pseudonymization tag. Instead, the potential alteration of content possibly induced by the deidentification process was measured using the BLEU score [33].

$$\text{BLEU} = \text{BP} \cdot \exp\left(\sum w_n \log p_n\right)$$

where BP is the brevity penalty, w_n the weight for each n-gram, and p_n the precision of n-grams. We set a value of 4 for the BLEU score calculation, aligning with common practice in NLP to capture up to 4-gram coherence, thereby ensuring a comprehensive evaluation of content preservation.

Ethical Considerations

Overview

This study was conducted as part of the Automated Processing of Emergency Department Visit Summaries for a National Observatory project, which aims to automate the processing of emergency department visit summaries for national observation purposes.

The study received the following regulatory approvals: (1) the Ethics Committee for Research in Science and Health, validating the compliance of the protocol with current ethical requirements; and (2) the National Commission on Informatics and Liberty, under decision DR-2022-235 (authorization request 922170), allowing the processing of data for this study.

Confidentiality and Data Protection

The data processing was carried out exclusively on a secure local server, specially dedicated to this purpose. This server meets the current security standards, ensuring the confidentiality, integrity, and protection of the processed information. All necessary technical and organizational measures have been implemented to prevent unauthorized access to the data and to ensure strict compliance with regulatory requirements.

Compensation

Since this study relies solely on the analysis of pre-existing medical data and does not require direct patient involvement, no financial compensation was provided.

Results

Data Overview

Very few notes contained PIIs categorized as email addresses and "other." These categories are included in the training sample due to an ad hoc selection process, which used filters to ensure representation, as half of the set was selected this way. Our examination of the test sample, which consists entirely of randomly selected clinical notes, reveals that names, places, and dates are the most prevalent types of PII. The categories of identifying data in the training and test sets are summarized in Table 2.

Regarding the length of clinical notes, they range from 8 to 3916 characters (with an average of 443, SD 289 characters) in the training set and from 3 to 2138 characters (averaging 439, SD 283 characters) in the test set. A total of 935 (31.2%) clinical notes in the test set contain at least one PII.

XSL•FO
RenderX

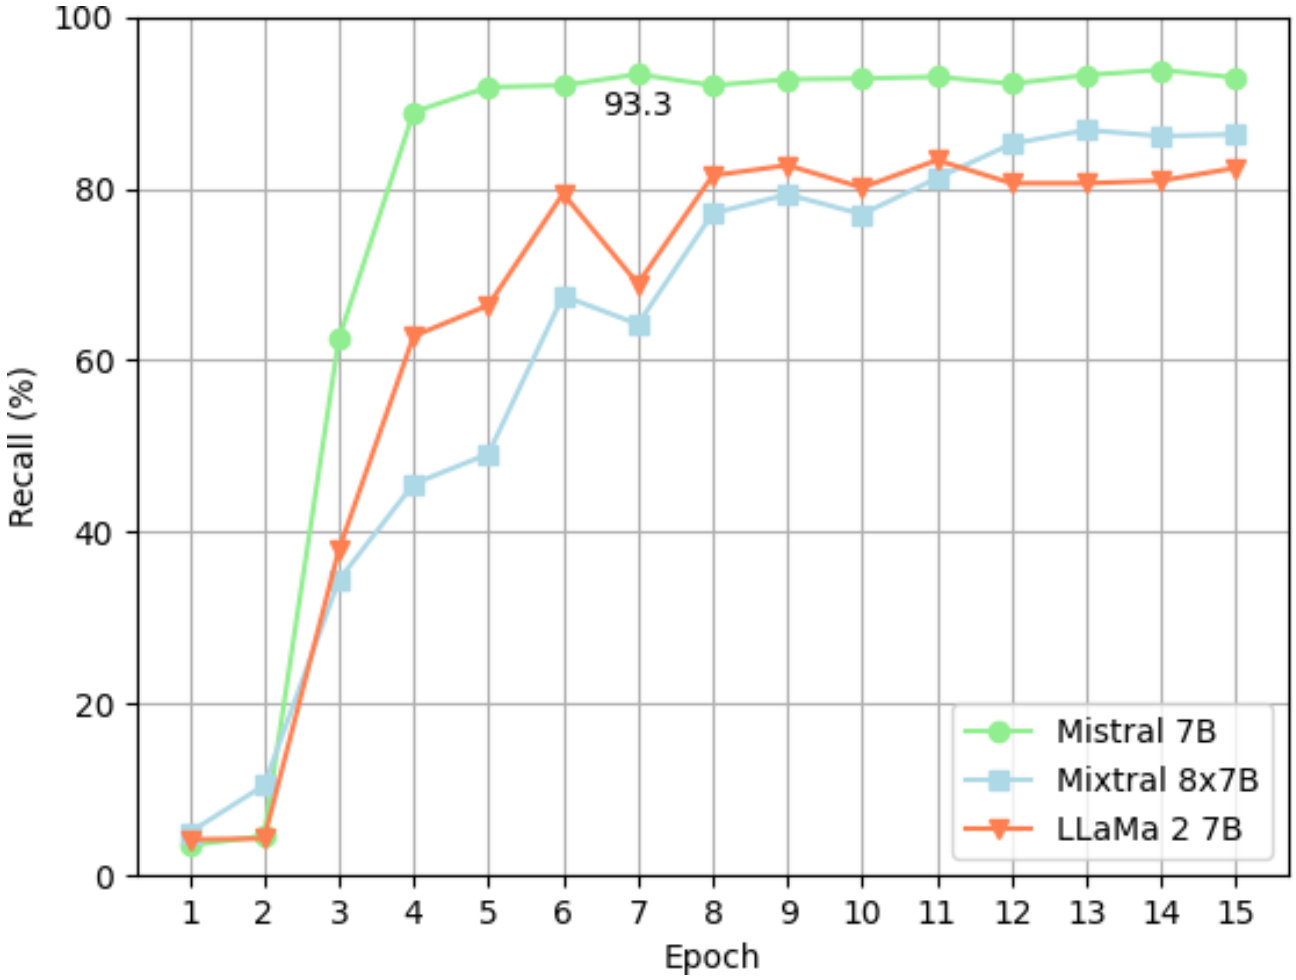
Performance Using PII-Based Metrics

Figure 2 plots the change in the F_1-score over the 15 epochs of fine-tuning for the 3 respective models. The Mistral 7B model quickly reaches a performance plateau, where its F_1-score stabilizes, whereas the Mixtral 8×7B and Llama 2 7B models exhibit a slower rate of improvement, with both reaching a plateau in their F_1-scores around the 12th epoch.

XSL•FO
RenderX

Figure 2. Plot of F_1-score by epoch: PII as statistical unit.

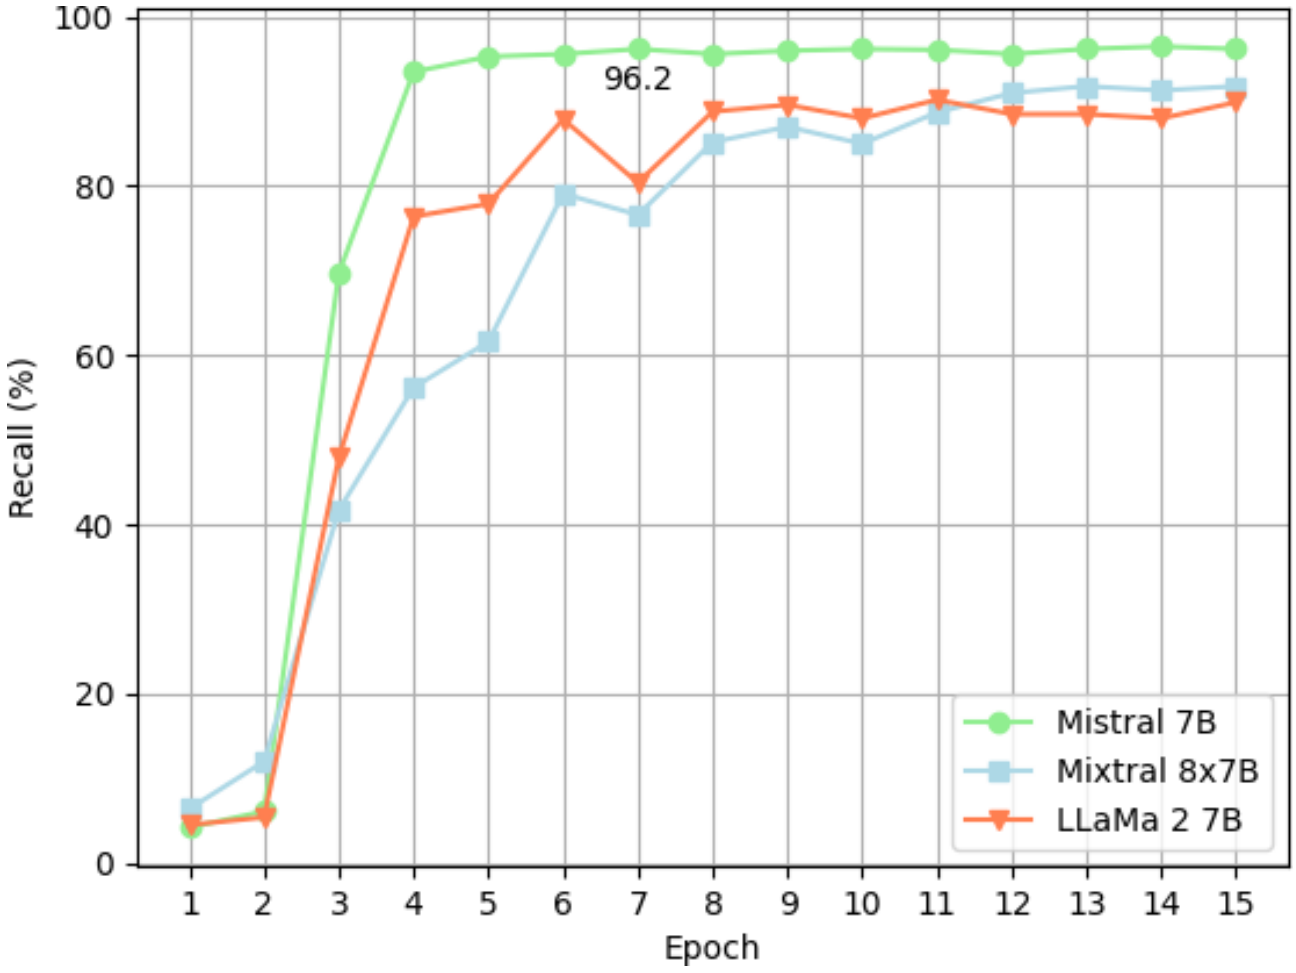
Recall Analysis



The recall estimates of the 3 models are shown in Figures 3 and 4.

Mistral 7B and Mixtral 8×7B achieved better overall recall. The Mistral 7B and Mixtral 8×7B models demonstrated marked enhancements in their deidentification efficacy across epochs, starting from the third epoch onward. Notably, the Mistral 7B model has shown a rapid improvement in performance, achieving a performance plateau by the sixth epoch. Conversely, the Mixtral 8×7B model's improvement trajectory was more gradual, reaching a stable performance level by the 13 epoch. The overall success rate appears not to improve beyond epoch 7 for the Mistral 7B model. Consequently, in the subsequent analysis, this epoch was selected for comparing success rates across categories.

As shown in Figure 5, Mistral 7B consistently outperformed Mixtral 8×7B and Llama 2 across all data identification categories. Despite Mixtral's performance improving over time, it still did not surpass Mistral 7B. Using Mistral 7B, a 100% (41/41) recall was observed for phone numbers (Figure 5) and recall was lower for locations than for names.



XSL•FO
RenderX

RenderX

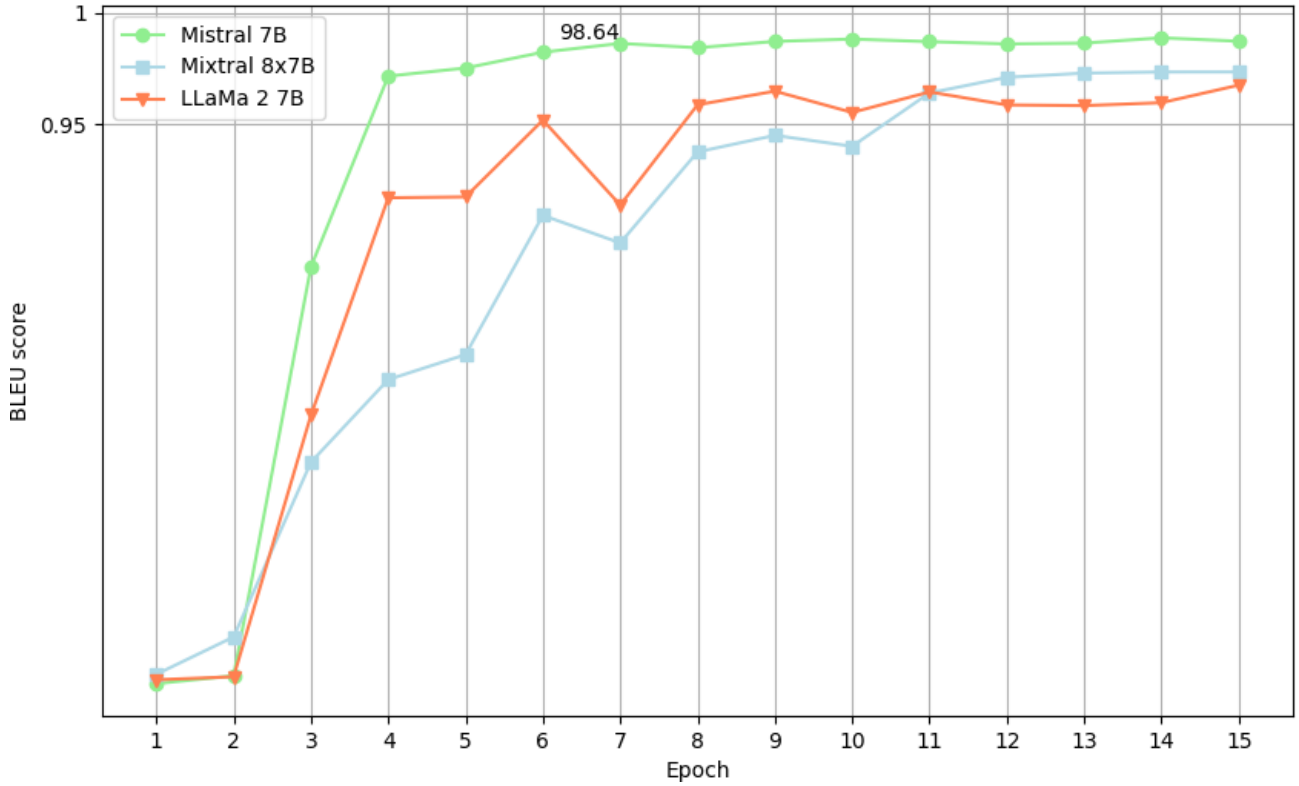
Figure 5. Plot of recall by epoch for PII: (A) Location, (B) Telephone, (C) Name, (D) Date. PII: personal identifying information.



BLEU Score

BLEU-4 scores were calculated to assess whether the models modified the texts at the note level. During the deidentification process, medical texts remained almost unchanged as demonstrated by a consistently high BLEU-4 score (Figure 6) beyond epoch 5.

XSL•FO
RenderX

Figure 6. Plot of BLEU score by epoch: clinical note as statistical unit. BLEU: bilingual evaluation understudy

Results Summary at Epoch 7

The Table 3 below presents a summary of performance metrics achieved by our models at epoch 7.

The results demonstrate that the Mistral 7B model outperforms both the Mixtral 8×7B and Llama 2 7B with a F_1-score of 0.9673. When using clinical note as the statistical unit, the recall is also much higher (0.9326) for Mistral 7B than Llama 2 and Mixtral 8×7B models.

Table . Fine-tuned models performance at epoch 7.

Model	Clinical notes	Personal identifying information		
	Recall	Precision	Recall	F_1-score
Mistral 7B	0.9326	0.9721	0.9625	0.9673
Llama 2 7B	0.6888	0.9596	0.8041	0.875
Mixtral 8×7B	0.6417	0.9852	0.7655	0.8616

Error Analysis

In epoch 7 of the Mistral 7B model, a total of 63 clinical notes were not properly pseudonymized, as detailed in Table 4. Among these, location (LOC) errors were the most frequent, with 44 instances. Deleting geographical and institutional identifiers then remains a significant challenge (with a recall of 86.1%). Specifically, 31 notes still included names of health or social service facilities, while 12 notes still included names of cities. Conversely, errors involving names (NAME) were significantly fewer, with only 4 instances, including 1 patient name and 3 doctors' names, resulting in a high recall of 99.8% for this category. Date-related errors (DATE) were observed in 14 notes (with a recall of 97.8%).

The test dataset, comprising 3000 clinical notes, underwent a post hoc examination to identify any inaccuracies resulting from manual annotations that would have been detected by all 15 versions of our 3 finely-tuned models, spanning epochs 1 to 15. Through this process, we were able to pinpoint 65 notes in which the model detected personally identifiable information through the medical histories that were categorized as anonymous (ie, without identifying data, 2066 clinical notes), in which the model detected personally identifying information that had been overlooked by human annotators.

XSL•FO
RenderX

Table . Summary of deidentification errors at epoch 7.

Errors	Count
Total	63
Returned ANONYMOUS	29
Annotation error	34
Errors in personal identifying information categories	
NAME	4
LOC[a]	44
DATE	14
OTHER	1

[a]LOC: location.

We observed that the models outperformed human annotation in 9 clinical records from the test set. Specifically, in these 9 records, 5 locations (LOC), 3 names (NAMES), and 1 date (DATE) were omitted during manual annotation. The remaining 53 records present annotation errors from the models. Therefore, the total number of actual personally identifiable information (PII) amounts to 1928, contrary to the 1919 initially identified by our experts.

Subsequently, corrections were made to the test dataset based on these findings, and main outcomes were recomputed in an additional sensitive analysis. The metric measurements after accounting for these modifications are only slightly altered from the original results (see Multimedia Appendix 2 for the details).

Discussion

Principal Findings

In this study, we assessed the performance of 3 generative NLP models in the deidentification of clinical text documents. The generative model Mistral 7B demonstrated the highest performance with an overall F_1-score of 0.9673. At the clinical notes level, the same model achieved an overall recall of 0.9326, with this rate increasing to 0.9915 for the deletion of names. The evaluation was based on a test dataset of 3000 clinical notes, among which only 4 notes failed to be fully deidentified for names; in one case, the identifying name was that of a patient. As the method relies on the use of generative models, we also measured potential text alterations generated by the process. Beyond the fifth epoch, the BLEU score consistently exceeded 0.9864.

Strengths

Our work distinguishes itself from the existing scientific literature by using a method that does not rely on NER and uses moderate-sized models. Instead, the use of generative large language models allows for the production of text that is pseudonymized by removing PII components. This is the reason why we added metrics that use clinical notes as the statistical unit. This led us to use the BLEU metric to assess potential text alterations. Another consequence of this method is that no hyperparameters are set which made it possible to avoid the use of separate test and validation dataset partitions. The size of our training and test samples, independently annotated by 2 experts, constitutes a significant strength in our study. To our knowledge, no other study has used a test sample of such size (3000 notes). Yet, it is crucial to have the means to detect rare errors if the ultimate goal is to develop a system that guarantees the pseudonymization of clinical texts. We deliberately limited our model selection to those whose implementation does not require powerful servers and can be executed on personal computers equipped with a consumer-grade graphics card. The largest model is Mixtral 8×7B, which has approximately 8 times more parameters than the other 2 models. Mixtral 8×7B shares the same architecture as Mistral 7B, with the distinction that each layer consists of 8 feed-forward blocks. Although training it requires significant memory capacity, this is not the case during the inference phase, during which only 2 of the feed-forward blocks are used, selected by a network acting as a router.

Limitations

Annotation Process Inaccuracies

Overview

During the annotation process, we observed some inaccuracies. To assess the impact of these inaccuracies on our metrics, we conducted a post hoc analysis, taking into account corrections made by the model. Although this analysis revealed few variations, it is important to note that some errors may still remain in the text set, undetected by the model. These undetected errors could potentially affect the overall performance of the model.

Model Choice

We opted for a fine-tuned large language model–based approach over a dedicated NER model due to pragmatic considerations. Our hypothesis was that a targeted human annotation process, with expert annotators pinpointing PII within texts, would be more effective than a broad NER annotation effort, given the same time investment. Focusing on essential PII elements helps us minimize the ambiguities that broader NER annotations often entail. This focus leads to improved precision and recall rates during the training phase. Furthermore, this approach is in line with the Automated Processing of Emergency Department Visit Summaries for a National Observatory project's objectives, which prioritize the accurate removal of PII from unstructured medical texts.

The default choice for identification tasks is usually a bidirectional transformer, starting from the hypothesis that the relationship of a word with its context before and after that word allows for better comprehension of the role of those words and therefore should be more suited for NER tasks. However, this hypothesis no longer holds when dealing with generative models. Since the goal here is to generate redacted text, the provided prompt has access to the entire corrected phrase. Consequently, relative to a given word, implications cannot be considered unidirectional.

Model Sharing Constraints

Overview

Another significant limitation is that our model was fine-tuned using nonanonymous clinical texts, which prevents us from sharing the model's weights with the community. Sharing the model's weights could potentially allow for the extraction of the original training data. This limitation restricts the model's reproducibility and its broader applicability across different research settings and medical domains.

Demographic and Textual Bias

The processed data are in free-text format, written by health care staff, which introduces significant variability. This variability is not only present between different services within the same health facility but also across various centers. Factors such as the content of clinical notes, the medical abbreviations used, writing styles, and the level of detail in documentation can differ greatly from one source to another. Such differences could potentially impact the performance of our models, making it essential to test and adapt our approach to data from diverse sources.

Comparison With Prior Work

Comparing the performance of our models with those documented in the literature presents challenges because our models are specifically fine-tuned to pseudonymize French-language clinical notes. Consequently, it is not feasible to apply them to the English-language databases traditionally used for benchmarking, such as i2b2 (i2b2 TranSMART Foundation) [34], MIMIC II (PhysioNet) [35], and MIMIC III (PhysioNet) [36].

In addition to these differences in benchmarking context, there are also divergences in the methodologies used for deidentification. Historically, deidentification of medical records has evolved from rule-based systems, which rely on predefined rules, regular expressions, and dictionaries, to more sophisticated machine learning approaches. Rule-based methods, while easy to implement and interpret, often fall short in handling the variability and unpredictability inherent in unstructured clinical texts. On the other hand, machine learning-based approaches offer more flexibility and adaptability, particularly when dealing with large and diverse datasets. These models can learn patterns directly from the data, making them more effective in identifying PIIs that deviate from standard formats. However, their effectiveness is heavily dependent on the quality and quantity of annotated data available for training. Moreover, machine learning models typically require significant computational resources and expertise in model tuning, which can be a barrier to adoption, particularly in resource-constrained settings.

Our proposed model leverages these advanced machine learning techniques, specifically fine-tuned for the French language. This focus allows our model to effectively capture and manage the linguistic intricacies specific to French clinical notes, such as frequent abbreviations and unstructured text entries, which are common in emergency department settings.

Additionally, our results demonstrate that while our model performs comparably to those trained on English-language corpora, certain challenges persist, particularly in the detection of location-based PIIs. This is likely due to the complexity introduced by variations in PII forms, such as acronyms and abbreviations, as well as the presence of typing errors, which are less predictable and harder to model.

Therefore, to compare performance metrics accurately, it is necessary to assess the complexity of clinical texts from these databases against those used in our study. In the Multimedia Appendix 1, we include examples of clinical notes from our dataset to demonstrate that PIIs can appear randomly within the text, in an unstructured manner, and that these PIIs, along with the rest of the text, often include numerous abbreviations. This tendency toward abbreviation is explained by the unique demands of emergency department settings, where nurses are required to perform efficient, real-time data entry into the hospital's information system. As a result, our dataset more closely aligns with MIMIC II, which features unstructured clinical notes made by nurses, as opposed to i2b2, where each type of information is distinctly separated, preventing the amalgamation of multiple PIIs within single sentences.

As shown in Multimedia Appendix 3 [37-43], our results (overall F_1-score of 0.9673) are on par with previous studies on English clinical text corpus that used an algorithm including models using self-attention [17,24,36,44]. The Multimedia Appendix 4 [37,38,43] summarizes study results that examined recall variations according to PII categories. These figures consistently show that the relative weakness of these algorithms, ours included, lies in a small number of errors concerning locations. Our dataset presents additional challenges for PII identification due to the presence of multiple variations of PII, including acronyms, abbreviations, and typing errors. Specifically, of the 44 notes with failed identification, 15 involved abbreviations or acronyms, and 2 contained typing errors.

Future Work

We aim to enhance the detection capabilities of PII in our medical notes by fine-tuning our model with newly annotated data. To achieve this, we plan to generate artificial clinical notes using commercially available application programming interfaces, such as GPT-4. These large language models, much more powerful than ours, can produce realistic notes containing PII and annotations, which will facilitate the training process and increase data diversity.

By generating a substantial volume of these artificial data, we can ensure equitable representation of different PII categories and evaluate 2 key aspects: identifying the optimal amount of

XSL•FO
RenderX

clinical notes needed to achieve the highest possible accuracy and recall, and comparing the effectiveness of models fine-tuned with real data versus those fine-tuned with artificially generated data.

Using this newly developed model based on artificial data, we aim to make it available as an open-source resource, benefiting the broader community. Additionally, this foundation will enable us to create a multilingual model capable of processing both English and French clinical notes. This multilingual model will allow us to perform performance comparisons against literature benchmark datasets such as i2b2 and MIMIC. The performance of these refined models will be evaluated using our corrected test set, along with newly annotated data from various emergency services.

This study is currently focused on data from an emergency department in France. In the subsequent phases, our goal is to extend this methodology to other services across France, with the ambition of creating a national French observatory on trauma. However, it is important to consider the potential for demographic biases in our model's performance.

By diversifying data sources, we aim to enhance the model's generalizability. If biases are identified in this process, we plan to retrain the model, either by using a specific portion of data from each service or by integrating synthetic data to mitigate these biases.

We intend to extend our methodology to other types of sensitive documents, such as medico-legal records, to evaluate the generalizability and effectiveness of our approach in protecting personal information across various domains.

We are also considering integrating explainability methods, similar to those used by Arnaud et al [45], to enhance the transparency of our model in PII detection. These techniques, based on transformer models and interpretability approaches such as LIME [46], which have already proven effective on triage note data similar to ours, could strengthen user trust and facilitate the adoption of our technologies in clinical settings.

Through this comprehensive approach, we aim to enhance the value and applicability of our models, contributing to the development of privacy-preserving technologies in the health care domain and strengthening the security of patients' sensitive information.

Ethical Considerations and Practical Implementations

The use of small to moderate-sized models is a key consideration in our approach. These models are generally capable of running on GPUs with at least 16 GB of VRAM, making them suitable for use on personal computers or within local infrastructures. This is particularly advantageous for institutions with limited resources, as it allows them to manage data privately and securely without relying on extensive external infrastructure. However, while local deployment ensures better control over sensitive data, it can also be time-consuming and may introduce challenges related to the interoperability of different systems.

One of the main challenges of this pipeline is its implementation across all participating emergency services, given that not all institutions may be equipped to efficiently manage these new procedures. The rationale behind implementing this process is rooted in a data-sharing initiative aimed at establishing a national observatory, which necessitates enhanced protection for the information being used.

At this stage, centralizing the data in a dedicated center with the necessary computational resources remains the simplest solution. This would allow for secure, controlled, and efficient management of patient data. Alternatively, the process could be implemented directly within health data warehouses, enabling these facilities to store and apply the deidentification process locally. Regardless of the approach, it is imperative that the use of this pipeline on health data is conducted within a legally and digitally controlled framework, authorized by the relevant authorities.

Given the potential risks of data reidentification, especially when dealing with unique clinical histories, we emphasize that pseudonymization alone is insufficient and should be accompanied by additional protection and security measures to prevent unauthorized access to sensitive data.

Conclusion

Our research underscores the significant capabilities of generative NLP models, with Mistral 7B standing out for its superior ability to deidentify clinical texts efficiently. Achieving notable performance metrics, Mistral 7B operates effectively without requiring high-end computational resources. These methods pave the way for a broader availability of pseudonymized clinical texts, enabling their use for research purposes and the optimization of the health care system.

Acknowledgments

This study was conducted under the Automated Processing of Emergency Department Visit Summaries for a National Observatory (TARPON) project by the Bordeaux Population Health-Assessing Health in a Digitalizing Real-World team and the Bordeaux University Hospital's emergency department. We thank the labeling team and the University Hospital of Bordeaux for their logistical support and data access.

Data Availability

The datasets generated or analyzed during this study are not publicly available due to the confidential nature of the patient data used.

Abstract

Background: Limited research exists evaluating artificial intelligence (AI) performance on standardized pediatric assessments. This study evaluated 3 leading AI models on pediatric board preparation questions.

Objective: The aim of this study is to evaluate and compare the performance of 3 leading large language models (LLMs) on pediatric board examination preparation questions and contextualize their performance against human physician benchmarks.

Methods: We analyzed DeepSeek-R1, ChatGPT-4, and ChatGPT-4.5 using 266 multiple-choice questions from the 2023 PREP Self-Assessment. Performance was compared to published American Board of Pediatrics first-time pass rates.

Results: DeepSeek-R1 exhibited the highest accuracy at 98.1% (261/266 correct responses). ChatGPT-4.5 achieved 96.6% accuracy (257/266), performing at the upper threshold of human performance. ChatGPT-4 demonstrated 82.7% accuracy (220/266), comparable to the lower range of human pass rates. Error pattern analysis revealed that AI models most commonly struggled with questions requiring integration of complex clinical presentations with rare disease knowledge.

Conclusions: DeepSeek-R1 demonstrated exceptional performance exceeding typical American Board of Pediatrics pass rates, suggesting potential applications in medical education and clinical support, though further research on complex clinical reasoning is needed.

(JMIR AI 2025;4:e76056) doi:10.2196/76056

Introduction

The integration of artificial intelligence (AI) in medical education and assessment raises important questions about the capabilities of large language models (LLMs) in understanding and applying pediatric knowledge. Recent advancements in AI have produced models with increasingly advanced medical reasoning capabilities [1,2], but limited research exists evaluating AI performance on standardized medical assessments. This study evaluates the performance of 3 leading LLMs (DeepSeek-R1 [DeepSeek AI, 2024], ChatGPT-4 [OpenAI, 2023], and ChatGPT-4.5 [OpenAI, 2024]) on a set of 2023 pediatric board examination preparation questions (2023 PREP Self-Assessment, American Academy of Pediatrics), a comprehensive resource containing case-based multiple-choice questions designed to simulate actual board examinations [3]. We hypothesized that newer AI models would demonstrate improved accuracy on pediatric knowledge assessment, potentially approaching the performance levels of board-certified pediatricians taking certification examinations.

Methods

Overview

We conducted a comparative analysis of 3 advanced LLMS (DeepSeek-R1, ChatGPT-4, and ChatGPT-4.5) using a set of 266 questions from the 2023 PREP Self-Assessment from the American Academy of Pediatrics. In compliance with fair use copyright law and with methods deemed exempt by the Healthy Steps Pediatrics Ethics Committee, we entered 266 questions and answer choices from the Pediatrics 2023 PREP Self-Assessment into the 3 LLM platforms. DeepSeek-R1 (DeepSeek AI, 2024), ChatGPT-4 (OpenAI, 2023, gpt-4-turbo, 128k context window), and ChatGPT-4.5 (OpenAI, 2024, gpt-4.5-turbo, 128k context window) were accessed through their respective web interfaces in February 2025.

The 2023 PREP Self-Assessment was selected as it represents the most comprehensive and current pediatric board preparation resource, designed by the American Academy of Pediatrics to mirror the content, format, and difficulty of actual American Board of Pediatrics (ABP) examinations. The questions cover

XSL•FO
RenderX

all major pediatric domains in proportions similar to the ABP content outline. The use of PREP questions was determined to constitute fair use for research purposes under 17U.S.C. §107, considering (1) noncommercial educational purpose, (2) factual nature of test questions, (3) limited amount used (266 of thousands of available questions), and (4) no market harm to the copyright holder. Questions were entered manually without reproducing answer explanations or proprietary content. As a subscription-based resource, the likelihood of PREP questions appearing verbatim in training datasets is low. However, we acknowledge that similar pediatric medical knowledge exists in publicly available resources like medical textbooks and journals that may have been included in model training.

Each AI model was presented with identical questions in their original multiple-choice format. All questions were text-based without images or clinical photographs. Each model was queried using standardized prompts: "Please answer the following multiple-choice question by selecting the best answer: [question text]." Default temperature settings were used (temperature=1.0 for ChatGPT models, default settings for DeepSeek-R1). No chain-of-thought or multistep reasoning prompts were used to maintain consistency across models. All queries were performed once without retries. Questions were presented sequentially without access to previous answers. Responses were collected and evaluated against the established correct answers. Performance was measured by calculating the percentage of correct responses for each model. In addition, 95% confidence intervals were calculated using the Wilson score method. Model performance differences were assessed using the McNemar test for paired comparisons.

To contextualize these findings, we compared the AI models' performance to published data on first-time pass rates for board-certified pediatricians taking the ABP examination. This comparison provides a benchmark for evaluating the clinical relevance of AI performance in pediatric knowledge assessment. It is important to note that the human percentages reported by the ABP represent pass rates—the proportion of examinees who achieve or exceed the passing threshold in a given year—rather than the raw percentage of questions answered correctly. The ABP does not publicly release its exact passing cutoff, but historical reports and candidate feedback suggest that it is approximately equivalent to answering about 70% of questions correctly [4]. Successful test takers often score well above this minimum, with average performance typically exceeding 80%. Therefore, while AI model performance in this study is expressed as the percentage of correct responses, the human figures used for comparison reflect an outcome-based measure (pass/fail) rather than direct accuracy.

Ethical Considerations

The Healthy Steps Pediatrics Ethics Committee is an institutional committee that evaluates research proposals within our affiliated private practice network. This committee consists of 3 board-certified pediatricians who review research for ethical considerations. The committee determined this study was exempt from formal institutional review board approval as it involved publicly available AI tools and did not include human subjects or protected health information.

Results

The 3 AI models demonstrated marked differences in performance when tested on 266 pediatric board examination preparation questions. DeepSeek exhibited the highest accuracy at 98.1% (95% CI 95.7% - 99.4%; 261/266 correct responses), outperforming both ChatGPT models (Table 1). ChatGPT-4 achieved an accuracy of 82.7% (95% CI 77.7% - 87.0%; 220/266 correct responses), while ChatGPT-4.5 showed improvement over its predecessor, with approximately 96.6% accuracy (95% CI 93.7% - 98.4%), missing only 9 questions. The difference between DeepSeek-R1 and ChatGPT-4.5 was not statistically significant (P=.38, McNemar test).

Error pattern analysis revealed that AI models most commonly struggled with questions requiring integration of complex clinical presentations with rare disease knowledge (Table 2). For example, DeepSeek's 5 incorrect answers primarily involved metabolic disorders and rare genetic syndromes, particularly questions requiring correlation between subtle biochemical abnormalities and uncommon clinical presentations. ChatGPT models additionally struggled with complex medication dosing calculations and interpretation of pediatric growth parameters in the context of genetic disorders. Notably, there was minimal overlap in the specific questions missed by each model, suggesting that different LLMs have distinct knowledge gaps despite similar training paradigms.

Table . Performance of large language models on 2023 Pediatric Board Examination Preparation Questions.[a]

Artificial intelligence model	Correct answers	Accuracy (%)	Comparison to ABP[b] pass rates[c]
Deepseek-R1	261	98.1	Exceeds typical ABP pass rate
ChatGPT-4.5	257	96.6	Upper threshold of ABP pass rate
ChatGPT-4	220	82.7	Comparable to lower range of ABP pass rate

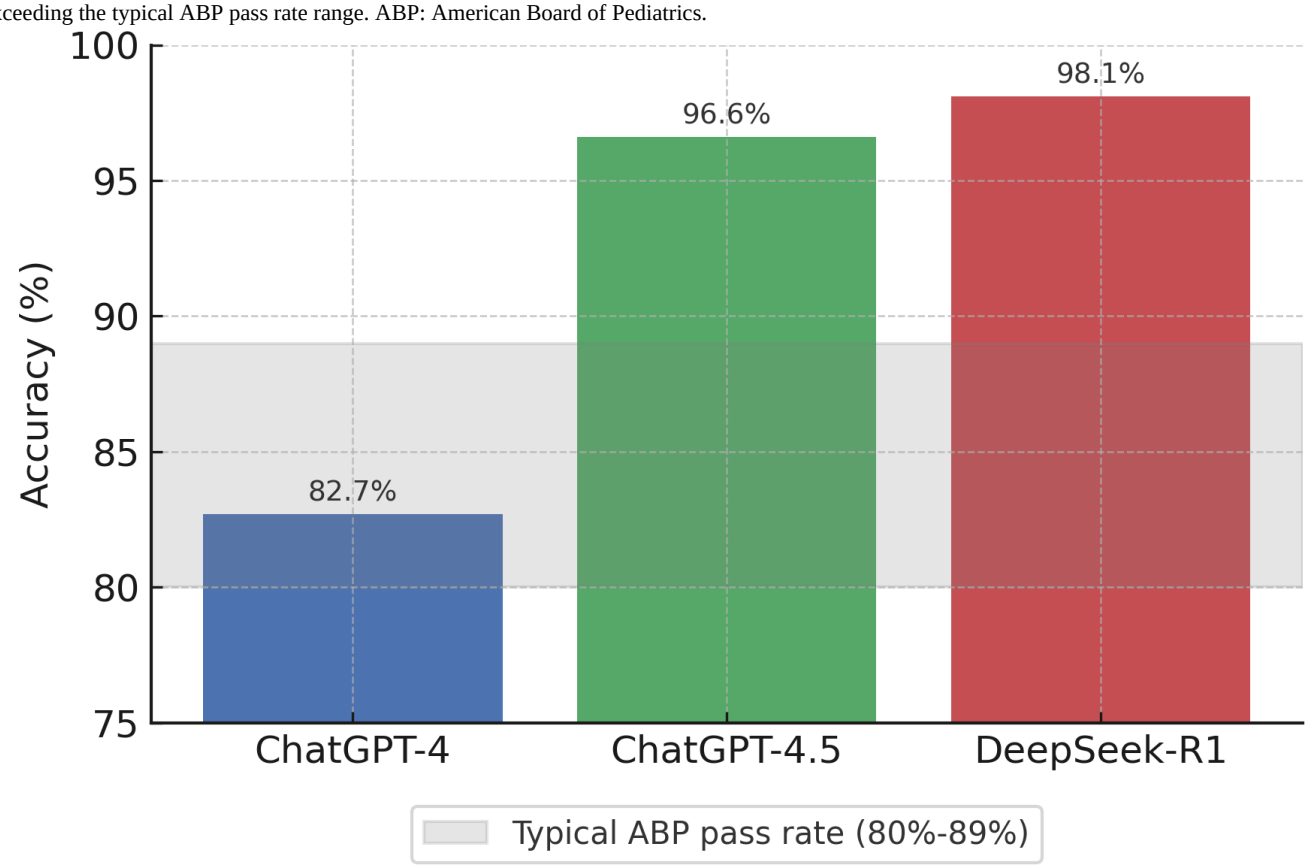
[a]Each model was tested on 266 multiple-choice questions from the American Academy of Pediatrics 2023 PREP Self-Assessment. Accuracy was calculated as the percentage of correct responses. Performance is contextualized relative to the typical first-time pass rates (80% - 89%) for board-certified pediatricians on the ABP examination. DeepSeek-R1, ChatGPT-4, and ChatGPT-4.5 were tested on identical questions. Pass rates represent historical ABP first-time exam performance.

[b]ABP: American Board of Pediatrics.

[c]ABP first-time pass rates for board-certified pediatricians typically range from 80% - 89% (80% in 2022 and 89% in 2024 for general pediatrics) [5].

XSL•FO
RenderX

Table . Error pattern analysis by knowledge domain.[a]



Knowledge domain	DeepSeek-R1 (N=5), n (%)	ChatGPT-4.5 (N=9), n (%)	ChatGPT-4 (N=46), n (%)
Metabolic disorders	3 (60)	4 (44)	15 (33)
Rare genetic syndromes	2 (40)	2 (22)	12 (26)
Medication dosing	0 (0)	2 (22)	10 (22)
Growth parameters	0 (0)	1 (11)	9 (20)

[a]Percentages indicate proportion of total errors for each model.

These results were compared to the published first-time pass rates for board-certified pediatricians taking the ABP examination, which typically range from 80% - 89% (80% in 2022 and 89% in 2024 for general pediatrics) [5]. As illustrated in Figure 1, DeepSeek's performance exceeded the typical range for human pediatricians on first-attempt board examinations, while ChatGPT-4.5 also performed at the upper threshold of human performance. ChatGPT-4's performance was comparable to the lower range of human pass rates.

These findings demonstrate substantial variability in AI model performance on pediatric knowledge assessment, with newer models demonstrating substantial capabilities on pediatric board questions. The following discussion contextualizes these results within the broader landscape of AI in medical education and clinical practice.

Figure 1. Accuracy of large language models on pediatric board examination preparation questions from the 2023 PREP Self-Assessment. ChatGPT-4, ChatGPT-4.5, and DeepSeek-R1 were each tested on 266 multiple-choice questions. The shaded area represents the typical first-time pass rate range (80% - 89%) for board-certified pediatricians on the ABP examination from 2022 to 2024. DeepSeek-R1 achieved the highest performance at 98.1%, exceeding the typical ABP pass rate range. ABP: American Board of Pediatrics.

Discussion

Our findings demonstrate that recent advancements in LLMs have produced AI systems capable of performing at or above the level of board-certified pediatricians on standardized examination questions. DeepSeek's exceptional performance (98.1% accuracy) represents a significant milestone in AI medical knowledge representation, exceeding typical ABP pass rates. The substantial performance gap between AI models highlights the rapid evolution of these technologies, with newer iterations showing marked improvements compared to older versions [4,6].

These results have important implications for medical education, board examination preparation, and potentially clinical decision support. AI models could serve as supplementary educational tools for pediatric trainees, offering accurate content knowledge while human educators focus on clinical reasoning, ethics, and

XSL•FO
RenderX

patient communication skills that remain challenging for AI systems [7,8].

AI models could revolutionize medical education through personalized learning pathways, instant feedback on clinical reasoning, and simulation of rare cases [9]. However, critical limitations remain in areas requiring human judgment, empathy, and ethical decision-making. For instance, while AI excels at factual recall, it cannot replicate the nuanced patient interactions, cultural sensitivity, or ethical reasoning essential to pediatric practice [10]. Future applications should focus on AI as a supportive tool that enhances rather than replaces traditional medical education, particularly in areas like case-based learning, differential diagnosis practice, and board examination preparation [11].

Limitations of this study include the use of multiple-choice questions rather than free-response clinical scenarios and the focus on knowledge recall rather than practical clinical decision-making. We cannot determine whether the AI models' performance reflects true clinical reasoning or pattern recognition based on similar questions in their training data. Additionally, while PREP Self-Assessment questions are designed to simulate board examinations, they may differ in difficulty and content distribution from actual ABP examinations, complicating direct comparisons with human pass rates. Important limitations exist in comparing AI performance to human ABP pass rates. The ABP examination involves 330 questions administered under timed, proctored conditions with associated stress factors, while our AI evaluation used 266 questions without time constraints or test-taking pressure. Additionally, human physicians integrate years of clinical experience, ethical reasoning, and patient interaction skills that are not assessed in multiple-choice formats. Therefore, while our results demonstrate strong knowledge recall by AI models, they should not be interpreted as evidence of superior clinical competence. Furthermore, these models have not been tested on their ability to gather historical information, perform physical examinations, or develop appropriate management plans in real clinical settings [12,13]. Future research should evaluate these AI systems on more complex clinical reasoning tasks and directly compare their performance to practicing pediatricians in simulated clinical scenarios.

Authors' Contributions

MM, AI, and AH conceptualized and designed the study, drafted the initial manuscript, critically reviewed and revised the manuscript, designed the data collection instruments, collected data, carried out the initial analyses, and critically reviewed and revised the manuscript. All authors approved the final manuscript as submitted and agree to be accountable for all aspects of the work.

Abstract

Background: Language, which is a crucial element of human communication, is influenced by the complex interplay between thoughts, emotions, and experiences. Psychiatric disorders have an impact on cognitive and emotional processes, which in turn affect the content and way individuals with these disorders communicate using language. The recent rapid advancements in large language models (LLMs) suggest that leveraging them for quantitative analysis of language usage has the potential to become a useful method for providing objective measures in diagnosing and monitoring psychiatric conditions by analyzing language patterns.

Objective: This study aims to explore the use of LLMs in analyzing spontaneous communication to differentiate between various psychiatric disorders. We seek to show that the latent LLM embedding space identifies distinct linguistic markers that can be used to classify spontaneous communication from 7 different psychiatric disorders.

Methods: We used embeddings from the 7 billion parameter Generative Representational Instruction Tuning Language Model to analyze more than 37,000 posts from subreddits dedicated to seven common conditions: schizophrenia, borderline personality disorder (BPD), depression, attention-deficit/hyperactivity disorder (ADHD), anxiety, posttraumatic stress disorder (PTSD) and bipolar disorder. A cross-validated multiclass Extreme Gradient Boosting classifier was trained on these embeddings to predict the origin subreddit for each post. Performance was evaluated using metrics such as precision, recall, F_1score, and area under the receiver operating characteristic curve (AUC). In addition, we used Uniform Manifold Approximation and Projection dimensionality reduction to visualize relationships in language between these psychiatric disorders.

Results: The 10-fold cross-validated Extreme Gradient Boosting classifier achieved a support-weighted average precision, recall, F_1, and accuracy score of 0.73, 0.73, 0.73, and 0.73, respectively. In one-versus-rest tasks, individual category AUCs ranged from 0.89 to 0.97, with a microaverage AUC of 0.95. ADHD posts were classified with the highest AUC of 0.97, indicating distinct linguistic features, while BPD posts had the lowest AUC of 0.89, suggesting greater linguistic overlap with other conditions. Consistent with the classifier results, the ADHD posts have a more visually distinct cluster in the Uniform Manifold Approximation and Projection projects, while BPD overlaps with depression, anxiety, and schizophrenia. Comparisons with other state-of-the-art embedding methods, such as OpenAI's text-embedding-3-small (AUC=0.94) and sentence-bidirectional encoder representations from transformers (AUC=0.86), demonstrated superior performance of the Generative Representational Instruction Tuning Language Model-7B model.

Conclusions: This study introduces an innovative use of LLMs in psychiatry, showcasing their potential to objectively examine language use for distinguishing between different psychiatric disorders. The findings highlight the capability of LLMs to offer valuable insights into the linguistic patterns unique to various conditions, paving the way for more efficient, patient-focused diagnostic and monitoring strategies. Future research should aim to validate these results with clinically confirmed populations and investigate the implications of comorbidity and spectrum disorders.

Introduction

Psychiatric disorders encompass a diverse range of conditions affecting an individual's thoughts, emotions, and behaviors. These disorders are characterized by complex and heterogeneous symptomatology, making it difficult to establish precise diagnostic criteria and monitor disease progression over time [1]. While standardized clinical interviews and questionnaires are commonly used, they rely on subjective assessments and can be time-consuming or insensitive to subtle changes, potentially leading to misdiagnosis and delayed intervention [2] .

Language, as a fundamental aspect of human communication, reflects the intricate interplay between thoughts, emotions, and experiences. Quantitative analysis of language usage has emerged as a valuable tool for providing objective measures for diagnosing and differentiating between different psychiatric disorders. Studies have demonstrated that language-based features, such as syntactic complexity, semantic coherence, and emotional valence, can serve as reliable markers for differentiating between psychiatric disorders. For instance, individuals with schizophrenia often exhibit disturbances in their speech patterns, characterized by disorganized syntax and impaired semantic coherence [3]. Similarly, individuals with borderline personality disorder (BPD) have higher levels of overall expressive language impairment, as well as decreased syntactic and lexical complexity [4].

Furthermore, quantitative analysis of language usage can aid in tracking disease progression and treatment response. Longitudinal studies have demonstrated that changes in linguistic patterns over time can be indicative of disease progression and treatment outcomes. For example, alterations in language usage have been correlated with changes in current depression symptoms [5]. In addition, "tentativeness," as measured by a higher degree of uncertainty, is correlated with quantitative levels of symptoms of anxiety measured by the Generalized Anxiety Disorder 7-item (GAD-7) scale [6]. These findings underscore the potential of quantitative language analysis as a sensitive and objective measure for monitoring disease trajectories and treatment efficacy.

Recent advancements in large language models (LLMs) have opened up exciting possibilities for quantitative assessment of neurological diseases [7,8]. Due to their transformer architecture, LLMs project strings of text (sentences, paragraphs, etc) onto a high-dimensional embedding space that represents the semantic and syntactic relationships between words and phrases. In this embedding space, linguistically similar texts are geometrically co-located. Therefore, we hypothesize that, given the differences in patterns of speech by individuals across psychiatric disorders, spontaneous use of language will occupy diagnosis-specific subspaces in the LLM embedding space. To test this hypothesis, we specifically focus on using embeddings derived from the Generative Representational Instruction Tuning Language Model (GritLM-7B) LLM [9] to classify posts originating from subreddits dedicated to six common conditions: schizophrenia, BPD, depression, attention-deficit/hyperactivity disorder (ADHD), anxiety, posttraumatic stress disorder, and bipolar disorder (BD) [10].

This investigation represents an innovative application of LLMs in the field of psychiatric disorders. By using LLM embeddings to analyze the spontaneous use of language in online discussion data, we aim to provide a proof-of-concept for an LLM-based framework to encourage further development of more objective, efficient, and patient-centered strategies for assessment, monitoring, and research.

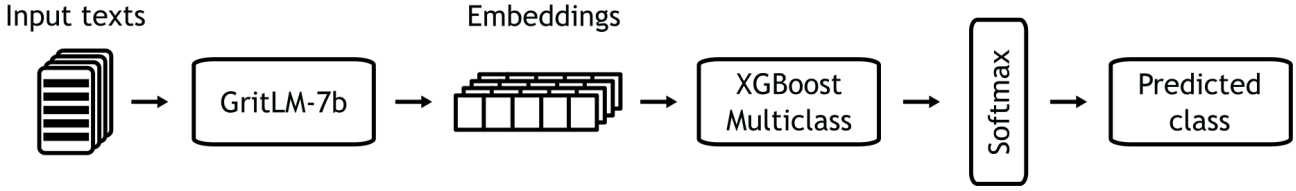
Methods

Data Collection

The dataset we used in this study was obtained from the publicly available dataset provided by Low et al [10], which can be accessed on Zendodo [11]. The dataset consists of posts from seven subreddits related to psychiatric disorders: r/adhd, r/anxiety, r/bipolarreddit, r/bpd, r/depression, r/ptsd, and r/schizophrenia collected between December 2018 and December 2019. These subreddits were chosen to encompass a broad spectrum of psychiatric conditions. Each post was examined for the presence of regular expressions directly related to the subreddit title, and any posts containing such references were excluded from the dataset (Table 1).

Table . Regex codes used to remove posts with potentially revealing words from within each subreddit.

Subreddit	Regex terms for cleaning
r/adhd	adhd|attention|hyperact
r/anxiety	anxiety
r/bipolarreddit	bipolar
r/bpd	borderline|bpd
r/depression	depress
r/pstd	ptsd|post-traumatic|post traumatic
r/schizophrenia	schiz



Embedding Generation

We generated embeddings using the GritLM-7B model [9] (Figure 1). The GritLM-7B model is based on Mistral 7B [12] and fine-tuned using both representational instruction tuning and generative instruction tuning, resulting in a model that achieves state-of-the-art performance for both generative and embedding tasks. Representational instruction tuning enhances

XSL•FO
RenderX

the model's ability to understand and represent the underlying structure and semantics of the input data. This process involves training the model on tasks that require it to generate meaningful embeddings or representations of the input text, which can then be used for various downstream tasks such as classification, clustering, or retrieval. Conversely, generative instruction tuning aims to improve the model's capability to generate coherent and contextually appropriate text based on given instructions or prompts. This involves training the model on tasks that require it to produce text outputs, such as summarization, translation, or creative writing. The overall training of the GritLM-7B model uses a loss function that is a weighted average of the loss functions for the individual representational and generative instructional tuning tasks, enabling the model to achieve a balanced proficiency in both comprehending and generating text.

Figure 1. Posts from subreddits related to psychiatric disorders: r/adhd, r/anxiety, r/bipolarreddit, r/bpd, r/depression, r/ptsd, and r/schizophrenia collected between December 2018 and December 2019 are used as input into the GritLM-7B model to generate an embedding. Embeddings of all posts are used as features in a cross-validated XGBoost classifier to predict subreddit of origin. GritLM-7B: Generative Representational Instruction Tuning Language Model; XGBoost: Extreme Gradient Boosting.

In this study, we focus on the representational component of the GritLM-7B model. For embedding tasks, GritLM-7B uses bidirectional attention followed by mean pooling of the final hidden state to generate the final representation. The model inference was performed on a single GPU (NVIDIA A10G) Amazon Web Services EC2 instance.

2D Visualization of Embedding Space

We began by standardizing the embedding matrix to ensure that each feature had zero mean and unit variance. This standard scaling process is crucial for normalizing the data and mitigating the effects of differing scales among features. Following this, we used Uniform Manifold Approximation and Projection (UMAP) to reduce the dimensionality of the scaled data, transforming it into a 2D representation. UMAP is a powerful nonlinear dimensionality reduction technique that preserves the local and global structure of the data. For our UMAP transformation, we set the number of neighbors to 50 and the minimum distance parameter to 0.05, chosen by visual inspection to optimize the balance between local and global data structure preservation.

The number of neighbors parameter determines the size of the local neighborhood UMAP considers when learning the manifold structure of the data. A higher number of neighbors allows UMAP to capture more of the global structure of the data, ensuring that the overall shape and relationships between clusters are well-preserved. This is particularly important in our context, where understanding the relationships between different conditions may provide insights into which conditions have features of spontaneous communication that overlap with other conditions. The minimum distance parameter controls how tightly UMAP packs points together in the low-dimensional space. A smaller minimum distance value allows points to be closer together, which can help in preserving the local structure and making clusters more distinct. Decreasing this parameter enhances the separation between different clusters, making it easier to identify and interpret distinct groups within a label that may reflect the heterogeneity of a particular condition. Finally, we visualized the resulting 2D UMAP representation by creating a scatter plot, where each point was colored according to its corresponding label, facilitating the identification of patterns and clusters within the high-dimensional data.

Classification Model

For the classification task, we used the Extreme Gradient Boosting (XGBoost) algorithm, using a multiclass classifier with a softmax objective function to predict the class labels for the posts from the 7 psychiatric disorder subreddits. Given that tree-based methods are not sensitive to the scale of the input features, we did not perform any standardization or normalization of the embeddings before using XGBoost. To address potential biases arising from class imbalance, we applied balanced class weighting, which assigns weights to each class that are inversely proportional to their frequencies. We configured the XGBoost classifier with the multiclass softmax objective function (multi:softmax) and retained the default parameter settings (eg, max_depth=6, learning_rate=0.3, n_estimators=100, booster=gbtree). No hyperparameter tuning was conducted. This approach ensured a straightforward implementation while leveraging the robust performance characteristics of the XGBoost algorithm for our multiclass classification task.

Performance Evaluation

To evaluate the performance of the classification model, we used 10-fold cross-validation. We calculated class-wise precision, recall, and F_1-scores to assess the performance of each psychiatric disorder–associated subreddit class. In addition, we computed macro and weighted average scores across all classes to provide a comprehensive evaluation of the model's performance.

Ethical Considerations

Our study strictly adheres to ethical guidelines for the use of internet-sourced data in research, ensuring that no harm comes to the individuals whose posts were analyzed.

This study used a publicly available dataset consisting of tens of thousands of posts from Reddit. The data were collected from forums that do not require registration or login to access and

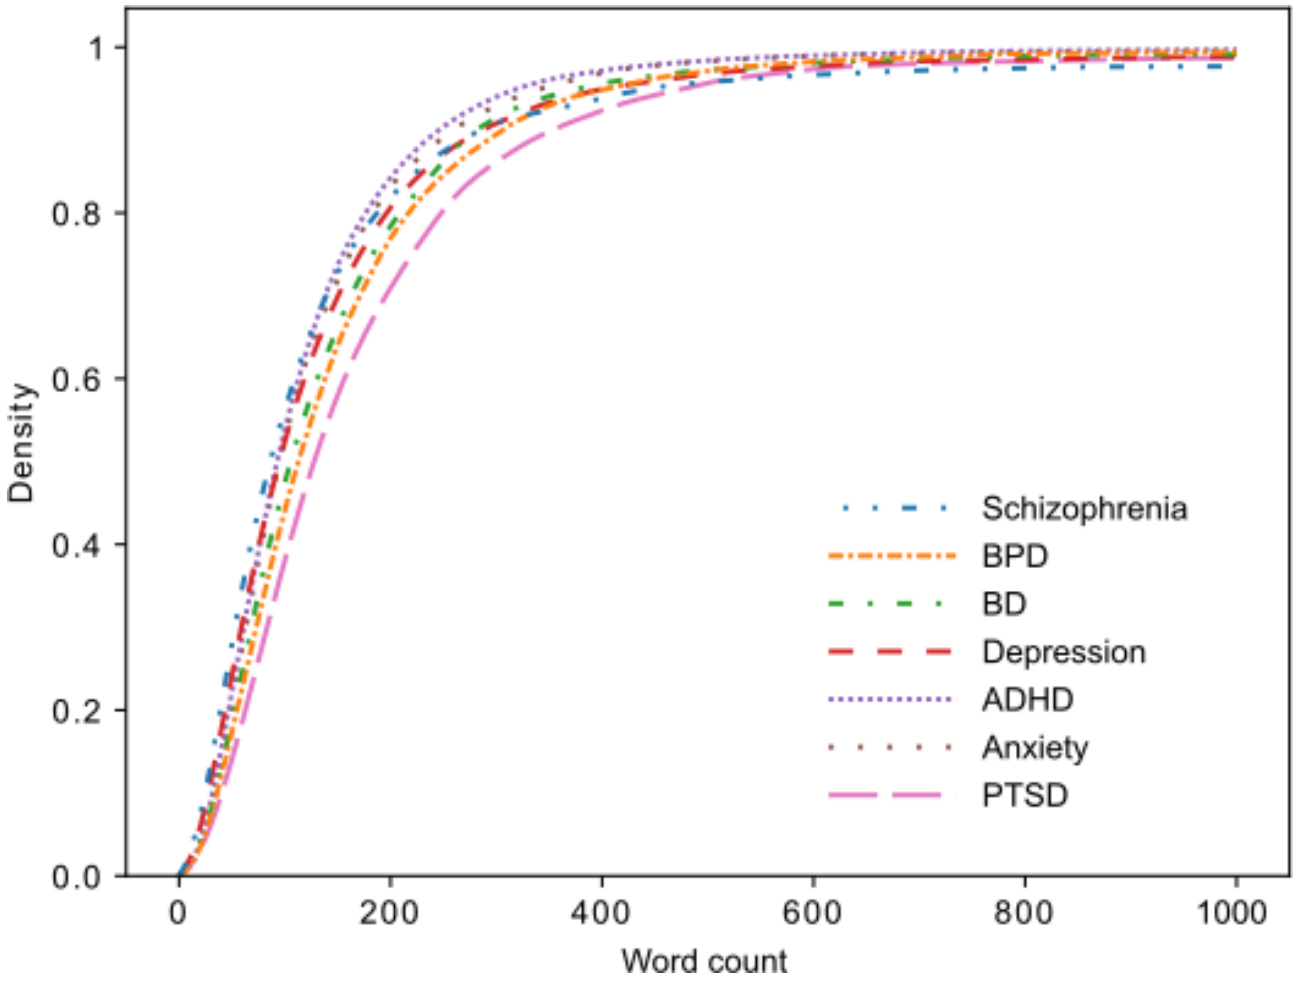
XSL•FO
RenderX

are therefore considered part of the public domain of the internet. In accordance with the journal's policy, the analysis of large-scale publicly available online text data is not classified as human participants research and thus does not require institutional review board approval.

To further protect user privacy, all analyses were conducted at the aggregate level, and no attempts were made to identify or contact individual users. Usernames and any potentially identifying information were excluded from the analysis and presentation of results. The research was conducted in accordance with ethical standards for the use of online data, including respect for user anonymity and contextual integrity.

Results

Data Description



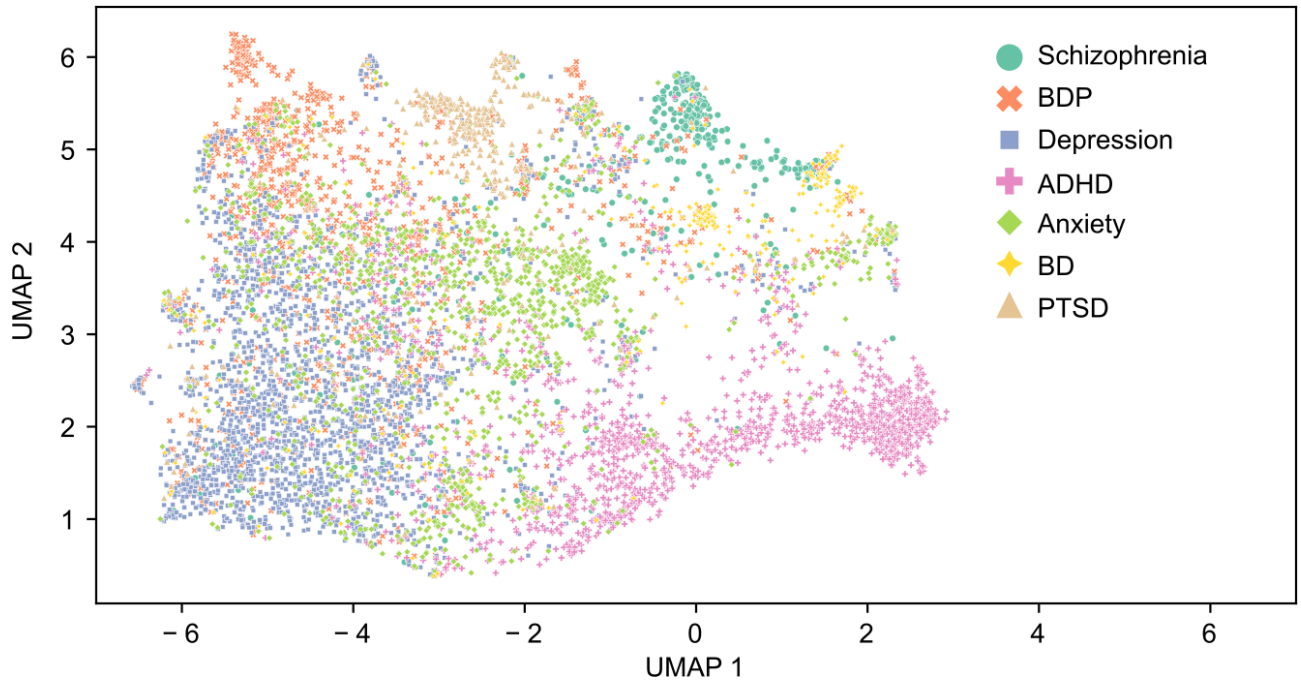
The data used in this study comes from seven distinct subreddits: r/adhd, r/anxiety, r/bipolarreddit, r/bpd, r/depression, r/ptsd, and r/schizophrenia. Following the removal of posts containing text that would be revealing of the subreddit (see "Methods" section), there was a nearly 7-fold difference between the total number of posts in each subreddit. The r/depression subreddit had the greatest number of posts (11,513 posts, 11,483 unique users) and the r/bipolarreddit had the least number of posts (1711 posts, 1633 unique users) (Table 2). Overall, 36,102 out of 37,195 (97.1%) posts were made by unique users. Among the users, 2 made 5 posts, 7 made 4 posts, and 54 made 3 posts. The remaining 36,039 (99.8%) made only 1 or 2 posts. No user made posts in more than one subreddit. All subreddits had mean and median lengths of approximately 150 words (Figure 2).

Table . Number of posts, unique users, and mean post length for each subreddit following post cleaning.

Subreddit	Posts, n	Unique users, n	Post length (words), mean (SD)
r/adhd	7568	7319	121.5 (106.2)
r/anxiety	6391	5990	126.4 (117.9)
r/bipolarredit	1711	1633	138.6 (124.9)
r/bpd	5849	5699	147.9 (132.6)
r/depression	11,513	11,483	132.2 (160.5)
r/ptsd	1954	1769	167.6 (158.0)
r/schizophrenia	2209	2209	123.4 (147.9)

XSL•FO
RenderX

Figure 2. Cumulative distribution of word count in individual posts for each subreddit used in the study, with the word count axis cut off at 1000 words to better show the distribution at lower word counts. ADHD: attention-deficit/hyperactivity disorder; BD: bipolar disorder; BPD: borderline personality disorder; PTSD: posttraumatic stress disorder.



Relationships Between Categories

We used the UMAP algorithm to generate a 2D representation of the embedding space facilitating the visualization of relationships between subreddits (Figure 3). This low-dimensional visualization reveals several qualitative features of the dataset. Notably, posts from r/anxiety subreddit are centrally located in the projection, adjacent to all other categories. This central positioning may indicate that the language used in discussions about anxiety is present across all subreddits. In addition, while some subreddits (r/ptsd, r/bipolarredit, r/adhd, and r/schizophrenia) have distinct clusters, the other 3 subreddits (r/anxiety, r/bpd, and r/depression) have more overlapping point clouds, suggesting greater linguistic similarity across the latter 3 subreddits.

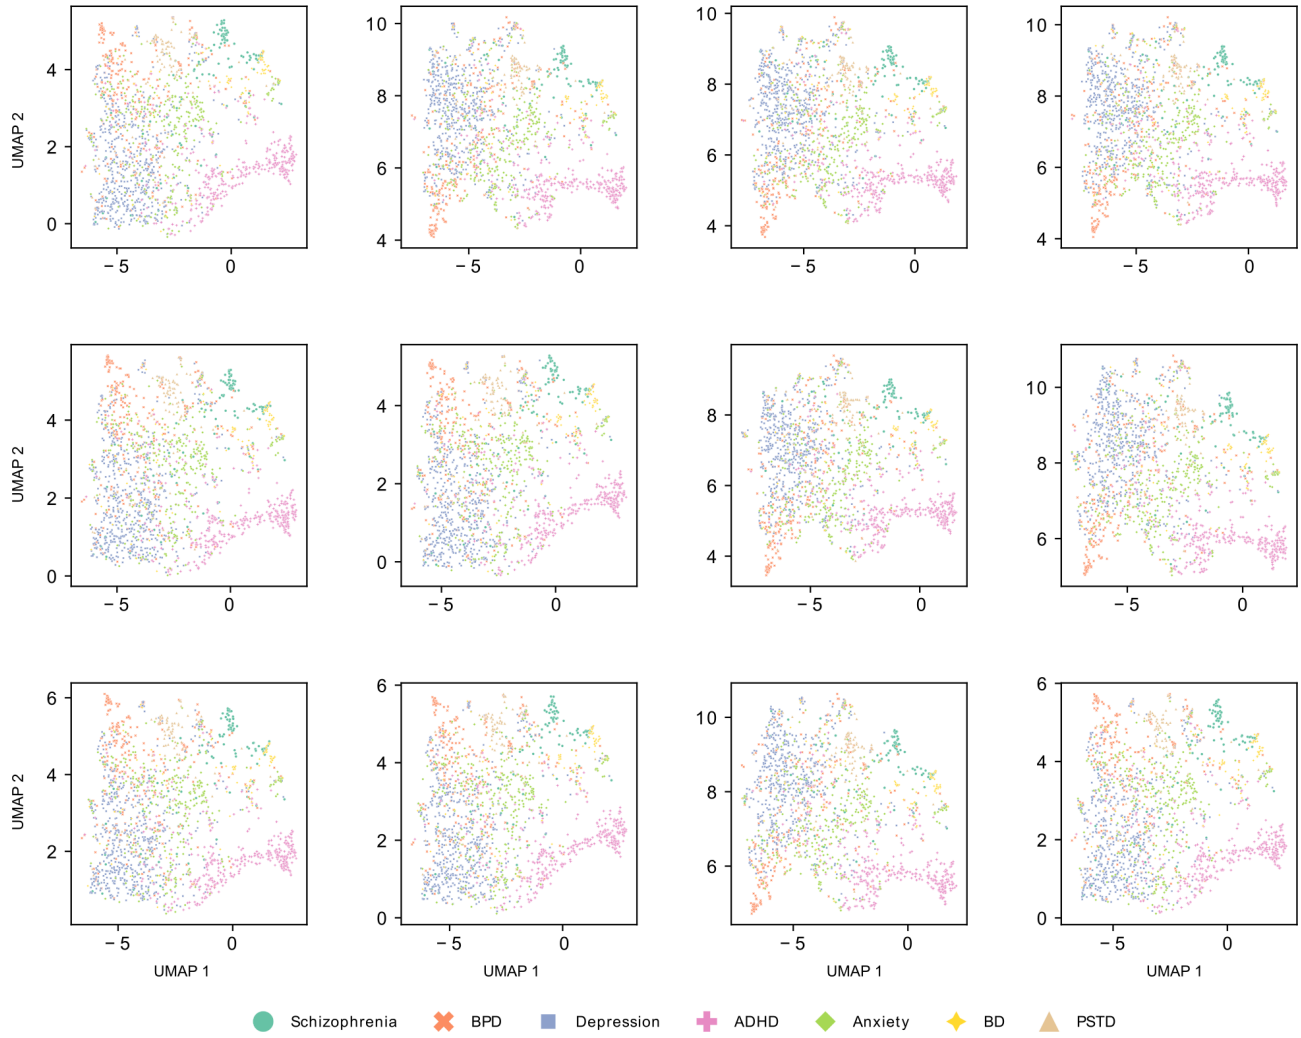

Figure 3. 2D UMAP of GritLM-7B embeddings of every fifth Reddit post, where each dot represents an individual post. ADHD: attention-deficit/hyperactivity disorder; BD: bipolar disorder; BPD: borderline personality disorder; GritLM-7B: Generative Representational Instruction Tuning Language Model; PTSD: posttraumatic stress disorder; UMAP: Uniform Manifold Approximation and Projection.

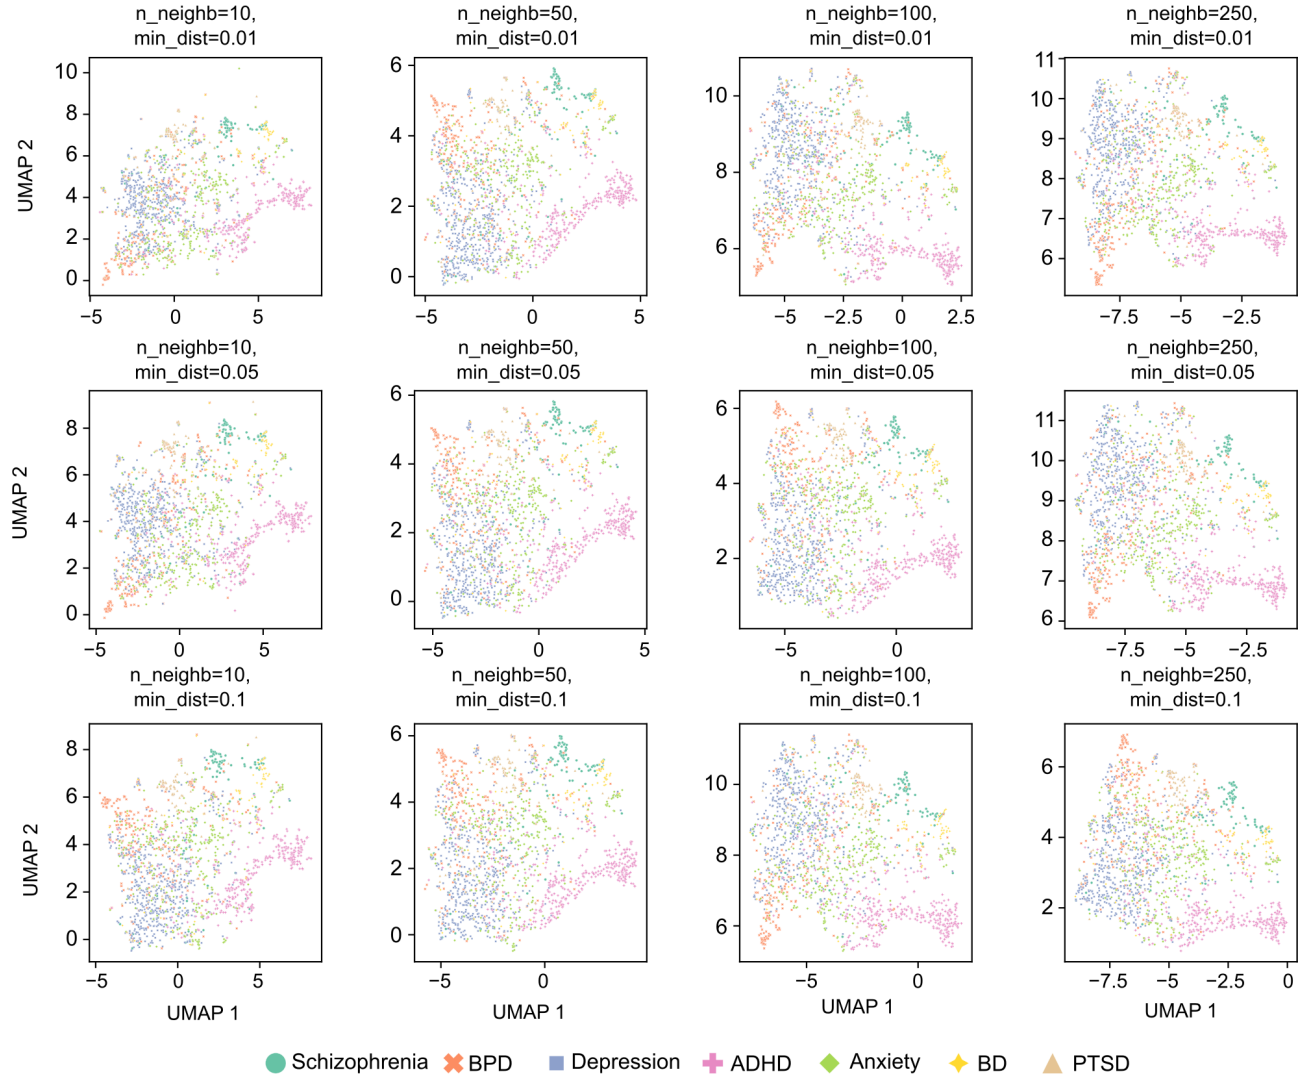
The UMAP algorithm is inherently stochastic and can be sensitive to initial conditions. However, UMAP is designed to preserve the global structure of the data, making it more stable and less sensitive to parameter changes and initial conditions compared with other dimensionality reduction algorithms such as t-distributed Stochastic Neighbor Embedding. To illustrate this stability, we present UMAP projections using the specified parameters with different random seeds (Figure 4) and with the same random seed but varying local neighborhood and minimum distance parameters (Figure 5). In both cases, only every 20th post was plotted to allow for easier visualization of the distribution of the different categories. The resulting plots consistently support the qualitative observations described above.



XSL•FO
RenderX

Figure 4. Additional projections of the GritLM-7B embedding data from the UMAP algorithm using the same parameters as in Figure 3, where each plot is generated by using a different random seed. ADHD: attention-deficit/hyperactivity disorder; BD: bipolar disorder; BPD: borderline personality disorder; GritLM-7B: Generative Representational Instruction Tuning Language Model; PTSD: posttraumatic stress disorder; UMAP: uniform manifold approximation and projection.

RenderX

Figure 5. Additional projections of the GritLM-7B embedding data from the UMAP algorithm, varying the local neighborhood and minimum distance parameters. ADHD: attention-deficit/hyperactivity disorder; BD: bipolar disorder; BPD: borderline personality disorder; GritLM-7B: Generative Representational Instruction Tuning Language Model; PTSD: posttraumatic stress disorder; UMAP: Uniform Manifold Approximation and Projection.

Classifier Performance

In addition to visualizing the embedding space of subreddit categories using UMAP, we used a 10-fold cross-validated XGBoost classifier to predict the subreddit of origin for each post. The support-weighted average precision, recall, and F_1-scores across all categories were 0.73, 0.73, and 0.73, respectively. The macroaverage precision, recall, and F_1-scores were 0.73, 0.68, and 0.7, respectively. Furthermore, the overall accuracy of the model was measured at 0.73.

At the individual category level, the model performed best on r/adhd (F_1-score=0.86), r/depression (F_1-score=0.77), worst on r/bipolarreddit (F_1-score=0.63), and r/bpd (F_1-score=0.58) (Table 3). These results indicate that the XGBoost classifier demonstrated moderate predictive performance in identifying the subreddit from which a post originated.

XSL•FO
RenderX

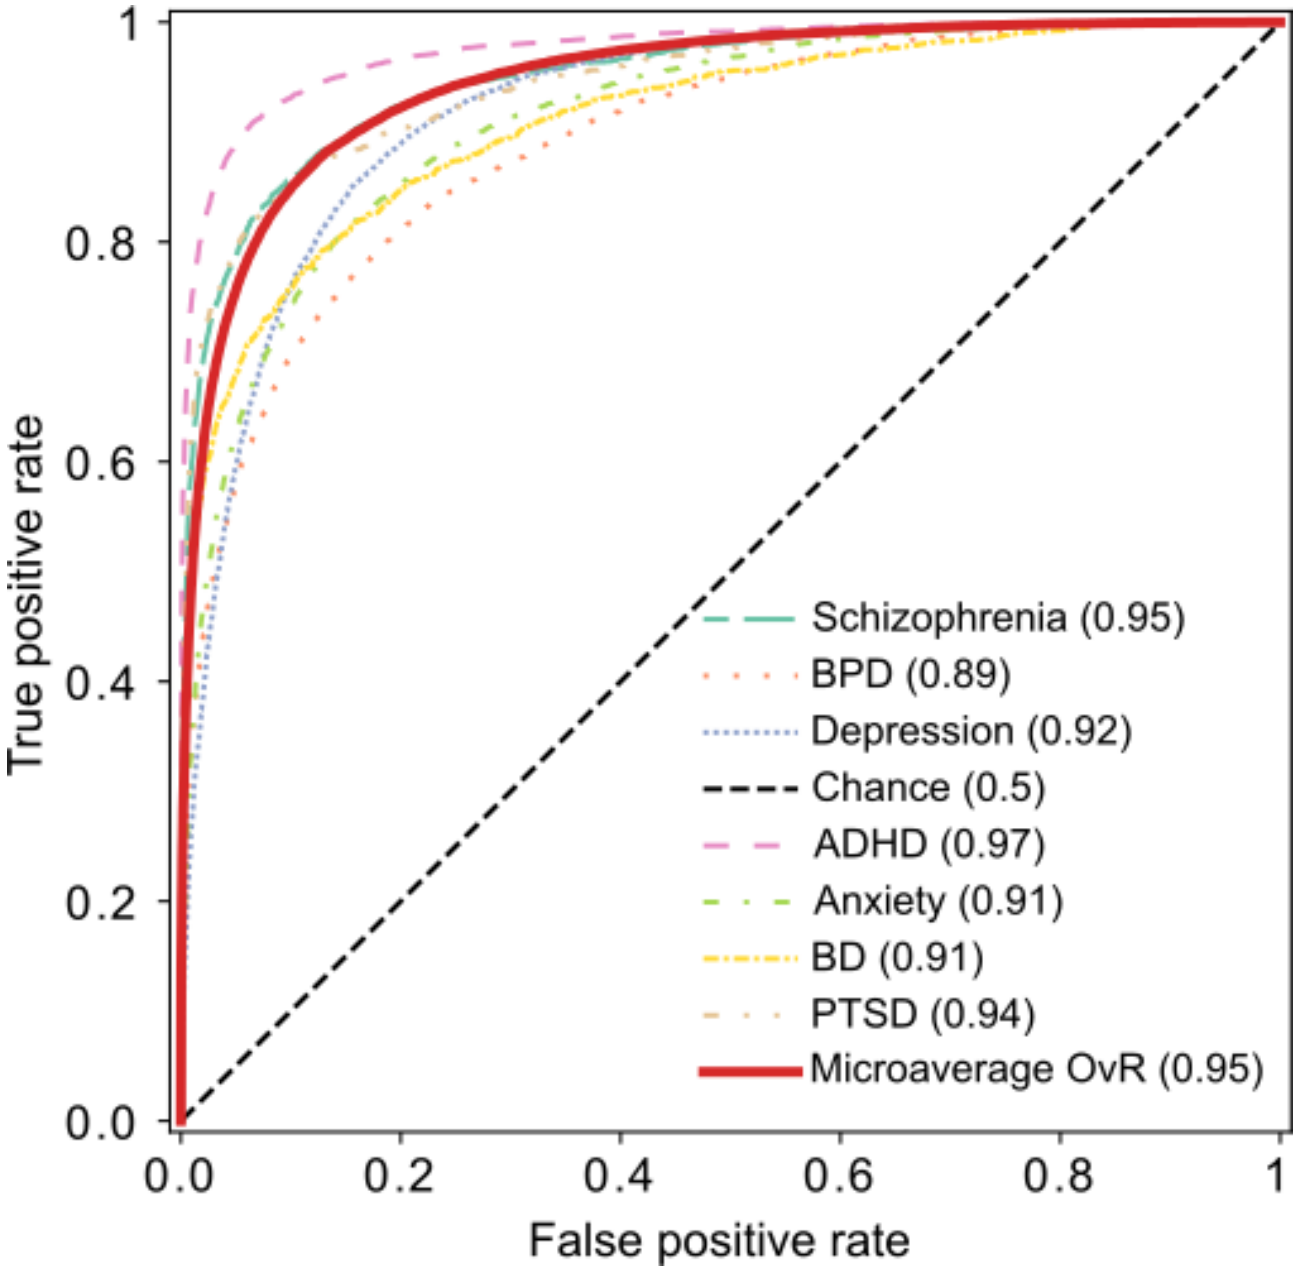

Table . Performance metrics of the Extreme Gradient Boosting multiclass classifier using Generative Representational Instruction Tuning Language Model (GritLM-7B) embeddings as features. Metrics are displayed for each individual subreddit, as well as the average performance across all subreddits, using a 0.5 classification threshold.

Subreddit	Precision	Recall	F_1-score
r/adhd	0.86	0.86	0.86
r/anxiety	0.66	0.69	0.67
r/bipolarredit	0.68	0.5	0.58
r/bpd	0.65	0.61	0.63
r/depression	0.73	0.81	0.77
r/ptsd	0.78	0.63	0.7
r/schizophrenia	0.76	0.62	0.69
Macroaverage	0.73	0.68	0.7
Weighted average	0.73	0.73	0.73

For each subreddit, we used the classifier probabilities to estimate the AUC for a one-versus-rest classification task (Figure 6). The AUC values were notably high, ranging from 0.89 to 0.97, indicating that posts within each subreddit are highly distinguishable from the other subreddits. The r/adhd subreddit had the highest AUC (0.97), suggesting that this topic is most distinct from other topics. Conversely, the r/bpd subreddit post had the lowest AUC (0.89) indicating that its posts may share more linguistic features with those of other subreddits.

XSL•FO
RenderX

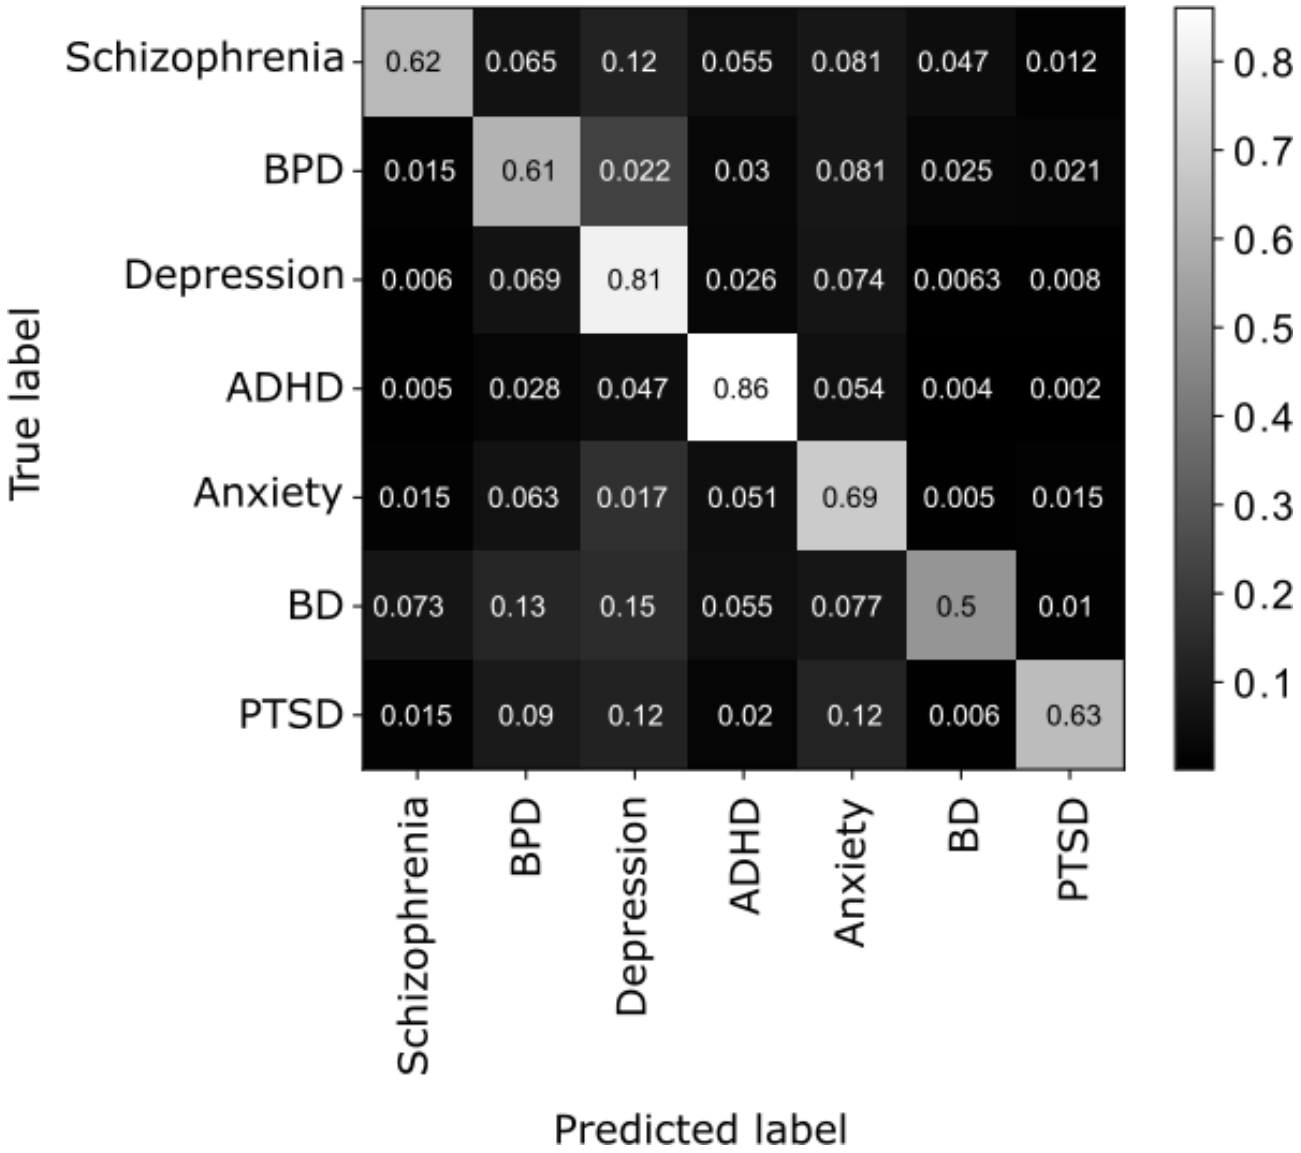

Figure 6. Receiver operating characteristic curve and area under the receiver operating characteristic curve (AUC) values for a one-versus-rest (OvR) Extreme Gradient Boosting (XGBoost) classifier using GritLM-7B embeddings, shown for each subreddit against all other classes. ADHD: attention-deficit/hyperactivity disorder; BD: bipolar disorder; BPD: borderline personality disorder; GritLM-7B: Generative Representational Instruction Tuning Language Model; PTSD: posttraumatic stress disorder.

We computed a confusion matrix to assess the performance of the multiclass classifier at both the individual category level and across pairs of categories (Figure 7). This analysis enables us to examine the misclassification rates between different categories and gain insights into the specific types of errors made by the classifier. The four most common true-predicted category confusions were identified as follows: r/bpd-r/depression, r/anxiety-r/depression, r/bipolarreddit-r/depression, and r/bipolarreddit-r/bpd. Notably, the model frequently misclassifies posts as originating from r/depression. This may result from users in r/bpd, r/anxiety, and r/bipolarreddit using language that is more similar to that used by users in r/depression. Interestingly, the confusion rates between r/anxiety, r/bpd, and r/bipolarreddit are less than 0.13, suggesting that linguistic overlap between these subreddits is less pronounced with each other than they each are with r/depression. In addition, this result may be partially explained by the overrepresentation of the r/depression class in the dataset that is incompletely offset by class weighting when training the model.

Figure 7. Confusion matrix from a multiclass Extreme Gradient Boosting classifier using GritLM-7B embeddings to classify posts into subreddits related to mental health conditions. ADHD: attention-deficit/hyperactivity disorder; BD: bipolar disorder; BPD: borderline personality disorder; GritLM-7B: Generative Representational Instruction Tuning Language Model; PTSD: posttraumatic stress disorder.

Finally, we compared the performance of GritLM-7B embeddings with other state-of-the-art methods for generating sentence embeddings, specifically OpenAI's text-embedding-3-small [13] and Sentence-Bidirectional Encoder Representations from Transformers (S-BERT) [14]. Across all evaluation metrics, the classifier using GritLM-7B embeddings outperformed those using OpenAI and S-BERT embeddings (Table 4). These results are consistent with previous findings that GritLM-7B achieves state-of-the-art performance on embedding-based tasks.

Table . Performance comparison of multiclass Extreme Gradient Boosting classifiers for categorizing posts into mental health–related subreddits, using embeddings from large language models (Generative Representational Instruction Tuning Language Model [GritLM-7B] and OpenAI) and S-BERT[a].

Large language models	Classifier performance		Weighted average		
	Accuracy	AUC[b]	Precision	Recall	F_1-score
GritLM-7B	0.73	0.95	0.73	0.73	0.73
OpenAI	0.7	0.94	0.7	0.7	0.7
S-BERT	0.54	0.86	0.47	0.45	0.46

Discussion

Principal Findings

The use of LLMs offer a novel approach to analyzing patterns of language usage from spontaneous, patient-generated communication. In the field of psychiatric disorders, this has the potential to revolutionize the way we diagnose and monitor these conditions. By analyzing the spontaneous use of language in online discussion data, we can gain valuable insights into the linguistic patterns that distinguish between different psychiatric disorders. In this study, we used embeddings derived from the GritLM-7B LLM to classify posts originating from subreddits dedicated to seven common conditions: schizophrenia, BPD, depression, ADHD, anxiety, posttraumatic stress disorder, and BD. Our work provides a proof of concept showing that modern LLMs can be effectively used to differentiate between spontaneous communication related to different psychiatric disorders. This novel application demonstrates the potential of LLMs to identify distinct linguistic markers associated with various mental health conditions, paving the way for innovative diagnostic and monitoring tools in psychiatric care.

We found that the XGBoost classifier using features generated from GritLM-7B embeddings exhibits high, though not perfect, performance. Symptoms of psychiatric disorders span a number of different modalities, such as sleep, appetite, and motor activity [15-17]. Therefore, in addition to standard reasons for misclassification such as overfitting and noisy or limited data, posts may be misclassified due to similarities in presentations across the different psychiatric disorders, or high rates of comorbidity between disorders. In our study, the pair-wise misclassification rates may reveal disorders where the presentation of symptoms that are likely to be revealed by spontaneous speech are more similar. For example, posts coming from r/bpd are likely to be misclassified as coming from r/depression. This is consistent with previous studies showing similarities in word usage [18] and high rates of comorbidity for BD and depression [19].

We observe a range of performances in the one-versus-rest classifiers across different disorders. Notably, BPD has the lowest AUC (0.89). This may be because BPD shares many symptoms with other conditions and is often comorbid with them [20]. A key differentiating factor between BPD and related conditions is the temporal nature of symptoms. In BPD, core symptoms are typically more variable and transient compared with their presentation in related conditions. The dataset used in this study consists mostly of single social media posts from each user, providing a cross-sectional view rather than a longitudinal one. This cross-sectional data does not capture within-subject symptom variability which may explain the reduced performance of the BPD classifier. In contrast, ADHD has the highest AUC (0.97). This could be because ADHD is a neurodevelopmental disorder, unlike the other conditions examined in this work. As a result, spontaneous communication related to ADHD may be more distinct from other conditions, leading to higher classifier performance.

Limitations

One limitation of analyzing posts from mental health disorder subreddits is that they may not necessarily originate from officially diagnosed patients. The individuals participating in these online communities may self-identify with a particular disorder without having received a formal diagnosis from a health care professional or maybe caregivers supporting a diagnosed individual. As a result, the content may not be directly clinically relevant. Furthermore, psychiatric disorders have high rates of comorbidity [21,22]. Posts within a single subreddit may come from an individual with multiple psychiatric pathologies, limiting classification into any one specific category. Finally, psychiatric disorders exist on a spectrum [23,24] and can have multiple subtypes [25,26], which may not be well-captured in a classification framework. Therefore, the insights gained from analyzing these posts should be interpreted with caution and may not fully represent the experiences and perspectives of clinically diagnosed individuals. However, future research could apply this methodology to free speech data generated by verified patients and leverage more precise clinical diagnostic labels, diagnostic history, and finer-tuned model predictions (eg, predicting subtype or severity) to derive further clinical findings.

In addition, since subreddits posts are unprompted, the content of the posts, in addition to the syntax and semantics may vary across the different subreddits. For instance, r/ptsd posts may be more likely to have references to traumatic events, while r/adhd posts may reference learning challenges more often. Therefore, the embedding space may separate the different categories by variations in the topics or themes across subreddits, in addition to features related to the way language is used in the posts. Nevertheless, this could still hold clinical significance as specific themes, like paranoia in schizophrenia or anhedonia in depression, have diagnostic relevance.

Embeddings used by LLMs are black-box numeric representations of the input text, making it difficult to interpret the features that are being used to separate classes and potentially limiting the usefulness and adoption in clinical applications. However, novel methods have shown that generative models may be useful for supporting interpretable embeddings [27]. In addition to state-of-the-art performance on representational tasks, GritLM-7B also performs highly on generative tasks. Thus, in combination with feature explanation, GritLM-7B may be better suited than models optimized for only representational tasks for leveraging generative approaches to interpreting clinically relevant features.

Conclusions

This study demonstrates the potential of using LLMs to analyze free speech for the diagnosis and monitoring of psychiatric disorders. The results suggest that LLMs can provide valuable insights into the linguistic patterns that differentiate various psychiatric conditions. These patterns can be leveraged to develop more objective, efficient, and patient-centered strategies for assessment, monitoring, and research. However, further research is needed to validate these findings in a well-defined clinical population and explore the limitations of this approach.

Abstract

Background: The recent availability of law enforcement and coroner or medical examiner reports for nearly every violent death in the United States expands the potential for natural language processing (NLP) research into violence.

Objective: The objective of this work is to assess applications of supervised NLP to unstructured data in the National Violent Death Reporting System to predict circumstances and types of violent death.

Methods: This analysis applied distilBERT, a compact large language model (LLM) with fewer parameters relative to full-scale LLMs, to unstructured narrative data to simulate the impacts of preprocessing, volume, and composition of training data on model performance, evaluated by F_1-scores, precision, recall, and the false negative rate. Model performance was evaluated for bias by race, ethnicity, and sex by comparing F_1-scores across subgroups.

Results: A minimum training set of 1500 cases was necessary to achieve an F_1-score of 0.6 and a false negative rate of 0.01-0.05 with a compact LLM. Replacement of domain-specific jargon improved model performance, while oversampling positive class cases to address class imbalance did not substantially improve F_1-scores. Between racial and ethnic groups, F_1-score disparities ranged from 0.2 to 0.25, and between male and female decedents, differences ranged from 0.12 to 0.2.

Conclusions: Compact LLMs with sufficient training data can be applied to supervised NLP tasks with a class imbalance in the National Violent Death Reporting System. Simulations of supervised text classification across the model-fitting process of preprocessing and training compact LLM-informed NLP applications to unstructured death narrative data.

KEYWORDS

natural language processing; NLP; violence; informatics; text classification; simulation; violent death; narrative; large language model; LLM; injury prevention; violent injury; coroner reports; police report

Introduction

Violent injuries are among the leading causes of death in the United States for individuals younger than the age of 44 years and are leading causes for young people aged 10 - 34 years [1]. The most comprehensive and detailed source of data on violent deaths in the United States is the National Violent Death Reporting System (NVDRS), aggregating information from death certificates, coroner or medical examiner reports, and law enforcement (LE) reports to characterize violent deaths [2]. Researchers have used structured data from NVDRS extensively to characterize the epidemiology of violent deaths including homicides [3-6], suicides [7-10], and those that result from legal intervention (police shootings) [11].

NVDRS has been widely used for its structured data, which captures information such as decedent characteristics, weapons, circumstances, and suspect information [12], and increasing attention has been given to the vast amounts of unstructured text data embedded within the narrative reports. Narratives provide rich details about the incident not necessarily captured in structured variables, such as nuanced descriptions of precipitating events and other contextual factors that are difficult to quantify.

A range of approaches have been applied to the use of NVDRS narratives in research on violent deaths. According to a recent review on the research use of textual NVDRS narratives over the past 2 decades, most studies used manual review or keyword searches of narratives [10,13,14], while 5% used machine learning tools designed to analyze unstructured text, known as natural language processing (NLP) [15]. Applications of NLP have included supervised learning tasks, such as classification, as well as unsupervised tasks, such as topic modeling. For instance, supervised NLP has been used to classify suicide related to driving cessation [16] and assisted living facilities

XSL•FO
RenderX

[17], examine suicide intent classification [18] and intimate partner homicide [19], and predict drug overdose deaths [20]. Latent class analysis has been used to reveal salient topics unrepresented in abstractor classification [21,22] and themes in youth suicide [23]. Most recently, researchers have used NLP to classify social determinants of health in suicide narratives [24] and inconsistencies, biases, and missing data in the narratives themselves [25-27].

Continued application of NLP to NVDRS is particularly important because the volume of NVDRS data will substantially increase over time. NVDRS has gathered data on over 500,000 deaths since 2003 and will grow by approximately 100,000 records annually moving forward as additional states and counties participate, underlining the importance of efficiently investigating research questions using NVDRS narratives and NLP methods.

Although large language models (LLMs) have generally performed better than other NLP approaches to narrative data in medical informatics domains, fewer applications of LLMs to NVDRS exist [24,28]. Applications of NLP to a related text narrative type, clinical notes from medical providers, have identified patient self-harm [29-34] and violence-related [35-38] outcomes often using LLMs or deep learning approaches. In part, researchers and practitioners may face particular challenges applying LLMs to NVDRS. One important challenge is that many outcomes of interest are likely to be infrequent or rare events that can present classification challenges due to sparse information about the outcome [39-41]. Further, NVDRS narratives are composed of police and coroner reports, which contain domain-specific language or jargon, such as the use of *ICD* (*International Classification of Disease*) codes. NVDRS data restrictions on sensitive data do not permit narratives to be stored in the cloud, thus limiting access to computing resources that are often used to train or fine-tune LLMs. Fourth, researchers documented racial disparities in narratives alongside gendered text differences in NVDRS [22,26,27]. Narratives involving victims from marginalized populations tend to be significantly shorter in length and are more likely to be missing altogether. These differences in data quality may result in models that generate predictions with similar patterns of subgroup bias.

To address these challenges, this paper conducts simulations of supervised text classification that span the machine learning pipeline, from data preprocessing and model training to the evaluation of predictions for potential racial or gender bias. Existing coded variables that record the type (eg, police shooting and drive-by shooting) or circumstances (number of nonfatal shooting victims and location of victim injuries) of the violent death are used as target outcomes used in simulations. Target outcomes with class imbalance were selected, as this setting is likely of most use to NVDRS applications, and models were fit using a compact LLM to reflect settings where computing resources are limited. By conducting simulations, this analysis aims to inform future applications of supervised classification using LLMs to NVDRS by establishing concrete benchmarks for understanding training data quantity, preprocessing needs, and to what extent NLP results in predictions reflecting existing racial or gender bias in narratives.

Methods

Data

This analysis used violent death records from NVDRS data from 2015 to 2020. The NVDRS gathers information about violent deaths including homicides, suicides, and deaths caused by LE. NVDRS combines data from death certificates, coroner or medical reports, and LE reports, providing context about violent deaths including information about mental health conditions, toxicology results, and other circumstances in addition to details about victim characteristics. Trained medical abstractors code information from reports about violent deaths into the over 600 variables that comprise the NVDRS surveillance system [12].

To obtain labeled outcomes for use as target outcomes in simulations, this analysis constructed measures from existing coded NVDRS variables that abstractors label. Because a substantial proportion of coded NVDRS fields group together case outcomes that are negative with those that are not known, this analysis instead relied on multinomial fields or combined separate NVDRS coded variables to obtain target outcomes for simulations. For instance, for case outcomes such as mental health crisis or drug involvement, outcomes are coded as “Yes” or as “No, not available, unknown,” which would not constitute a labeled outcome.

These constructed outcomes include 4 binary outcomes likely to be recorded accurately when known. The first outcome is whether or not a homicide is a legal intervention homicide, meaning the shooter was a LE officer. Literature suggests that these homicides are well-recorded in NVDRS and less subject to noisy labeling or measurement error [11]. The second outcome is whether or not a homicide is classified as a drive-by shooting. The third outcome is whether a homicide occurred at home or not, and the fourth outcome is whether or not additional victims were nonfatally shot in the course of a homicide event. We constrain the sample to where the weapon type is listed as a firearm, and the abstractor manner of death is a homicide. Taken together, these outcomes represent a range of language complexity and frequency less subject to label noise by constructing outcomes.

Ethical Considerations

The Northeastern University institutional review board deemed that this research did not require review, as it did not involve human participants.

Statistical Analysis

This analysis compared model performance across 4 configurations of training data and text composition using a compact LLM. The configurations examined included preprocessing of text data as well as the amount and composition of the training data. Specifically, the analysis first varied the amount of training data that the model was fitted on to inform how much randomly sampled training data must be annotated to train an LLM to predict NVDRS outcomes. Second, because positive class cases were often infrequent, the analysis simulated the oversampling of positive class cases in training data. Specifically, oversampling included a larger proportion of

XSL•FO
RenderX

additional positive class cases, holding the negative class cases constant, to inform what composition of training data was most effective to include as training data.

This analysis additionally simulated different preprocessing techniques for unstructured text data. NVDRS text may be domain-specific, as it comprises police and coroner reports, which use both jargon and abbreviation. To simulate the impacts of clarifying common abbreviations, this analysis replaced NVDRS abbreviations with unabbreviated text. For example, often when NVDRS abstractors referred to victims and suspects in the report narratives, the abbreviations "v" for victim and "s" for suspect appeared rather than the full word. Abbreviations referring to victims, suspects, police, and gunshot wounds were replaced (Table S1 in Multimedia Appendix 1).

Finally, the analysis simulated omitting coroner report text from the training data. Coroner reports may contain extraneous text such as toxicology reports that may be noisy in the context of prediction focused on criminal justice outcomes. Further, compact LLMs have limited token lengths, which constrain the number of words in an input narrative, and the combination of coroner and homicide reports can exceed the token length in some LLM applications. Because our outcomes are LE-focused, the analysis simulated the omission of potentially extraneous narrative information.

The analysis began by preprocessing the coroner and police narrative by removing special characters including numbers, punctuation, and capitalization as is standard. Police and coroner report narratives were combined into a single field in order to use the information available in both narratives (with the exception of the LE narrative–only simulation).

Next, the analysis turned to creating simulated data. First, a test set on which the model outputs were to be evaluated was randomly selected. The test set consisted of a random sample of 30% of each outcome's records, which was then held out from any selection into the training data.

To vary the amounts of training data, the analysis used different training data record counts, each with a different amount of training data. These splits ranged from a minimum of 100 cases, increasing in increments to 200, 500, 1000, 1500, and up to 2000 cases. Each split was randomly sampled from the full dataset specified for each outcome so that each training split maintained a proportion of positive and negative cases that approximates the true proportion. The prior sample was included in the next iteration to isolate the impact of adding additional training data, not adding different training data. For instance, to obtain 500 cases, first, the prior 200 cases were preserved, and an additional 300 were sampled to comprise 500 cases.

To simulate the impacts of language replacement and LE-only text, the analysis followed the procedure process outlined earlier to randomly select training data in the same 100, 200, 500, 1000, 1500, and 2000 increments.

In the second configuration of training data, the composition of positive class cases was altered from the true proportion in the training data. Instead of randomly sampling cases, the proportion of positive class cases was increased in the training data by adding additional positive class cases to the negative class cases. The positive class cases were incrementally increased until they comprise 10%, 20%, 30%, 40%, and up to 50% of the training data starting from a baseline of 1000 cases, as lower amounts of training data were not performant in this application. For instance, to obtain training data composed of 10% positive class cases for legal intervention homicide, the process started with randomly sampled training data with 1000 records, of which 54 were legal intervention homicides and 940 were not. To the 940 negative class cases, 59 additional positive class cases were added so that the total number of positive class cases was 113 (54+59), and the total was 1059 cases, of which approximately 10% (113/1059) were legal intervention homicides.

For each of the configurations described earlier, distilBERT, an LLM with fewer parameters but comparable accuracy to large-scale LLMs, was used [41]. Compact LLMs better allow for simulations because of fewer computational needs and because NVDRS data restrictions do not permit cloud storage and computing. The distilBERT models were fine-tuned on training data to select model parameters. Parameters were selected in initial fine-turning using 2 outcomes (legal intervention and drive-by). Because model parameters in each fine-tuned model were identical, these parameters were applied to each training data configuration (Table S2 in Multimedia Appendix 1). Because our target outcomes are imbalanced, we add a weighted trainer to account for class imbalance. Configurations are summarized in Table S3 in Multimedia Appendix 1.

Classification performance was measured using learning curves, which plot performance metrics relative to differing splits of labeled training data to evaluate classifier model performance. Binary classification model metrics including precision and recall in addition to metrics considered useful for imbalanced class problems, including an F_1-score, were used. Finally, to analyze classification performance by subgroup, learning curves were created for sex, race, and ethnicity subgroups.

Results

Classification outcomes differed by the proportion of positive to negative cases in each outcome (Table 1). The most rare positive class outcome was a police shooting (n=4489, 5.9%) followed by drive-by shootings (n=6575, 9.2%) and shootings where additional individuals were nonfatally shot (n=8052, 15.2%) in the course of the homicide. The most prevalent outcome was whether an individual is shot in their home (n=16,850, 24.8%) relative to another location outside the home. Victims of homicide in the sample tended to be male (n=4319-11,321; 67.2-96.2%), Black or African American (n=44,546-43,357, 58.5% - 60.5%), and young, with the most frequent age range between 25 and 34 years (Table 1). Intimate partner violence characterizes over a tenth of homicides overall but within cases where an individual is injured at home, intimate partner violence (n=17,226, 26.5%) occurred in over a quarter of cases. Legal intervention homicides were most likely associated with mental health problems and alcohol use.

Circumstances were known for almost all cases of legal intervention and drive-by shootings, but less information was

XSL•FO
RenderX

known about the circumstances of homicide where additional individuals were shot or when they were injured at home (Table 2). Circumstances were known in 71% (n=30,774) of homicides of Black decedents in contrast to 83.7% (n=8698) among Hispanic and non-Hispanic White decedents. The median number of words in a narrative for a LE narrative ranged from 80 - 83, whereas coroner and medical examiner narratives ranged from 88 to 91 words in length. Legal intervention homicides had the most lengthy narratives (115 for LE and 120 for coroner and medical examiner). Narrative length differed by race and sex. Among LE narratives, the median length for Black decedents was 98 words but 132 for non-Hispanic White decedents. Narrative length differed among male and female decedents. Female decedents had longer narratives for each homicide outcome. Female decedents shot at home had a median narrative length of 124 words in contrast to male decedents shot at home with a length of 92 words.

[a]CME: coroner and medical examiner.

Table 3 displays classification performance by F_1-score for each model type. Training data of approximately 1500 cases achieved an F_1-score of at least 0.6 for each outcome, though at 1000 cases, the majority of outcomes was at or exceeding 0.6. The

XSL•FO
RenderX

exception was the number nonfatally shot. Figure 1 plots learning curves by F_1-score in Table 3. Replacement language models tended to perform best (Table 3 and Figure 1) with the highest F_1-score in all save 6 model interactions. In particular, language replacement models consistently obtained the highest F_1-score for legal intervention homicides (Table 3 and Figure 1). Similarly, language replacement models featured higher precision scores for a subset of outcomes (Figure 2 and Table S4 in Multimedia Appendix 1). Less substantial difference occurred with recall (Figure 3 and Table S4 in Multimedia Appendix 1) and the false negative rate (Figure 4) between models. Omitting coroner or medical examiner reports performed worse across outcomes (Figures 1-4). Language replacement models trained on 1500‐2000 narratives obtained low false negative rates ranging from 1% to 5% of true cases resulting in a misclassified outcome (Figure 1 and Table S4 in Multimedia Appendix 1).

Table . F_1-scores by model outcome, training data, and model type.

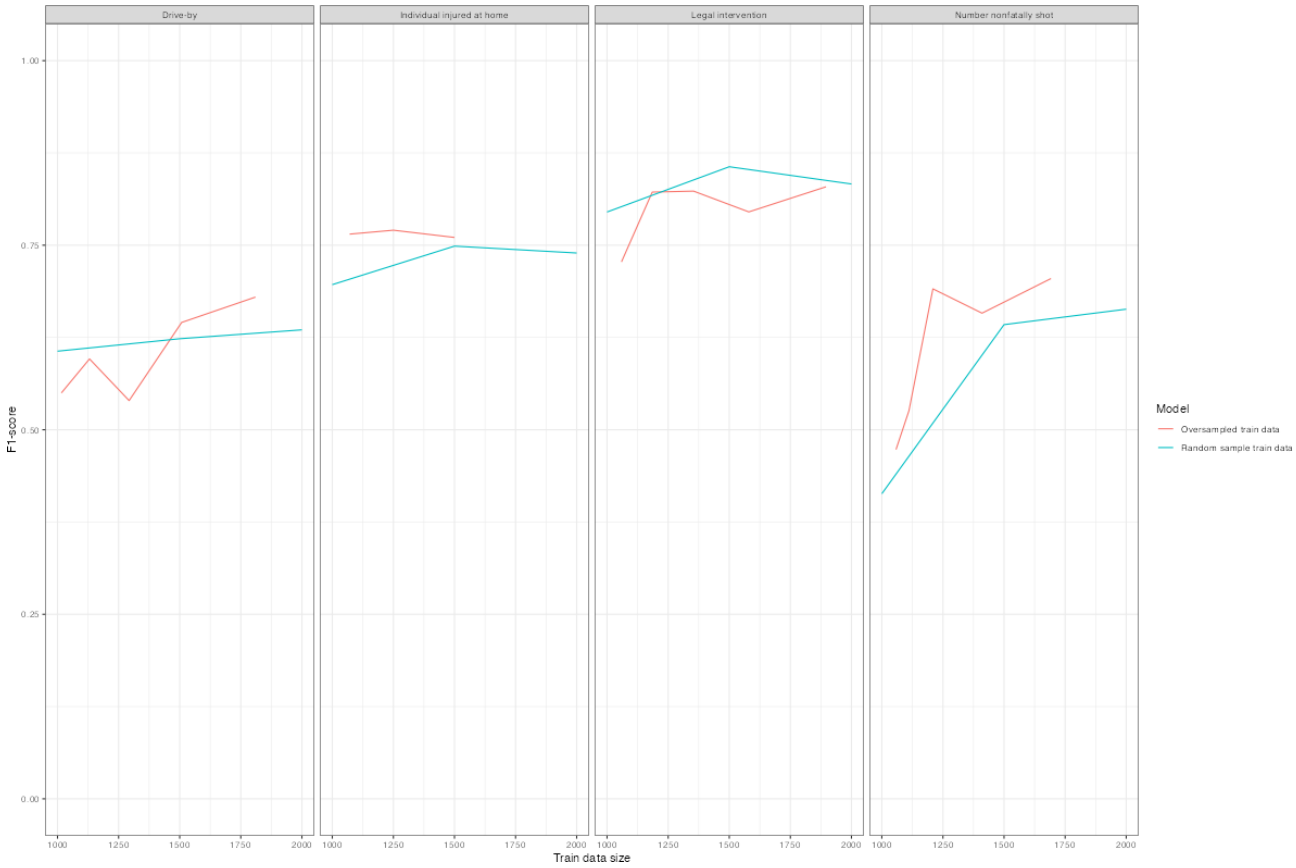
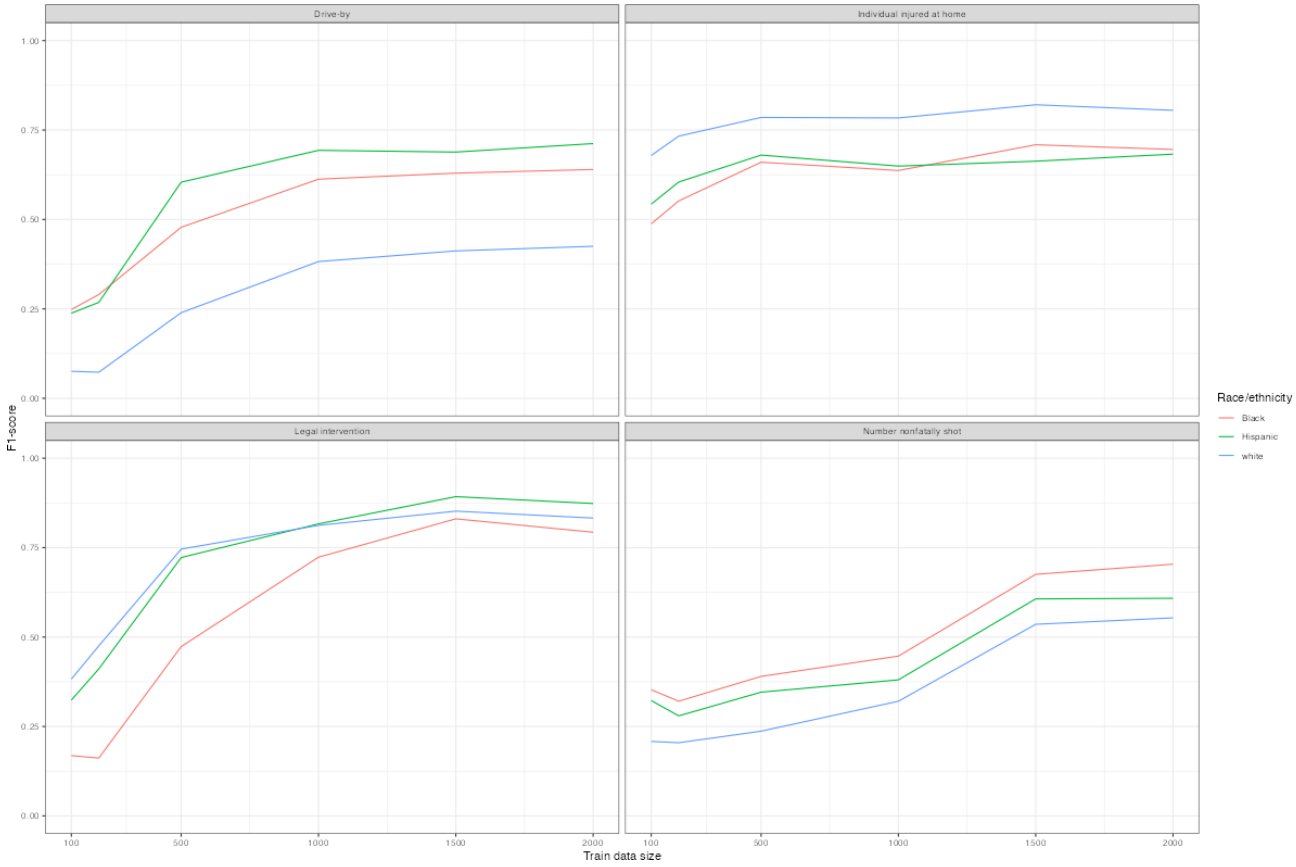
Figure 4. Learning curve by outcome, model type—false negative rate. False negative scores are plotted for distilBERT models, distilBERT models with language replacement, and models that do not use LE narratives. Training data randomly sampled and corresponding to amounts of 100, 200, 500, 1000, 1500, and 2000 randomly sampled training datasets are plotted according to each model performance metric. Test sets reporting results are identical across models for each outcome variable. LE: law enforcement.



Oversampling positive class cases was negligibly helpful in improving F_1-scores (Figure 5). For instance, oversampling for legal intervention homicide to be composed of 20% positive class cases resulted in the addition of 580 positive class cases added to training data and an F_1-score of 0.795 (Table S5 in Multimedia Appendix 1 and Figure 5). Relative to adding 500 randomly sampled cases, which would result in an F_1-score of 0.771 (Table S5 in Multimedia Appendix 1), the F_1-score gain from oversampling was 0.024 (0.795-0.771) and therefore modest.

Figure 6 plots F_1-scores of distilBERT language replacement models, as these models tended to perform best overall and may capture linguistic differences most accurately across subgroups. Predictions differ by race or ethnicity and sex across models. Legal intervention homicide victims who were White or Hispanic were most often correctly classified as such, and Black decedents were least likely to be correctly classified (Figure 6 and Table 4). The prediction difference is substantial for legal intervention victims with lower amounts of training data, though the gap persisted with higher volumes of training data. White decedents shot at home were most often correctly predicted, while Black and Hispanic decedents were least likely. Female decedents were less often correctly predicted than male decedents except if they were shot at home (Figure 7). Among models with at least 1500 records of training data, F_1-score disparities ranged from 0.2 to 0.25 by race and ethnicity, and between male and female decedents with differences ranging from 0.12 to 0.2 (Table 4).



XSL•FO
RenderX

Figure 5. F_1-learning curve for oversampled positive class cases versus baseline language replacement model. F_1-scores are plotted for distilBERT models fit with language replacement for both randomly sampled training data and oversampled training data. Oversampled training data correspond to an increment of a 10% increase in the proportion of positive class cases included in training data. The exact training dataset counts are in Table S4 in Multimedia Appendix 1. Random train data is plotted at 1000, 1500, and 2000 randomly sampled training data records for reference.

Discussion

Principal Findings

This analysis simulated the NLP model-fitting process to demonstrate how different training and preprocessing decisions impact model performance in the supervised classification of violent death narratives. Results show that the compact LLM approach is useful for predicting rare NVDRS outcomes relative to naive prediction baselines. The best model for drive-by shootings achieved an F_1-score of 0.635 (Table 3) for an outcome, where the proportion of positive class cases was 9.2%. For context, if the model had correctly classified only the 9.2% of positive class cases, it would have achieved an F_1-score of 0.162. While variation exists across outcomes in the rate of improvement over a naive prediction, the improvement in F_1-scores across infrequent NVDRS events demonstrates that a compact LLM approach is useful.

Simulations suggest that fine-tuning compact LLMs on NVDRS text requires approximately 1000 - 1500 training data records to achieve an F_1-score of at least 0.6. However, substantial variation existed between outcomes. For drive-by shootings and for whether a victim is injured at home, the learning curves flatten at 1000 cases and do not make further F_1-score gains with the addition of additional training data. Legal intervention (police shootings) continues to make additional F_1-score gains beyond 1000 cases and achieve an F_1-score of 0.75 at 2000 cases. Similarly, for the number of victims nonfatally shot, the addition of training data beyond 1000 cases substantially improves the F_1-score to 0.66 at 2000 cases.

In addition, preprocessing data to reduce domain-specific jargon resulted in improved model performance. Oversampling the positive class cases in training data does not increase prediction accuracy substantially over randomly sampled training data. Predictions differed by race, ethnicity, and sex.

Results suggested that compact LLMs are useful but require training data to correctly classify outcomes of interest. Random sampling and labeling a sufficient number of cases (approximately 1000) combined with a weighting layer is an effective classification strategy. Relative to recent few-shot and zero-shot learning applications using similar data sources [29], simulation findings differ, in that the volume of training data required is more substantial. The additional training data may be a function of a class imbalance in the target outcome, as other applications use more prevalent outcomes.

Differential prediction by subgroup is not explainable by outcome frequency or narrative length alone. For instance, White decedents of police shootings are less prevalent than Black decedents in the sample but are more often classified correctly. Similarly, female decedents have longer median narratives for all outcomes but are less likely to be correctly classified. This finding expands upon the current literature, which has found systematic data missingness in NVDRS [28,38-40]. Further research should characterize sources of differential prediction, whether input narratives or exacerbation by NLP classifier, and

XSL•FO
RenderX

examine fairness-aware models particularly if the prediction is used for decision-making or resource allocation in public health settings.

Limitations

This research is subject to several limitations. First, results from a compact LLM may not fully generalize to new LLMs with additional sophistication or to different language contexts beyond NVDRS. Label noise from NVDRS annotators may mean that results understate the performance of compact LLMs, which is consistent with police shootings tending to be the outcome type that is most accurately predicted. The potential for differential prediction by subgroup raises concerns about fairness and equity in model performance. Further investigations into the sources of this differential prediction are needed to ensure that NLP applications do not exacerbate existing disparities.

Conclusions

Compact LLMs with simple text changes can effectively predict rare NVDRS outcomes. For researchers using supervised machine learning to expand knowledge of violent deaths beyond existing coded fields, applying compact LLMs to sufficient training data can be a valuable approach. While future advancements will likely improve access to privacy-compliant, more sophisticated LLMs for analyzing sensitive data, this study provides a useful baseline for researchers pursuing similar efforts in the interim while underlining the potential for differential prediction by subgroup.

Abstract

Background: There is considerable need to improve and increase the detection and measurement of depression. The use of speech as a digital biomarker of depression represents a considerable opportunity for transforming and accelerating depression identification and treatment; however, research to date has primarily consisted of small-sample feasibility or pilot studies incorporating highly controlled applications and settings. There has been limited examination of the technology in real-world use contexts.

Objective: This study evaluated the performance of a machine learning (ML) model examining both semantic and acoustic properties of speech in predicting depression across more than 2000 real-world interactions between health plan members and case managers.

Methods: A total of 2086 recordings of case management calls with verbally administered Patient Health Questionnaire—9 questions (PHQ-9) surveys were analyzed using the ML model after the portions of the recordings with the PHQ-9 survey were manually redacted. The recordings were divided into a Development Set (Dev Set) (n=1336) and a Blind Set (n=671), and Patient Health Questionnaire—8 questions (PHQ-8) scores were provided for the Dev Set for ML model refinement while PHQ-8 scores from the Blind Set were withheld until after ML model depression severity output was reported.

Results: The Dev Set and the Blind Set were well matched for age (Dev Set: mean 53.7, SD 16.3 years; Blind Set: mean 51.7, SD 16.9 years), gender (Dev Set: 910/1336, 68.1% of female participants; Blind Set: 462/671, 68.9% of female participants), and depression severity (Dev Set: mean 10.5, SD 6.1 of PHQ-8 scores; Blind Set: mean 10.9, SD 6.0 of PHQ-8 scores). The concordance correlation coefficient was ρ_c=0.57 for the test of the ML model on the Dev Set and ρ_c=0.54 on the Blind Set, while the mean absolute error was 3.91 for the Dev Set and 4.06 for the Blind Set, demonstrating strong model performance. This performance was maintained when dividing each set into subgroups of age brackets (≤39, 40 - 64, and ≥65 years), biological sex, and the 4 categories of Social Vulnerability Index (an index based on 16 social factors), with concordance correlation coefficients ranging as ρ_c=0.44 - 0.61. Performance at PHQ-8 threshold score cutoffs of 5, 10, 15, and 20, representing the depression severity categories of none, mild, moderate, moderately severe, and severe (≥20), respectively, expressed as area under the receiver operating characteristic curve values, varied between 0.79 and 0.83 in both the Dev and Blind Sets.

Conclusions: Overall, the findings suggest that speech may have significant potential for detection and measurement of depression severity over a variety of ages, gender, and socioeconomic categories that may enhance treatment, improve clinical decision-making, and enable truly personalized treatment recommendations.

Introduction

Background

The prevalence and impact of behavioral health (BH) problems are at an all-time high. As many as 1 in 3 individuals throughout the United States have a BH condition [1]. Rates of subclinical needs are even higher, fueled in part by the psychological and social effects of the pandemic; as many as 1 in 2 individuals reports 1 or more symptoms of depression or anxiety [2]. In fact, the prevalence of depression symptoms increased more than 3-fold during COVID-19 [3]. At the same time, only 40% of those with BH conditions, and even fewer with subclinical needs, receive care of any kind, due to challenges with and delays in detection, perceived need, stigma, a paucity of providers, and other factors, and less than 15% of individuals with serious BH conditions receive minimally adequate treatment [4]. For those who do receive care, there is an average lag time of 11 years from the time of symptom onset to first treatment, during which time symptoms often worsen and other comorbidities may develop [4].

The current state of BH care and high levels of unmet need reflect a reactive and downstream approach to the identification and treatment of BH problems that has characterized the industry for decades. Effectively and efficiently meeting BH needs requires a more proactive, upstream, and personalized approach that meets individual needs earlier in their clinical trajectories with right-sized and person-fit interventions [5]. Emerging innovations in data science and technology, particularly developments in advanced data analytics and the availability of high-quality, patient-driven digital interventions, present unprecedented opportunities to transform and innovate the field of BH care and reduce enduring, high rates of unmet need.

One particularly promising innovation for advancing detection and delivery of proactive, personalized, and data-informed treatment is digital phenotyping. Digital phenotyping involves the detection of phenotypes, or behavioral signals, that may indicate or predict the presence of a BH problem. Translated by machine learning (ML) models and collected through passive data collection via smartphones, wearables, or other communication devices, these data signals may serve as clinically, and potentially preclinically, useful markers of BH problems. The potential relevance and use of digital phenotyping, which has been identified as the "next frontier" for personalized and proactive care within the field of oncology [6], have attracted particular interest and attention in the field of BH care and personalized psychiatry, with recent calls for accelerated applications to clinical practice [7-9]. In their review of research in this area, Huckvale et al [7] declared, "Many...studies appear to anticipate that digital phenotyping should play a role in routine clinical practice, for example by enhancing aspects of clinical diagnosis and treatment through earlier detection of condition onset, relapse or treatment response."

Most of the research examining digital phenotyping for the detection of BH problems has focused on detection of depression [10]. The opportunity to engage passive and objective ML technology for better detecting depression presents particular opportunities in light of the fact that depression is undetected in approximately 50% of individuals with the condition in high-income countries, and in 80% - 90% of individuals with depression in low- and middle-income countries [11]. In addition to opportunities that automated detection of depression provides for increasing low screening rates in most clinical and community settings, ML presents significant promise for overcoming underreporting and underdetection due to stigma, lack of evaluative service access, misattribution of symptoms to physical illness or age-related factors, or underrecognition of symptoms. In addition, the use of ML for detecting depression offers significant potential for increasing *earlier* identification and intervention, enhancing clinical efficiency through more accurate triage and treatment performance monitoring, improving fidelity through the use of objective measures, providing decision support, and personalizing BH care. As Galatzer-Levy and Onnela [12] recently declared, "Ultimately, the development of clinically meaningful digital measurements and their implementation in real-world contexts will permit optimized and personalized treatments targeted to the individual's emergent presentation and needs."

Prior Work

Among the most promising applications of digital phenotyping is the use of speech as a vocal biomarker of depression and other BH conditions [13]. The application of speech analysis in this context includes models for moment-by-moment analysis of the semantic patterns ("what" is said) or the acoustic properties (eg, tone, pitch, loudness, duration, articulation, transitions, and prosody) of speech, or the application of both. Increasing research has demonstrated the promise of speech analysis, including generally increasing accuracy in overall detection of depression and other conditions [7]. Despite this promise, research to date has been primarily conducted in controlled contexts and uses, and there has been very limited examination or application of this technology in real-world settings [7,14]. As Koutsouleris et al [14] recently noted, "While these innovations promise to revolutionize health care, little progress has been made toward real precision mental health applications. Implementation of these applications is often an afterthought."

Research on the use of speech analysis for measuring BH symptoms has consisted primarily of small-sample feasibility or pilot studies with nonrepresentative samples [7,14-16]. For example, in a scoping review of speech analysis for measuring mood disorders conducted by Flanagan et al [15], approximately 80% of studies were pilot or feasibility studies with sample sizes ranging from 1 to 73 participants. Similarly, in their review, Chia and Zhang [10] reported a mean sample size of 60. Moreover, many studies have consisted of analysis of "toy" datasets or controlled proof-of-concept studies involving highly controlled designs that, while promising for establishing the potential of a technological innovation, have yielded findings that are not necessarily generalizable or have use or effectiveness for real-world use [10,17]. These designs include use of analog speech tasks (eg, responding to a singular question, reading formulated passages, and answering questions about everyday life, often referred to as "closed-form" tests) that are often not comparable with real-world clinical settings or real-life contexts.

XSL•FO
RenderX

In addition, many studies examining speech analysis in the BH context have had important methodological limitations, including frequent reporting of selected metrics, such as reporting of sensitivity without specificity, leading to the recent call for research in this area to report multiple metrics, including robust metrics, such as the concordance correlation coefficient (CCC), that are not as biased to specific context, use case, and data label distributions [13]. Many studies have also relied on binary classifications (above or below cutoff score for clinical significance) for screening tools, which limit opportunities for promoting precision and personalization in BH care. Furthermore, research on speech analysis in detecting and measuring BH symptoms has almost exclusively relied on the use of single methods of analysis (predominantly acoustic analysis). Opportunities for leveraging and combining analysis of acoustic and semantic properties of speech may yield greater accuracy and precision in detecting and predicting BH conditions.

Goal of This Study

As mentioned previously, the application of digital phenotyping within BH care has approached a defining moment and key turning point for the field. In their review of the current state of digital phenotyping within the field of BH, Huckvale et al [7] have urged for "practical and coordinated action...to help accelerate both research and the ultimate development of real-world health applications for digital phenotyping." In an effort to help advance real-world application of digital phenotyping for promoting earlier and automated detection and measurement of depression, this study evaluated the performance of an ML model of the semantic and acoustic properties of spoken language in predicting depression in a naturalistic context by analyzing more than 2000 interactions between health plan members and case managers. Additionally, the study sought to test model performance beyond "presence or absence" dichotomous predictions, examining classificatory accuracy at multiple levels of depression from none or minimal to severe. Furthermore, model performance was tested across age, sex, and sociodemographic factors and in BH and non-BH case management contexts. This project, which is unique in its breadth and scope, aims to assess the accuracy of speech analysis for detecting and measuring depression severity in routine clinical settings. We hypothesize that the ML models used in this study will demonstrate robust predictive accuracy across variations in age, gender, care management context, and Social Vulnerability Index (SVI).

Methods

Experimental Design

The current quality improvement project evaluated the performance of the combined semantic-acoustic ML speech analysis model in predicting depression severity from existing recordings of case management calls, with BH case managers who are licensed independent mental health providers. Specifically, the performance of the ML model in care management conversations between insured members and BH case managers was evaluated by retrospectively comparing the actual scores from the Patient Health Questionnaire—9 questions (PHQ-9) administered by the case managers. The predicted Patient Health Questionnaire—8 questions (PHQ-8) scores were derived from the qualities (acoustic biomarkers and semantic content) of vocal productions of the same members conversing with care managers while engaged in discussion other than the PHQ-8 administration. It was secondarily sought to examine model performance in non-BH contexts where the PHQ-9 is not routinely administered using a subsample of calls with non-BH case managers. For both BH and non-BH calls, model predictions were compared with PHQ-8 scores from an associated metadata file.

Ethical Considerations

On each of the calls analyzed, the PHQ-9 was verbally administered. Members consented to the recording of the call for quality and training purposes. This study was designated as a quality improvement project by the institutional review board of the Allegheny Health Network and therefore exempt from ongoing institutional review board oversight. The project was also reviewed and approved by the Highmark Health Enterprise Data Governance Committee to ensure that it comported with internal data protection standards and applicable privacy, legal, and regulatory requirements, including deidentification of data. There was no compensation provided as recordings were made in the normal course of business.

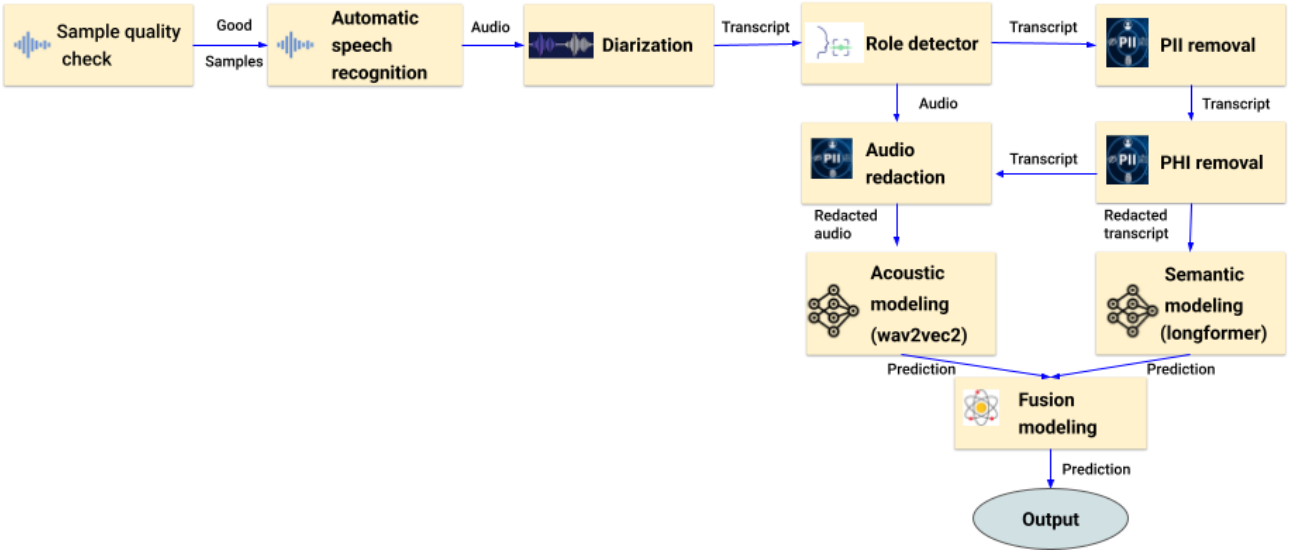
Measures

Depression Severity

The PHQ-9 is a widely used self-report measure of depression symptom severity. Frequency of depression symptoms are endorsed by patients using a 4-point scale, ranging from 0 ("Not at all") to 3 ("Nearly every day"). PHQ-9 scores range from 0 to 27. Higher scores reflect greater depression severity. Scores of 0-4 are classified as "none to minimal," 5-9 are classified as "mild," 10-14 are classified as "moderate," 15-19 are classified as "moderately severe," and 20-27 are classified as "severe." The PHQ-9 has been shown to be an internally consistent, valid, and reliable measure of depression severity [18,19]. For this study, the last item of the PHQ-9, which assesses for suicidal or self-injurious thoughts, was omitted given the use of archival data where further probing of responses was not feasible. Its inclusion requires different clinical considerations and handling in research settings. The adapted scale with item 9 removed is referred to as the PHQ-8 and has been shown to have strong psychometric characteristics, including the ability to accurately predict depression [20].

ML Speech Analysis Model

The semantic-acoustic model evaluated in this study has demonstrated robust results for accurate prediction of depression symptom severity and acceptable rates of error [21-23]. The proprietary ML model includes both acoustic and semantic models. The acoustic model takes as input the raw speech signal (rather than precomputed features such as pitch or energy). The production acoustic workflow is built on a pretrained open-source wav2vec2 architecture [24] and is trained on proprietary audio data. The system consists of 4 segment models, each trained with specific configurations, and 3 segment fusion models that integrate outputs from the segment networks.



XSL•FO
RenderX

Predictions from the segment fusion models are weighted to generate the final acoustic score.

The semantic model (referred to also as a natural language processing model) takes as input the output of a commercial automatic speech recognition (ASR) system. The model is based on the Longformer architecture [25], designed to efficiently handle long conversational contexts using advanced mechanisms such as dilated sliding window attention. Model training involves a proprietary fine-tuning approach using depression-specific data, using high-quality proprietary transcripts paired with PHQ scores. Further refinement is conducted using conversational samples, also labeled with PHQ scores. Labeled training data come from a large corpus of proprietary spoken language datasets labeled with PHQ-8 values. Both models take advantage of publicly available data for model pretraining, including text corpora for the natural language processing model.

To generate the final depression severity prediction, the outputs of the acoustic and language model are combined using a linear weighting; the weight is optimized using the CCC metric on the Development set. Figure 1 illustrates the overall ML analysis, from data preprocessing to prediction generation.

Figure 1. Deep learning architecture and processing pipeline. PHI: Protected health information; PII: personally identifiable information.

Identification of Case Management Calls and Metadata

A total of 2626 recordings of case management calls were included. They took place between January 2019 and January 2023. Of these calls, 2083 had full item-level data for the first 8 items of the PHQ-9, which were collected verbally during the course of calls. Calls corresponded to unique members from 44 different US states and were completed by 46 case managers. The majority of case managers completed multiple calls, and approximately one-third completed 20 or more calls. Each call recording had an associated metadata file containing member age, biological sex, zip code, whether the call was conducted by a BH case manager or non-BH (eg, medical and surgical) case manager, and PHQ-9 item-level data. Exclusion criteria for recordings included member age less than 18 years, speechmail messages, presence of any speakers beyond the case manager and the member, recordings in which the member was not present, and diarization failures (failures to correctly segment audio into single-speaker time regions). These exclusion criteria constituted 76 of the 2083 calls, leaving a total of 2007 calls for the analysis.

Partitioning the Data

The evaluation was conducted in 2 phases. To establish datasets for both phases of the project, the 2007 recordings and their metadata were partitioned by randomly assigning them to a development dataset (Dev Set) consisting of approximately two-thirds of the total available calls (n=1336) and a test dataset (Blind Set) consisting of approximately one-third of the total available calls (n=671). There was no speaker overlap across these datasets. The partitions were constructed to ensure reasonably equal representation of the metadata, including the distribution of PHQ-9 severity (none, mild, moderate, moderately severe, and severe). The Dev Set and Blind Set were securely delivered via secure file transfer protocol to Ellipsis Health, which performed all further data processing and analyses of the calls and metadata. The Blind Set was held back until phase 1 was completed.

The 2 datasets (Dev and Blind) were well matched; however, there were data curation errors such as inclusion of voicemails, conversations in a different language (mostly involving a language interpreter), and minors (younger than 18 years). Subsequent to the delivery of each dataset, 76 recordings, 44 from the Dev Set and 32 from the Blind Set, were found to meet exclusionary criteria through review of metadata (ie, age) and through diarization tool flags indicating a single speaker or more than 2 speakers. These 76 recordings were removed from the analyses. However, because the audio tracks were not reviewed by the annotators, other recordings meeting exclusionary criteria were included in the Dev and Blind Sets. An analysis was conducted, and it is estimated that inclusion errors constituted 3% of the total recordings analyzed.

Data Preprocessing

Upon receiving call recordings, Ellipsis Health performed diarization, ASR, and redaction of personally identifiable

XSL•FO
RenderX

information using Amazon Web Services Amazon Transcribe [26]. Redaction of protected health information was performed using Amazon Comprehend Medical [27]. Speaker role detection and time stamp generation on turns in conversation (ie, transition from member to case manager and vice versa) were performed using proprietary algorithms from Ellipsis Health. The redacted output of the ASR process, which included transcripts of both the member and the case manager with PHQ-9 content removed, was used by the semantic model. Meanwhile, the diarized, redacted audio containing only the member's speech, with PHQ-9 content masked, was used by the acoustic model. The outputs of the semantic and acoustic models were used (after weighting) to arrive at the fused output, using the Dev dataset.

Manual Annotation

To remove the verbally administered PHQ-9 from the calls, a manual annotation process was performed to identify the regions in the transcripts where the PHQ-9 was administered. Ellipsis Health used a team of professionals separate from the team conducting tests of the ML model (ie, ML team) to perform manual annotation, which consisted of annotators being presented with the case manager portion of the transcript from each call and having them identify the regions that contained the PHQ questions. These annotated regions of audio samples were masked in white noise for the acoustic model analysis, and the corresponding text was removed from the transcripts for the semantic model analysis.

Model Refinement on the Dev Set

In phase 1, the semantic-acoustic model was applied to the Dev Set (n=1336), and hyperparameters (eg, learning rate in optimization algorithms, number of hidden layers, and number of iterations in training a neural network) were optimized to minimize the CCC [28].

Tests on the Blind Set

Phase 2 of the project was conducted to evaluate the performance of the semantic-acoustic ML model established in phase 1. The Blind Set used in phase 2 was provided to Ellipsis Health without any accompanying PHQ-9 scores to ensure a blinded test of the model. Other than absence of PHQ-9 scores, the provided metadata categories were the same categories as provided for the Dev Set. ASR was conducted, followed by personally identifiable information and protected health information redaction of both the audio and transcript, using the same process as for the Dev Set. Manual annotation of the recordings was performed as in phase 1 and the verbally administered PHQ-9 was masked in the audio file and removed from the call transcript. The ML team then conducted tests of the ML model to predict depression severity scores for the Blind Set and across the metadata subgroups of the Blind Set. Recorded PHQ-9 scores from the original calls in the Blind Set were subsequently provided to the ML team, and PHQ-8 scores were then derived from these PHQ-9 scores and then compared with ML model predictions of the PHQ-8 scores to complete the test of model accuracy.

In light of the fact that overreporting and underreporting are well-known phenomena of surveys, including on sensitive measures such as the PHQ-9 [28-30], a preliminary exploration of the possible presence of such when responding to the PHQ-9 was conducted by examining for sizeable discrepancies between PHQ-8 labels and predicted depression scores. Overreporting and underreporting were defined as a difference of ≥2 categories of classification between the model prediction and the PHQ-8 score, as this would likely cause a significant change in a care pathway for a patient, and this condition was found in 42 of the 2007 total recordings. Five licensed therapists were recruited to listen and rate the member for severity of depression symptoms (none, mild, moderate, and severe). They were assigned recordings such that 1 therapist listened to each of the 42 recordings, but in 25 of those calls at least 2 therapists provided an additional assessment. The therapists were blinded to all information, including the PHQ score and section of the recording where the survey was administered, the model predictions, and demographic information. A PHQ-8 score predicted by ML model was defined as agreeing with a mental health provider assessment if their assessment was the same or within 1 severity category difference.

Metrics

The ML model results included CCC, mean absolute error (MAE), area under the receiver operating characteristic curve (AUROC), and sensitivity and specificity at the point of equal error rate (EER) for the Dev Set and the Blind Set. All classification analyses were conducted with the PHQ-8 as the criterion or observed score. Predicted scores from the ML regression models were binned according to the following PHQ-8 depression severity classifications: none or minimal (0 - 4), mild (5-9), moderate (10-14), moderately severe (15-19), and severe (20-24). Next, ROC analyses were conducted, comparing predicted to observed scores across 5 binary classifications at the 4 PHQ-8 cutoffs (5, 10, 15, and 20): 0-4 versus 5-24, 0-9 versus 10-24, 0-14 versus 15-24, and 0-19 versus 20-24. AUROC and sensitivity and specificity at the EER were calculated at each cutoff and reported for the ML model.

Results

Comparison of Member-Level Metadata

Data demographic distributions for members were comparable across both datasets. Ages ranged from 18-98 years in the Dev Set and 18-92 years in the Blind Set (Table 1). Approximately two-thirds of members across the Dev Set (910/1336, 68.1% of participants) and Blind Set (462/671, 68.9% of participants) were female. Member zip code was used to establish the SVI [31], which is based on 16 social factors, including socioeconomic status (eg, below poverty and unemployed), household characteristics (eg, single parent and aged 65 years or older), and housing type or transportation (eg, crowding and no vehicle). In each dataset, members were predominantly in the low-moderate range for social vulnerability and the majority of calls were BH case management calls (Table 1).

Moderate	328 (25.6)	174 (25.9)
Moderately severe	263 (19.7)	141 (21.0)
Severe	112 (8.4)	64 (9.5)

[a]SVI: Social Vulnerability Index (1 = least vulnerable, 4 = most vulnerable).

[b]CM: case management.

[c]BH: behavioral health.

[d]PHQ-8: Patient Health Questionnaire—8 questions.

[e]None or minimal=0 - 4, mild=5 - 9, moderate=10 - 14, moderately severe=15 - 19, and severe=20 - 24. Percentages may not add up to 100% due to rounding.

Regression Results for Overall Tests of the ML Model

Results for the test of the ML model on the Dev Set (n=1336) produced a CCC of ρ_c=0.57, which is superior to results expected by chance (ρ_c=0.10-0.20). CCC showed minimal decrease in the test of the ML model on the Blind Set (ρ_c=0.54; n=671). Furthermore, MAE values for the ML model tests across datasets were 3.91 and 4.06 for the Dev Set and Blind Set, respectively. These values for MAE are equivalent to less than the score range (5 points) of a single PHQ-8 severity classification.

Classification Results for Overall Tests of the ML Model

The AUROC at PHQ-8 cutoff of 10 (ie, “moderate” depression, the traditional cutoff for the majority of clinical care pathways [31,32]) was consistent for the ML model as applied to the Dev Set (0.83) and Blind Set (0.81), which are identical to the respective mean AUROC values over the different cutoff points (Table 2, top panel). In particular, results for the ML model (AUROC=0.81) on the Blind Set indicate the robustness of the model in its ability to identify individuals with PHQ-8 scores above 10 using novel call data (ie, data without PHQ-8 labels and not previously used for model refinement).

Table . Regression and classification results for overall tests of the machine learning model.

Statistic	Dev Set (n=1336)	Blind Set (n=671)
CCC[a]	0.57	0.54
MAE[b]	3.91	4.06
AUROC[c]		
Mean[d] across cutoffs[e]	0.83	0.81
Cutoff 5	0.81	0.85
Cutoff 10	0.83	0.81
Cutoff 15	0.83	0.79
Cutoff 20	0.83	0.79
Sens=Spec[f]		
Mean across cutoffs	0.74	0.73
Cutoff 5	0.73	0.76
Cutoff 10	0.75	0.72
Cutoff 15	0.74	0.72
Cutoff 20	0.76	0.72

[a]CCC: concordance correlation coefficient.

[b]MAE: mean absolute error.

[c]AUROC: area under the receiver operating characteristic curve.

[d]Mean across 4 cutoffs (5, 10, 15, and 20).

[e]Cutoff numbers were chosen as these are the points where the depression severity category boundaries occur.

[f]Value of both sensitivity and specificity at point of equal error.

AUROC values across the 4 cutoff thresholds and across both datasets ranged from 0.79 to 0.85 (Table 2). The lowest AUROCs were observed for the ML model (AUROC=0.79) on the Blind Set at PHQ-8 cutoffs of 15 and 20 (“moderately severe” and “severe” depression). Of note, the size of the subsample of members in the Blind Set with scores ≥20 was only 64 members and may have contributed to the lower AUROC values for this classification. See Table 1 for information on sample sizes across classifications for all 3 datasets.

As shown in Table 2, the mean sensitivity and specificity at the point of equal error across the 4 classifications was stable for ML model performance. Across the 4 PHQ-8 cutoff scores, sensitivity and specificity values ranged from 0.72 at a cutoff of 10, 15, and 20 for the ML model test on the Blind Set to 0.76 for the ML model test on the Dev Set at a cutoff of 20 and on the Blind Set at a cutoff of 5. As observed with AUROC, values at the lower end of the range for sensitivity and specificity may have been affected by smaller subsample sizes (eg, Blind Set with PHQ-8 ≥20).

Model Performance Across Metadata Subgroups

ML model performance was evaluated across metadata subgroups based on age in years (18 - 39, 40 - 64, and ≥65), sex (male and female), and BH case management versus non-BH case management and across the 4 SVI levels (1=least vulnerable and 4=most vulnerable).

The ML model performance between the 2 datasets (Dev Set and Blind Set) within their subgroups (age [Table 3], sex [Table 4], type of case management call [Table 5], and SVI [Table 6]) reveals both consistent and relatively similar AUROC cutoff at 10 and EER values with AUROC cutoff at 10 ranging from 0.81 to 0.83 and sensitivity and specificity at point of equal error ranging from 0.73 to 0.75, implying good model stability and robustness. See Figures S1-S12 in Multimedia Appendix 1 for ROC curves (overall and per subgroup on Blind Set). CCC ranged from 0.44 to 0.61, with the lowest (0.44) occurring in the most highly socially vulnerable group in the Blind Set and the highest (0.61) occurring in both the least socially vulnerable group of the Dev Set and the ≥65 years age group in the Blind Set. In most cases, the lower CCC values occurred where sample sizes were approximately 100 or fewer individuals, and our previous work [33] suggests a minimum count of approximately 200 individuals for robust estimates of prediction performance. MAE values ranged from 3.62 in the ≥65 years age group of the Blind Set to 4.57 in the non-BH group of the Blind Set. The 2 highest MAE values were associated with subgroups with sample sizes of approximately 100 or fewer participants, comparable with results for the CCC.

Finally, within the Dev Set, 3.1% (42/1336) of recordings showed sizable discrepancies (divergence equivalent to 2 or more PHQ-8 categories) between administered PHQ-8 and ML-predicted depression score that could imply PHQ-8 response underreporting (actual depression score much lower than predicted depression score) or overreporting (actual depression score much higher than predicted depression score). A review of these discrepancies by 5 independently licensed clinicians, who were blinded to the administered score, yielded PHQ-8 categorization of members' vocalizations that were consistent with the ML model categorization twice as often as they were with the administered PHQ-8 score.

Discussion

Principal Results

The current evaluation, leveraging speech analysis to detect depression symptoms across different levels of severity within a large real-world clinical case management context, represents, to our knowledge, the first evaluation of its kind. Overall, the findings for the combined acoustic-semantic ML model demonstrate strong model performance across a variety of key metrics. The AUROC value of approximately 0.81, the overall CCC value of 0.54, and mean of the sensitivity and specificity at the EER of 0.73 in the Blind Set demonstrate robust clinical support for the model's ability to accurately predict severity of depression. These results compare favorably to previous research, which has primarily relied on much smaller samples and incorporated pilot, simulation, or controlled study designs [29,30]. Whereas many prior studies have focused on application of acoustic or semantic speech analysis, this study reports on an approach that combined information from both semantic and acoustic-based models. Future development and testing of speech analysis models should continue to explore the benefits of combining acoustic and semantic models.

It is noteworthy that the model performed consistently across all major subgroups and PHQ-8 classification levels, with AUROC values ranging from 0.79 to 0.85 and CCC values ranging from 0.44 to 0.61. However, the model did undercharacterize individuals at the highest PHQ-8 level (ie, "severe" depression), likely due to smaller sample size in this category of depression on which this model was trained. Among the most promising findings from the subgroup analyses was the model's strong accuracy in predicting depression severity among older adults across key metrics. This finding is particularly significant, given that older adults have the highest rates of undetected depression [34], are often less likely to recognize or self-report symptoms of depression [35], and may experience depression with fewer dysphoric symptoms and more somatic complaints, which can be misattributed to physical illness [36,37].

The model's ability to detect depression symptoms at lower severity levels offers significant real-world potential for early identification and person-fit and right-sized interventions earlier in individuals' clinical trajectories. In addition to its ability to classify depression presence (PHQ-8<10 vs ≥10), the model performed well across specific PHQ-8 severity levels, particularly in the minimal and mild ranges. This suggests promising applications for early, proactive, cost-effective, and lower-intensity interventions (eg, digital interventions, BH coaching, and peer or social support) that may prevent symptom progression and reduce relapse rates. Notably, beyond the personal and clinical benefits, earlier interventions and prevention of depression may also have significant financial implications, potentially reducing health care costs associated with advanced-stage depression treatment.

Beyond BH contexts, the model's performance in general medical (non-BH) case management calls suggests even greater potential for broadening depression detection. The model achieved a comparable level of performance (AUROC cutoff 10=0.81; range=0.79-0.85) in non-BH case manager calls, indicating potential for integrating depression detection into clinical decision-making in settings where the PHQ-9 is not routinely administered and where depression is often undetected

XSL•FO
RenderX

[38]. Furthermore, the potential financial impact of enhanced depression detection in non-BH contexts is considerable, especially given that the total cost of care for members with both a BH condition and a chronic physical health condition, experienced by many members in medical-surgical case management, is approximately 3 times higher than for those with the same condition but no BH diagnosis [39,40]. The foregoing, notwithstanding, findings related to model performance in non-BH case management should be considered preliminary in light of the smaller sample size (n=110, Blind Set sample). Accordingly, additional application of speech analysis in non-BH contexts and other physical health settings is warranted.

The findings with respect to the overreporting and underreporting on the PHQ-8 offer insights into the potential for speech-based analysis to enhance depression detection objectivity [41-43]. Specifically, speech analysis may be less susceptible to bias, whether conscious or unconscious, relative to subjective report or traditional measurement. The observed trend of likely underreporting on the PHQ-8 (ie, the administered score being much lower than the predicted score) aligns with prior research on the impact of stigma, lower BH literacy, and other factors that contribute to self-report bias and underreporting of depression [44]. On the other hand, overreporting on the PHQ-9 (ie, the administered score being much higher than the predicted score) may suggest heightened or exaggerated response tendencies, personality characteristics, or efforts to obtain help [45].

Finally, this study highlights important opportunities for speech analysis and other digital phenotyping approaches to improve administrative and clinical workflows. It is noteworthy that case managers spent nearly 20% of total call time administering the PHQ-9. From an efficiency standpoint, this is time that could be better allocated to establishing a therapeutic alliance, collaborating to identify and define BH goals, addressing ambivalence and other potential obstacles to achieving those goals, and directly addressing the member's chief concerns. Greater efficiency also establishes opportunity for case managers to interact with more members. From a clinical process standpoint, time spent administering measures such as the PHQ-9 can be awkward and even frustrating for members and may adversely affect rapport and engagement. Furthermore, inconsistencies in PHQ-9 administration can introduce errors or variability in measurement, potentially leading to misinterpretation of symptoms. In contrast, having objective, real-time data on depression severity could provide valuable insights for clinical decision-making and for providing proactive and personalized treatment plan.

Strengths and Limitations

This study has several key strengths, including its large sample size, evaluation of speech analysis in a real-world clinical context, use of naturalistic conversations versus analog speech tasks (such as reading-defined passages or phrases, or repeating specified sounds), integration of both semantic and acoustic properties of speech, and analysis of model performance across subgroups and depression severity levels using numerous evaluation metrics. At the same time, there are several limitations that should be considered when interpreting the current findings and guiding future research.

While the large sample size included in this real-world evaluation is unique in the field of digital phenotyping [15], the sample sizes for some of the subanalyses, including the analyses of the non-BH calls and the highest PHQ-9 severity level ("Severe") condition, were relatively small. Given this, caution should be exercised when interpreting these findings. Moreover, data on member race and ethnicity were not available. As such, the generalizability of the current results to different ethnic, cultural, and linguistic groups cannot be definitively determined. That said, the acoustic-semantic speech model was developed and trained on a very large and diverse sample [23,46].

Furthermore, prediction of depression by the model, like with any ML model, includes a degree of error or imprecision. In the current analysis, this was equivalent to approximately 4.06 points on average (the reported MAE) on the PHQ-9, which itself has imperfect accuracy [47]. As such, predicted scores should be interpreted with this in mind. With additional data, precision is likely to further increase.

In addition, the collection of the case management recordings on a single audio channel posed a challenge for this study, necessitating the use of ASR for conversion of speech to text, diarization for speaker separation, and speaker attribution labeling. While these processes generally have low error rates, they are not entirely error-free. Diarization was performed using a leading commercial tool as manual processing of calls would have required listening to and annotating thousands of hours of recordings, a time-intensive process that is also prone to errors. Additionally, the use of automatic speech processing better reflects how an actual implementation would be performed in a real-world setting. However, diarization errors (ie, poor or missing speaker separation) were encountered, and these errors propagated through the preprocessing and annotation pipeline, affecting both automated speaker attribution and removal of PHQ-8 content.

Furthermore, data curation errors observed (eg, inclusion of voicemails and conversations with minors), inevitable in a real-world dataset of this kind, may have impacted performance (in both positive and negative directions); on balance, however, these likely did not have more than a negligible effect on the reported performance metrics. Many of these challenges and resulting errors may be attenuated in prospective implementations (vs the current retrospective-focused analysis) in the future, given that (1) current call management systems routinely record speakers on separate channels, significantly mitigating the challenges of diarization (many legacy systems do not have diarization capability but some may be specially configured to do so), and (2) formal implementation of this technology within the case manager's workflow would limit inclusion of irrelevant (eg, voicemail messages) or inappropriate (eg, minors and different languages) calls through either call management software technology or manual exclusion by the case manager according to inclusion and exclusion criteria.

Future Studies and Real-World Deployments

The successful deployment of AI-driven speech analysis for depression detection requires careful integration into existing health care workflows. One promising approach is its integration into telehealth platforms, where it could facilitate real-time assessment and early detection during virtual consultations. Embedding the model into electronic health records, virtual scribe technology or clinical decision support systems could further enhance its use by providing clinicians with objective, data-driven insights alongside traditional assessments. This study represents a step toward the rigorous validation of AI-based health care tools, ensuring their accuracy and reliability across diverse populations. For successful deployment, ensuring security, safety, and compliance with Health Insurance Portability and Accountability Act, General Data Protection Regulation, and other data protection regulations is essential, along with continuous monitoring of system performance on test datasets to maintain reliability and accuracy. Additionally, clinician adoption depends on ensuring that the tool is user-friendly and seamlessly integrates into existing workflows without adding unnecessary burden.

Although the data used in this study are deidentified, future studies and real-world deployments should incorporate a protocol for obtaining explicit informed consent from members, ensuring ethical transparency and alignment with established guidelines for digital health interventions. One of the primary challenges in ML-based depression detection is the mitigation of bias, as algorithmic outputs may be influenced by dataset imbalances or systemic biases. In this study, bias evaluation was conducted across key demographic subgroups, but future research should expand on bias mitigation strategies and assess ethical AI deployment frameworks to ensure equitable model performance across diverse populations.

Additionally, AI governance is a critical factor in real-world deployment, necessitating adherence to key principles such as transparency, fairness, and accountability. Transparency ensures that AI models operate in a manner that is understandable, explainable, and accessible to stakeholders, including clinicians and patients. Fairness requires that models are developed and validated in a way that minimizes bias and ensures equitable performance across diverse populations, preventing disparities in mental health assessments. Accountability involves establishing clear oversight mechanisms to monitor AI decision-making, ensuring that these technologies align with ethical standards, regulatory requirements, and best practices for patient care. Future research and implementation should prioritize these principles to foster trust and reliability in AI-driven mental health tools.

Finally, while the ML model demonstrated strong predictive performance, it is important to emphasize that this tool is intended for initial assessment and triage and not for medical diagnosis. The model is designed to support early identification and risk stratification, which should be followed by clinician evaluation and judgment. This tool is not intended to replace traditional diagnostic methods.

Conclusions

There is an urgent need to enhance detection and measurement of depression. Implementing digital phenotyping through the use of speech as a digital biomarker of depression offers significant promise for improving and accelerating depression identification and treatment. In short, the current evaluation, involving the examination of combined acoustic and semantic speech analysis for predicting depression symptom severity across PHQ-9 classification levels in a large real-world clinical context, represents the first evaluation of its type. The results reported herein provide strong support for the application and use of a readily available and unobtrusive biomarker, namely, what and how of spoken language, for detecting and measuring depression in real-world practice at this important time. This easily accessible biomarker has significant potential for application in health care settings, ranging from “preclinical” case management contexts to patient-provider interactions. It is hoped that the current findings help to advance the development and application of novel ML technologies for automating and enhancing depression symptom measurement and for informing and advancing clinical decision-making, next-best actions, and personalized treatment recommendations. Moving analysis of speech for the detection of depression symptoms—not long ago deemed science fiction—to clinical reality presents considerable opportunities for changing the paradigm of BH care to be more efficient, personalized, proactive, and upstream-focused.

Acknowledgments

This project was supported by the Richard King Mellon Foundation (grant 10714). The authors would like to acknowledge the Ellipsis machine learning and data analysis contributions of Piotr Chlebek, Tomasz Rutowski, Amir Harati, Tulio Goulart, Robert Rozanski and Yang Lu; the generous contributions of Farshid Haque and Tahmida Nazreen for proofreading and formatting of the manuscript, and of Marija Stanojevic for comments on the machine learning portions of the manuscript. The authors would also like to acknowledge Nina Roth for her extensive support in manuscript preparation.

Data Availability

The datasets presented in this paper are not readily available because many that support findings for this study are proprietary. Requests to access the datasets should be directed to MA, mike@ellipsishealth.com.

Abstract

Background: The digital transformation of health care has introduced both opportunities and challenges, particularly in managing and analyzing the vast amounts of unstructured medical data generated daily. There is a need to explore the feasibility of generative solutions in extracting data from medical reports, categorized by specific criteria.

Objective: This study aimed to investigate the application of large language models (LLMs) for the automated extraction of structured information from unstructured medical reports, using the LangChain framework in Python.

Methods: Through a systematic evaluation of leading LLMs—GPT-4o, Llama 3, Llama 3.1, Gemma 2, Qwen 2, and Qwen 2.5—using zero-shot prompting techniques and embedding results into a vector database, this study assessed the performance of LLMs in extracting patient demographics, diagnostic details, and pharmacological data.

Results: Evaluation metrics, including accuracy, precision, recall, and F_1-score, revealed high efficacy across most categories, with GPT-4o achieving the highest overall performance (91.4% accuracy).

Conclusions: The findings highlight notable differences in precision and recall between models, particularly in extracting names and age-related information. There were challenges in processing unstructured medical text, including variability in model performance across data types. Our findings demonstrate the feasibility of integrating LLMs into health care workflows; LLMs offer substantial improvements in data accessibility and support clinical decision-making processes. In addition, the paper describes the role of retrieval-augmented generation techniques in enhancing information retrieval accuracy, addressing issues such as hallucinations and outdated data in LLM outputs. Future work should explore the need for optimization through larger and more diverse training datasets, advanced prompting strategies, and the integration of domain-specific knowledge to improve model generalizability and precision.

Introduction

Overview

In recent years, the health care sector has witnessed a significant shift toward digital systems for managing medical information, including electronic health records (EHRs), diagnostic imaging tests, and bureaucratic records. This transition has been further accelerated by the COVID-19 pandemic, which popularized telemedicine as a means to reduce contagion risks, minimize travel, and improve access to health care in remote areas [1-3]. However, the increasing reliance on digital systems has led to the generation of vast amounts of unstructured medical data, posing challenges for efficient information extraction and use.

The complexity of managing unstructured medical data necessitates innovative approaches to support clinical and sociological studies, optimize research, and enhance diagnostic precision. In this context, the potential of generative artificial intelligence (AI) solutions, particularly large language models (LLMs), has emerged as a promising avenue for automating the extraction of structured clinical information from unstructured medical reports.

This study investigated the feasibility of leveraging LLMs, specifically through the LangChain framework, to address key challenges in health care data digitalization, such as accuracy, scalability, and integration into existing workflows. It evaluated the performance of leading LLMs in extracting critical data categories, including patient demographics, diagnostic details, and pharmacological information. By exploring the capabilities of generative AI in this domain, this study aimed to enhance clinical decision-making, optimize resource allocation, and improve overall efficiency in health care systems.

Background

LLMs are advanced AI systems grounded in deep learning architectures, predominantly using transformer networks, that are trained on extensive textual corpora. These models are designed to capture complex linguistic patterns and semantic relationships, enabling them to process, generate, and predict human language with a high degree of accuracy. In health care, LLMs have the potential to contribute to transformative changes in health care by improving diagnostic precision, assisting in clinical decision-making processes, and facilitating communication between patients and health care providers [4,5]. LLMs are capable of delivering foundational knowledge, contextual analysis, and accessible information, making them valuable tools for patient education and clinical consultations [6]. They can also be integrated into medical practice responsibly and effectively, providing tools that address the needs of various medical disciplines and diverse patient populations [7].

LLMs are pretrained models, meaning that they possess the capacity to comprehend and generate text without the need for extensive additional training. This capability introduces significant challenges in managing the vast quantities of unstructured medical data generated, as extracting relevant information from these sources is inherently complex. LLMs, using a transformer architecture, excel in a multitude of domains, demonstrating remarkable capabilities in natural language processing (NLP) tasks and text comprehension. The essence of pretraining lies in enabling these models to predict the next word in a given text, a computational process that underpins their performance across various tasks, demonstrating their advanced design [8]. Transformers are based on multilayer neural networks that are trained with large datasets.

Traditionally, text processing has been conducted using recurrent neural networks (RNNs), a type of neural network architecture specifically designed to handle sequential data, such as text. RNNs eliminate the need for explicit word history modeling by naturally incorporating temporal dimensions, allowing the network to retain relevant information from previous time steps. RNNs operate by encoding feature vectors for each word, constructing input vectors from word embeddings, and incorporating outputs from prior hidden states, either through copying or time-step delays. Typically, the softmax function serves as the activation function. An important aspect of RNNs is backpropagation through time, which adjusts weights based on the sequence's context. Ultimately, the output layer produces a probability distribution for each word based on prior words and contextual features.

To enhance word prediction accuracy, this study explored the use of sociolinguistic features, such as sequences of discourse-related tags that provide syntactic information, to enhance word prediction accuracy. In addition, we used clustering techniques to delineate conversation topics, acknowledging that linguistic choices are influenced by the thematic context, while incorporating log-scaled frequency considerations. Furthermore, we factored in the sociosituational context, which encompasses variables such as the conversational context (eg, interview, spontaneous discussion, phone call, or academic seminar), the relationships between participants, and their quantity. These considerations collectively contributed to a more precise word prediction model [9].

To equip LLMs for tackling complex challenges and transcending the constraints of generalized composition inherent in thought chain prompts, which are often based on limited examples, a novel "from more to less" prompting approach has been introduced. This innovative methodology aims to combine structured NLP techniques with self-consistent decoding mechanisms. The proposed approach unfolds in sequential phases, commencing with the decomposition and resolution of subproblems. This involves furnishing consistent examples showcasing the resolution of subproblems and compiling lists of previously answered subquestions along with their solutions. It is noteworthy to emphasize that consistent decoding, in this context, refers to the coherent and logical interpretation of information during the model's generation process. This "from more to less" approach lays the foundation for leveraging bidirectional interactions, thereby enhancing the performance of LLMs in complex tasks [10].

Given the distinct characteristics of LLMs and specific operational considerations, the primary focus of this study lies in addressing the challenges associated with health care digitalization. This research places a significant emphasis on information extraction, with a notable shift toward document

XSL•FO
RenderX

analysis as opposed to the conventional extract, transform, load or extract, load, transform processes commonly applied to structured datasets. This approach, broadly categorized, aims to unveil structured information from unstructured or semistructured texts, representing a more expressive method that enhances communication.

It is essential to note that the extract, transform, load typically refers to the process of extracting, transforming, and loading data into a structured format, while the extract, load, transform process reverses the sequence by loading data first and then transforming it. Our work underscores the significance of document analysis as a specialized area within the broader field of empirical NLP, involving the extraction and encoding of information in the context of health care digitalization [11].

To be more precise, in our experiment, we will collect various medical reports in PDF. Using prompts, we will attempt to extract diverse clinical information, such as age, weight, family medical history, date of birth, or potential allergies. This information will be used to enhance our local data model, thus optimizing diagnostic monitoring by reducing the need for manual inquiries and the time spent on nonautomated searches. The experiment will be conducted through the implementation of the LangChain framework in Python, with concurrent use of models from OpenAI (GPT 4o), Meta (Llama 3 and 3.1), Google (Gemma and Gemma 2), and Alibaba (Qwen 2 and Qwen 2.5).

The advancements in LLMs have significantly expanded their applications across various domains, particularly in health care, where they have demonstrated substantial utility. As we explore the intricacies of LLMs, the transition from foundational understanding to practical implementation becomes evident. In the preceding section, an exploration of the fundamental architecture of LLMs underscores their training methods and transformative capacities across diverse disciplines.

This study focuses on the integration of these models into medical practice by drawing the attention to the practical implications of LLMs in health care digitalization. The ensuing discussion delves into the strategic application of LLMs to address intricate health care challenges, emphasizing their pivotal role in information extraction and meticulous document analysis. This discussion lays the groundwork for our empirical endeavors, where LLMs are used to extract critical clinical information from medical reports, enabling the optimization of diagnostic monitoring and reducing reliance on manual efforts.

Related Works

Multiple experiments have been conducted using LLMs to analyze documents, using metrics that evaluate fluency (whether the generated text is coherent), correctness (if the prompt response is appropriate), and the quality of citations (if the cited passages are suitable). These experiments involve combining automated metrics with human evaluation, which uses qualitative metrics to assess aspects such as utility and the coherence of citations, assigning scores on a scale from 1 to 5. Evaluation metrics were adapted for each dataset, incorporating custom accuracy measures tailored to the specifics of each dataset [12].

Network syntactic analysis, a method used for modeling knowledge about document components by delineating their geometric properties, lexical entities, and relationships, has emerged as a prominent technique. An example of its application is seen in the use of the FRESCO (Frame Spatial-Temporal Correspondence) semantic network language. In this experiment, FRESCO was used to analyze business letters, facilitating the extraction of structural elements such as the sender, recipient, date, and main body. This approach facilitates a comprehensive specification of knowledge concerning these structural components, contributing to accuracy and completeness in the modeling process.

The accuracy of structural entity recognition is high when the visual organization of document elements (position, size, images, and text formatting, etc) can be used to identify the sender. However, this accuracy may decrease when the information is not concentrated in a specific location and is instead scattered across different sections of the letter. This situation can lead to document rejection, but the use of network analysis, combined with layer-specific knowledge, can optimize information extraction and automatic response generation [13].

Given that current transformer-based neural networks use probabilistic techniques, it is interesting to note that decades ago, probabilistic experiments were conducted based on research into the use of logistic regression for obtaining ad hoc data, where a regression equation is fitted to learn data. The variables used in the equation are often statistical averages. Linear regression is used to identify simple yet effective probabilistic paths by combining search cues. The effectiveness of information retrieval has been enhanced through manual reformulations of topics [14].

This approach mirrors earlier probabilistic retrieval methods, such as staged logistic regression, which combined multiple retrieval clues to improve relevance estimates. These foundational techniques, though simpler, share conceptual similarities with modern transformer-based models, where embeddings and attention mechanisms probabilistically weigh token importance. The evolution from manual reformulations and regression-based methods to automated neural networks underscores the enduring role of probabilistic thinking in enhancing retrieval effectiveness [15].

The integration of knowledge graph (KG) structures has emerged as a pivotal resource in the realm of text document analysis. Through the application of advanced NLP techniques, this approach facilitates the extraction of critical entities, such as geographical locations, temporal references, and personal names, followed by the use of specialized tools to address ambiguities and spelling variations. This approach, known as “occurrence data,” emphasizes the preservation of terms, phrases, and entities throughout the analytical process.

The integration of NLP with KG structures enhances textual comprehension by focusing on contextual relationships, which facilitates precise information retrieval and analysis. The use of KG structures in text document analysis enables deeper insights and a refined understanding of data, overcoming the limitations of traditional keyword-based search approaches and expanding the scope of scientific exploration and data analysis.

XSL•FO
RenderX

Once the various entities have been extracted, the KG construction process commences. Each extracted entity represents a labeled node, and for each source of the various entities, a corresponding node is added. In the graph, a weight-1 edge is introduced between entities that co-occur within a document, signifying their simultaneous presence. However, when adding new nodes to the graph, care must be taken to ensure that no preexisting node with the label of the entity already exists, as in such cases, the existing node is repurposed.

To account for the diverse nature of entities, each node is equipped with a set of nature properties, allowing us to record the type of entities (eg, distinguishing between individuals and geolocations). If a vertex to be inserted already exists, as is the case with locations and dates, the vertex's weight is increased incrementally. The resulting graph is both weighted and undirected, offering a wide range of query capabilities that can be tailored as needed. The structure of the links between nodes also allows for flexibility in the types of data that can be retrieved [16].

Recent advancements in KG augmentation have demonstrated the benefits of integrating textual information to enhance entity representations. For instance, recent work by Abaho and Alfaifi [17] proposes a multitask framework that leverages dense retrieval to select highly relevant text descriptions for KG entities, subsequently augmenting the KG embeddings with these descriptions. This approach addresses the limitations of using single text descriptions by introducing a retriever model that automatically identifies richer and more contextually relevant text sources. Building on these advancements, this study explores the application of graph neural networks (GNNs) in NLP, focusing on KG rewiring and document classification.

Leveraging GNNs' capabilities, we advance text analysis by uncovering hidden semantic connections and improving recommendation systems. By using GNN-driven techniques to analyze semantic graphs and detect complex patterns in text data, our comparative analysis of GNN models, applied to KGs derived from modern art biographies, demonstrates their potential to enhance classification accuracy, manage noise, and provide deeper insights into text construction. These methods, combined with transformer-based models such as SBERT (sentence-bidirectional encoder representations from transformers) for encoding text descriptions, achieve significant performance gains, highlighting the importance of integrating multiple text descriptions to capture diverse contexts. This research paves the way for broader applications of GNNs and dense retrieval techniques in fields requiring detailed text analysis and sophisticated KG interpretation [18].

In the medical field, a substantial portion of data remains unstructured today, encompassing concepts such as emails, data streams, voice and video recordings, as well as digital documents. Structured data's growth tends to be more gradual. Automated text mining includes a range of methods that facilitate access to relevant information. Recent attention has been focused on NLP, as techniques from other domains, such as information retrieval and extraction (automated extraction of structured data from unstructured sources), are adapted and integrated into this context [19].

Data extraction often leads to the discovery of tabular data, which are frequently embedded within text, particularly in medical diagnoses. Traditional machine learning models struggle to efficiently process information in this format, while LLMs also face limitations in this regard. In response, methodologies such as TEMED-LLM have been developed, which include 3 key components: reasoning-extraction, result validation and correction, and training (preferably of an interpretable model based on the extracted tabular data) [20].

With the aforementioned goal in mind, efforts have been directed toward tasks such as SCHEMA-TO-JSON, a task focused on the extraction of structured records from tables and other semistructured data sources, such as a web page. This task takes as input a table that can optionally be supplemented with context from the same document, along with an extraction schema that specifies the attributes to be extracted for different records that may contain varying numbers of attributes. As a result, it generates a sequence of JSON objects represented by an array of key-value pairs, each paired with a record type, condensing the information into a more accessible format.

An approach for table extraction called InstructTE is applied, which demonstrates competitive performance in both accuracy and precision, with an emphasis on balancing the two. It only requires a human-constructed extraction schema, incorporating an error recovery strategy. The schema approach helps the extraction process adhere to a predefined structure, improving the accuracy and consistency of the extracted information. Primarily, human-driven prompting is used to direct LLMs during the extraction of data from complex tables [21].

In addition, other data extraction experiments have been conducted, focusing on radiological results that may not necessarily be textual reports. In the case of textual data, a state-of-the-art question-answering system was used, contrasting with radiologist annotations [22]. On the other hand, for nontextual data, a manual extraction of various tomographies was performed, where the reports were randomly partitioned into training and validation sets based on a natural language rule to extract report attributes (resulting in high precision in identifying occlusion, distal, or basilar, of several large blood vessels) [23].

Methods

Models

In this study, we carefully selected specific versions and configurations of LLMs to ensure clarity and replicability in our experimental setup. For GPT-4o, the model used corresponds to the GPT-4o-2024-08-06 version, released in May 2024. This version, also known as GPT-4 Omni, is optimized for high-complexity, multistep tasks, with training data extending until December 2023. GPT-4o includes a context window of up to 128,000 tokens and shows superior performance compared to GPT-4 Turbo, achieving twice the processing speed while reducing computational costs by 50%.

The Llama 3 model, developed and publicly released by Meta in April 2024, was evaluated in its 8 billion parameter (8B) configuration. This version incorporates a tokenizer vocabulary

XSL•FO
RenderX

of 128,000 tokens and uses grouped query attention mechanisms to enhance performance on complex text tasks. Pretraining for Llama 3 was conducted on a dataset comprising 15 trillion tokens, with approximately 5% of the dataset consisting of languages other than English. Posttraining included strategies such as supervised fine-tuning, preference optimization, rejection sampling, and proximal policy optimization. In addition to Llama 3, the updated Llama 3.1 version, released in July 2024, was also included in our study. Llama 3.1 incorporates architectural refinements, including enhanced attention mechanisms, and supports up to 405 billion parameters in its largest configuration. For this study, we used the 8B version of both models for consistency. Quantization from 16-bit to 8-bit numerics was applied to optimize computational performance, and both versions support a context window of up to 128,000 tokens.

The Qwen 2 and Qwen 2.5 models, developed by Alibaba Cloud, were evaluated in their 7 billion parameter (7B) configurations. Qwen 2, updated 3 months before this study, incorporates specialized bias terms for queries, keys, and values, significantly improving its attention mechanisms. This model was trained on a multilingual dataset spanning 27 languages, making it particularly robust for cross-linguistic applications. Qwen 2.5, released 2 months before our experiments, includes additional advancements in reasoning capabilities, such as chain-of-thought and program-of-thought techniques, which improve performance on tasks requiring structured and logical reasoning. Qwen 2.5 was pretrained on an expanded dataset of 18 trillion tokens, further refining its multilingual and contextual generation capabilities.

Finally, the Gemma models, derived from Google's Gemini generative chatbot, were also evaluated. Gemma 1, featuring 7 billion parameters, uses a decoder-only architecture designed for sequential text generation. It was trained with a context length of 8192 tokens, optimizing it for tasks requiring strict sequence fidelity. Gemma 2, with 9 billion parameters, incorporates advanced techniques such as grouped-query attention and root mean square normalization (RMSNorm) to enhance its multihead attention efficiency and model stability. Gemma 2 is particularly effective at selectively processing broader contexts while maintaining focus on smaller windows of words.

These configurations reflect a balance between computational feasibility and robust benchmarking across diverse model architectures. All models were evaluated under identical experimental conditions to ensure consistency and comparability of results.

Data

The documents under examination consist of clinical histories from diverse origins, lacking a standardized format. Sourced from various hospitals and medical conventions with heterogeneous organizational structures, these documents pose a unique challenge due to their nonconformity to a single medical specialty (eg, cardiology, gynecology, and psychiatry, etc). This diversity results in a broad clinical and pharmacological spectrum, encompassing a wide range of clinical conditions and medication types.

The dataset used in this study comprises 100 Spanish medical reports in PDF format, carefully selected to represent a broad spectrum of clinical scenarios. These documents are unstructured medical records, primarily consisting of free-text narratives without a standardized format. They include sections related to patient demographics (eg, age), clinical diagnoses, prescribed medications, diagnostic tests, and reasons for consultation. The length of the documents varies, with some being concise summaries and others containing more detailed descriptions of patient histories and treatments.

The heterogeneity of these cases, spanning various medical specialties (eg, cardiology, internal medicine, and family medicine) and levels of complexity, reflects the real-world variability encountered in clinical practice. This diversity is intentional, as the study aims to evaluate how effectively health care professionals can retrieve critical information from medical histories in time-sensitive clinical settings.

The dataset is fully anonymized, with no personally identifiable information included. The anonymization process was conducted by the source institutions (the Spanish Society of Internal Medicine, the Asturian Society of Family and Community Medicine, the Spanish Society of Cardiology, and the Faculty of Medicine at Francisco Marroquín University) before their provision for this study. These institutions followed their internal guidelines and ethical standards to ensure that all personal identifiers, such as patient names, addresses, and contact information, were removed or replaced with generic placeholders (eg, "Patient X"). This preexisting anonymization ensures that the dataset is ethically compliant and suitable for research purposes.

While the lack of a standardized format poses challenges for information extraction, it also provides a realistic representation of the variability found in real-world medical records. This makes the dataset particularly valuable for evaluating the adaptability and robustness of LLMs in processing unstructured clinical data.

Spanish was chosen as the language for this study because, despite being the second most spoken language in the world, there is a noticeable gap in the number of studies conducted in Spanish compared to those in English. Addressing this gap is crucial to ensure that advancements in medical data-processing technologies are accessible and applicable to Spanish-speaking health care professionals and systems. This focus enhances the study's relevance to a global audience while supporting the development of tools tailored to underrepresented linguistic contexts.

To extract data from these documents, we used a zero-shot prompting data extraction technique [24], designed to enhance performance in tasks involving reasoning with linguistically untrained or previously unexposed information within a specific task or domain, using *Pydantic*. Building on this approach, we created a predefined prompt based on a template querying specific categories: "nombre" (name and surname), "edad" (age), "diagnostico" (diagnosis), "medicamentos" (drugs), and "pruebas" (medical tests). The prompt is structured as shown in Figure 1.

XSL•FO
RenderX

Figure 1. Prompt structure.

```
prompt_template = """
En base al contexto dado, responde en el formato indicado

Contexto: {context}

Pregunta: {question}

Formato de las instrucciones: {format_instructions}

Respuesta útil:"""

QA_CHAIN_PROMPT = PromptTemplate(
    template=prompt_template,
    input_variables=["question", "context"],
    partial_variables={"format_instructions": parser.get_format_instructions()},
)

rag_chain = (
    {"context": retriever, "question": RunnablePassthrough()}
    | QA_CHAIN_PROMPT
    | llm
    | parser
)

resultado = rag_chain.invoke("Obtener información sobre el paciente").json(ensure_ascii=False)
```

This code defines the prompt template and the retrieval-augmented generation (RAG) chain, which guides the model in extracting structured information from unstructured PDF documents. The prompt is designed to ensure consistency and alignment with the predefined JSON schema. Using the information extracted from the documents, the code formats and prepares the corresponding prompt, proposing a structure that chains the categories according to predefined fields. This process ensures that the extracted data are organized and ready for further analysis or integration into downstream applications. It is important to note that our dataset comprises approximately 100 PDF documents written in the Spanish language.

Computational Resources and Implementation Details

This study was conducted using a PC equipped with an Intel Core i7 processor, an Nvidia GeForce RTX graphics card, and 16 GB of RAM. This setup provided sufficient computational power to process the dataset and run the models efficiently within a local environment. While not using extensive GPU clusters, this configuration demonstrates the feasibility of applying these methods using accessible hardware.

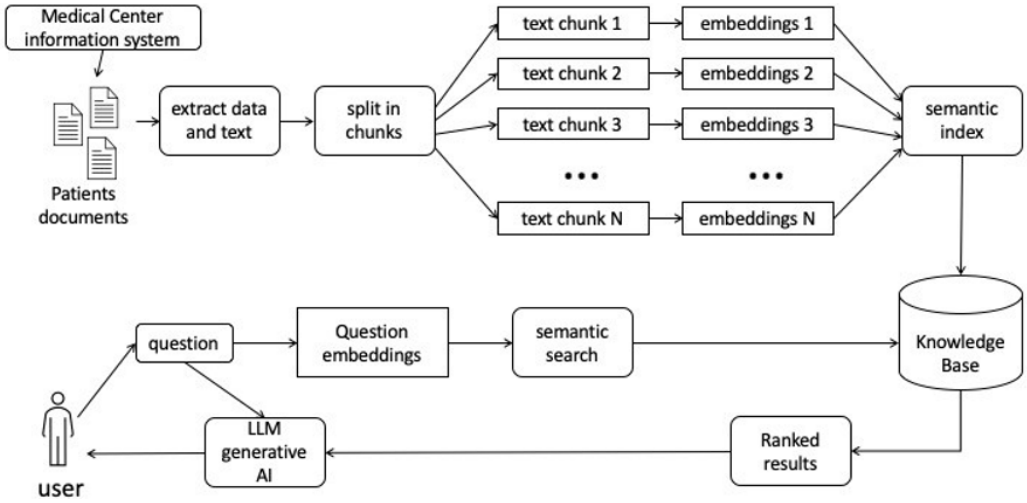
Preprocessing steps included extracting text from PDF files and segmenting the content into manageable chunks using a semantic chunker. The semantic chunker was specifically used to ensure that the chunks maintained semantic coherence, a critical requirement to minimize hallucinations during information extraction, particularly in the sensitive context of health care. This approach allowed the model to process contextually relevant pieces of information, thereby improving the reliability of the results. The processed chunks were stored in a Facebook Artificial Intelligence Similarity Search (FAISS) vector database for retrieval purposes, although this specific choice of database did not influence model performance directly and was used primarily for organizational convenience.

The JSON schema was defined using Python's *Pydantic* library to ensure consistency in the extracted information. Prompt templates were carefully designed to query specific attributes, including name, age, diagnosis, medications, and tests, enabling structured data extraction.

Although the dataset itself cannot be shared due to confidentiality constraints, future work will explore the creation of synthetic datasets that mimic the structure and complexity of the original data to facilitate reproducibility. The implementation scripts used for processing, running models, and generating results are available upon reasonable request to the corresponding author. Detailed configurations, including prompt templates and hyperparameter settings, can also be shared to support replication efforts.

Retrieval-Augmented Generation

RAG is an approach that enhances LLMs by integrating information retrieval during the generation process, aiming to address issues such as factual inaccuracies and hallucinations observed in the output of LLMs [25]. The use of a semantic chunker ensured that only meaningful and contextually relevant information was fed into the retrieval and generation process, directly impacting the accuracy and reliability of the outputs. This methodological choice reflects the critical need for precision in health care applications, where even minor inaccuracies could lead to significant risks.



Traditional models, such as naive RAG, follow a conventional methodology involving indexing, retrieval, and generation. In this paradigm, original data undergo cleansing, conversion, and segmentation into manageable chunks represented as vectors through an embedding model. While naive RAG provides a structured approach, it often faces challenges in retrieval precision, recall, and handling outdated information, which can

XSL•FO
RenderX

affect the quality of generation. In this study, semantic chunking was used to address these challenges by ensuring that retrieved information retained contextual relevance, thus improving the reliability of the generation process in a critical domain like health care [9].

The advanced RAG paradigm introduces optimization strategies in the preretrieval process, focusing on enhancing data indexing, fine-tuning embedding models, and postretrieval processes such as reranking and prompt compression. Furthermore, the modular RAG paradigm provides versatility and flexibility by integrating various methods to enhance functional modules, making it increasingly prevalent in the domain. Advanced RAG is considered a specialized form of modular RAG, showcasing a relationship of inheritance and development among the 3 paradigms [26]. A sort of schematic graphic abstraction is shown in Figure 2.

Figure 2. General schematic representation of retrieval-augmented generation for data extraction from documents. AI: artificial intelligence; LLM: large language model.

While our exploration focused on the basic yet impactful facets of RAG, we specifically used a zero-shot prompting strategy combined with semantic chunking. The semantic chunker, implemented using LangChain, divides the extracted text into semantically coherent segments by analyzing the differences in embeddings between sentences. In our implementation, we used the SemanticChunker class with only the embeddings parameter configured, leveraging OpenAI embeddings to generate vector representations of the text. This approach ensures that the text is split into meaningful and contextually relevant chunks, which are then used in the retrieval and generation process.

The semantic chunker works by determining when to "break" apart sentences based on differences in their embeddings. When the difference between two sentences exceeds a predefined threshold (automatically calculated by the chunker), they are split into separate chunks. By relying solely on the embeddings parameter, we allowed the chunker to use its default settings for threshold calculation and chunk size, ensuring a balance between semantic coherence and practical usability. This simplicity in configuration was chosen to maintain efficiency while still achieving high-quality chunking results.

The retrieved chunks are integrated into the prompt as contextual information for the LLM during response generation. To ensure the model prioritizes the retrieved information over its pretrained knowledge, we structured the prompt to explicitly instruct the model to base its responses on the provided context. The prompt template included the context (the top 3 most relevant chunks, selected based on their embedding similarity to the query using FAISS), the user query or task to be performed, and format instructions to ensure the output adhered to the required structure.

The integration was implemented using LangChain, where the retriever (FAISS) fetched the most relevant chunks, and the prompt template combined these chunks with the query and format instructions. This approach ensured that the model's outputs were grounded in the retrieved information, aligning with the structured schema of the task. For a detailed implementation of the prompt structure and retrieval process, refer to the Data section.

The semantic chunker, implemented using LangChain and the corresponding LLM embeddings, ensured that the retrieved chunks were semantically coherent and contextually relevant. By relying on embedding similarity (cosine similarity) and selecting the top 3 chunks, we minimized the risk of irrelevant or fragmented information being included in the prompt. The retrieval process was implemented using FAISS, a highly efficient library for similarity search in high-dimensional spaces. FAISS indexed the document chunks as vector embeddings, enabling fast and accurate retrieval of the most relevant chunks based on their semantic similarity to the query.

When a query is received, its embedding is generated using the same embedding model used for the document chunks. This ensures that both the query and the chunks are represented in the same vector space, allowing for a direct comparison of their semantic similarity. The similarity between the query embedding and each chunk embedding is calculated using cosine similarity, a metric that measures the cosine of the angle between two vectors in the embedding space. The top 3 chunks with the highest cosine similarity scores were selected for inclusion in the prompt.

XSL•FO
RenderX

This method inherently validated the relevance of the chunks, as only those with the highest similarity to the query were used. The decision to use semantic chunking was informed by prior studies, which highlight its ability to enhance precision in information extraction and semantic analysis, particularly in complex domains such as health care [27]. The combination of FAISS for efficient retrieval and cosine similarity for semantic comparison ensured that the retrieved information was both accurate and contextually appropriate, aligning with the structured schema of the task.

Furthermore, the simplicity of this approach—using similarity search and a straightforward prompt structure—allowed us to maintain efficiency while achieving high accuracy. Unlike more complex reasoning techniques such as chain-of-thought, our implementation focused on minimizing computational overhead without sacrificing precision. This was particularly important in the health care domain, where even minor inaccuracies could lead to significant risks. By combining semantic chunking with RAG, we ensured that the generated outputs were both accurate and contextually appropriate, aligning with the structured schema of the task.

Upon mounting the file system that serves as the source for our data, five steps are undertaken to structure and process the information systematically. The first step is source file (PDF) specification. Leveraging the PyPDFLoader class from the *pypdf* package within the Python programming language, specifically executed in a Jupyter Notebook environment, we systematically manage the content of PDF files. This includes the extraction of pertinent information from a predefined directory housing a curated selection of clinical documents across various categories. The subsequent use of PyPDFLoader facilitates the streamlined processing of content from each document with the corresponding LLM. The semantic chunker was used to divide the extracted text into semantically coherent segments. This approach was critical in reducing irrelevant or fragmented information, ensuring only contextually relevant chunks were used in the retrieval and generation process. The second step is query schema creation. The formulation of a structured query is conducted to generate a JSON-style schema, systematically aligned with key patient attributes such as name, age, diagnostic tests, diagnosis, and medication. Ensuring adherence to this specified schema is imperative. The object-oriented programming paradigm by Python, implemented within a Jupyter Notebook, is instrumental in defining the class that underpins this schema, thereby ensuring seamless data extraction and subsequent processing. The third step is prompt formatting. Before submitting the prompt for processing by the LLM, we rigorously format it to align precisely with the schema defined by *Pydantic*. This formatting process, executed in Python and complemented by the *Pydantic* library for data validation within the Jupyter Notebook framework, ensures that the response from the LLM strictly adheres to the predefined schema. The fourth step is model interaction. The transmission of the formatted prompt to the LLM is facilitated through serialization. This serialization process is executed using Python, either through the OpenAI application programming interface or the Ollama library, contingent upon the specific case. The LLM, embedded within a Jupyter Notebook, retrieves embeddings and pertinent data, applying predefined processing rules from various data models. The culmination of this interaction is directed toward a .bin file, serving as a repository for valuable embeddings. The retrieved chunks were directly appended to the input prompt as contextual information for the LLM. This facilitated structured and accurate response generation aligned with the predefined JSON schema. The fifth step is result formatting. The outcomes of the prompt, critically, are not processed as plain text but undergo transformation into JSON format. This strategic conversion enhances clarity and eases interpretation, ensuring a structured representation of the results. The Python-based implementation, within the Jupyter Notebook environment, facilitates subsequent processing and detailed analysis.

The execution of this methodology was conducted on high-performance hardware equipped with advanced processors, sufficient memory, extensive storage, and specialized hardware optimized for accelerating LLM computations. The computational environment, seamlessly integrated with the efficiency of a Jupyter Notebook, constitutes a critical component of our execution framework.

Our comprehensive workflow unfolds within the structured formalism of Python programming, harnessing the versatile capabilities of a Jupyter Notebook. This robust combination not only facilitates the extraction and structuring of data from medical reports but also ensures dynamic and efficient handling throughout the entirety of the process. The integration of advanced hardware, including an Intel Core i7 processor, an Nvidia GeForce RTX graphics card, and 16 GB RAM, provided a solid computational foundation for executing the complex tasks involved.

A critical component of this workflow was the use of a semantic chunker, which ensured that the data segments processed and retrieved maintained semantic coherence. This step significantly improved the reliability of the retrieval and generation processes, particularly in a health care context where accuracy and contextual relevance are paramount. By prioritizing semantically meaningful chunks, the methodology reduced the risk of hallucinations and irrelevant outputs, thus aligning the generated results more closely with the intended objectives.

The decision to use semantic chunking was informed by its demonstrated advantages in prior studies, which highlight its ability to enhance precision in information extraction and semantic analysis, reduce time and memory costs, and improve the handling of complex structures [27]. These benefits align closely with the requirements of our task, where maintaining semantic coherence and contextual relevance is essential for ensuring the accuracy and reliability of the generated outputs.

For a comprehensive evaluation of the model's performance, including detailed metrics such as accuracy, precision, recall, and F_1-score, see the Evaluation and Results sections. These sections provide an in-depth analysis of how RAG improves the accuracy and reliability of the generated outputs, particularly in the context of health care applications where precision is paramount.

XSL•FO
RenderX

The evaluation of our RAG-based approach focused primarily on the generation component, as detailed in the Evaluation and Results sections. Metrics such as accuracy, precision, recall, and F_1-score were used to assess the quality of the final outputs, ensuring that the generated responses were both accurate and contextually appropriate.

For the retrieval component, we used a pragmatic approach to select the top 3 chunks (k=3) based on cosine similarity to the query. This decision was guided by the structure and size of the clinical documents, which typically consisted of approximately 2 pages with a consistent format. Given this limited scope, retrieving 3 chunks provided a sufficiently strict yet manageable amount of context for the generation process. This approach minimized the risk of including irrelevant or fragmented information in the prompt while ensuring that the most relevant content was prioritized.

While a separate evaluation of the retrieval process (eg, using metrics such as Recall@K [28] or mean reciprocal rank [29]) was not conducted, the observed performance in the generation phase—coupled with the structured nature of the source documents—supports the effectiveness of our retrieval strategy. Future work could explore more granular evaluations of the retrieval component to further optimize the balance between chunk relevance and computational efficiency.

Given the specific nature of our task—extracting structured information from medical documents stored in external repositories—a comparison with a pure LLM prompting approach (without retrieval) is not applicable. Our methodology is designed to leverage the retrieval of relevant chunks from the documents themselves, ensuring that the generated outputs are grounded in the specific content of the source material. This approach is fundamentally different from traditional LLM prompting, which relies solely on the model's pretrained knowledge and does not incorporate external document retrieval.

Moreover, fine-tuning the model with proprietary data was not considered necessary or viable for this study. Fine-tuning typically requires a large amount of annotated data, which can be costly and time-consuming to produce, particularly in specialized domains such as health care. Instead, our zero-shot prompting strategy, combined with semantic chunking and RAG, provides a scalable and flexible solution for extracting structured information from medical documents without the need for extensive training data. This approach allows us to maintain high accuracy and reliability while minimizing computational overhead and resource requirements.

Code and Implementation Details

To ensure transparency and reproducibility, the implementation of this study, including preprocessing, semantic chunking, model prompting, and result generation, was conducted in Jupyter Notebook using Python. The notebooks contain detailed steps for extracting structured information from unstructured medical reports and demonstrate the application of advanced LLMs in a clinical context. The complete codebase, including configuration parameters, prompt templates, and examples for executing RAG workflows, is publicly available on GitHub [30]. This repository ensures that the methodology can be replicated or adapted to other datasets and scenarios.

Evaluation

To quantify the model's performance, we evaluated its outputs across the 5 categories of the JSON schematic framework (name, age, diagnosis, tests, and medications) using standard metrics derived from the confusion matrix. These metrics include accuracy, precision, recall, and F_1-score, which collectively provide a comprehensive assessment of the model's effectiveness in extracting structured information from medical reports.

The ground truth for evaluation was established by manually annotating a subset of the dataset, ensuring that each patient attribute (name, age, diagnosis, tests, and medications) was accurately labeled. This annotated dataset served as the reference for comparing the model's predictions. The distribution of entities in the ground truth varied across categories, with some categories (eg, diagnoses and tests) having a higher frequency of positive instances compared to others (eg, names and ages). This imbalance highlights the importance of using metrics such as precision, recall, and F_1-score, which are more informative than accuracy in scenarios with uneven class distributions.

Our evaluation approach aligns with the methodology used by Fornasiere et al [31], who used Mistral 7B for medical information extraction tasks, including medication and timeline extraction. Similar to our study, they used standard metrics such as precision, recall, and F_1-score to evaluate model performance. However, while our study focused on a zero-shot prompting approach, it explored multiple prompting strategies, including zero-shot, few-shot, and sequential prompting. Their results demonstrated that few-shot and sequential prompting significantly improved model performance, particularly in tasks requiring detailed information extraction, such as identifying medication dosage and frequency.

In terms of performance, they reported an F_1-score of 0.683 for medication extraction using a few-shot approach with JSON output, which is comparable to our model's performance in similar categories. However, their study also highlighted challenges in extracting full medication details, achieving lower F_1-scores for tasks involving dosage and frequency extraction. This aligns with our findings, where the model struggled to achieve high recall in categories such as names and ages, likely due to the variability and complexity of the data [31].

While our study primarily used a zero-shot approach, fine-tuning represents a powerful alternative for enhancing model performance in domain-specific tasks such as medical information extraction. Fine-tuning involves adapting a pretrained LLM to a specific domain by continuing its training on a smaller, task-specific dataset. This process allows the model to better capture domain-specific terminology, context, and nuances, which are critical in health care applications.

For example, models such as BioBERT and ClinicalBERT have demonstrated the effectiveness of fine-tuning in medical NLP tasks. BioBERT, a domain-specific adaptation of bidirectional encoder representations from transformers (BERT), was

XSL•FO
RenderX

fine-tuned on biomedical text corpora and achieved state-of-the-art performance in tasks such as named entity recognition and relation extraction in the biomedical domain. Similarly, ClinicalBERT, fine-tuned on clinical notes from EHRs, has shown superior performance in extracting clinical concepts and predicting patient outcomes. These models highlight the strengths of fine-tuning, particularly its ability to improve precision and recall in complex, domain-specific tasks.

However, fine-tuning also has its limitations. It requires a substantial amount of annotated data, which can be costly and time-consuming to produce, particularly in specialized domains such as health care. In addition, fine-tuned models can overfit if the training dataset is too small or not representative of the broader domain. This can limit their generalizability to new or unseen data. Despite these challenges, fine-tuning remains a valuable approach for improving model performance in tasks where domain-specific knowledge is critical [32].

In a recent study by Ntinopoulos et al [33], the performance of multiple LLMs was evaluated for data extraction from unstructured and semistructured EHRs. Their findings revealed that models such as Claude 3.0 Opus, GPT-4, and Llama 3-70b achieved outstanding accuracy (>0.98) in both entity extraction and binary classification tasks. These results are consistent with our observations, where the model demonstrated high precision and recall in extracting structured information from unstructured PDFs. However, Ntinopoulos et al [33] also highlighted challenges in handling long, unstructured texts, particularly when relevant information is scattered throughout the document. This aligns with our findings, where the model struggled with categories such as ages and medications, likely due to the variability and complexity of the data.

Specifically, the variability in how ages and medications are expressed (eg, “45 años” vs “45 y/o” or “Paracetamol” vs “Acetaminofén”), combined with the lack of explicit contextual cues, makes these categories particularly challenging to extract accurately. In addition, the dispersion of relevant information across the document further complicates the extraction process. In unstructured PDFs, critical details such as ages or medications may appear in different sections, often without clear labels or consistent formatting. This contrasts with more structured data, where information is typically organized in predictable ways (eg, tables or labeled fields). The need for the model to navigate and interpret such dispersed information adds another layer of complexity.

In addition, Ntinopoulos et al [33] emphasized the importance of response consistency across multiple iterations of the same prompt, a factor that we consider critical for ensuring the reliability of our model in real-world applications. In their study, models such as Claude 3.0 Opus and GPT-4 demonstrated high consistency, with minimal variation in responses across multiple runs. This is particularly important in clinical settings, where inconsistent outputs could lead to errors in patient care or data analysis. While our current evaluation focuses on accuracy and recall, future work will include consistency assessments to further validate the model’s robustness. This aligns with the broader trend in the field, where consistency is increasingly recognized as a key metric for evaluating the reliability of LLMs in health care applications [33].

To complement these consistency considerations, we used standard evaluation metrics to quantify the model’s performance. Accuracy measures the overall correctness of predictions, precision evaluates the relevance of the extracted data, recall assesses the system’s ability to capture all pertinent information, and the F_1-score provides a balanced measure that accounts for both precision and recall. These metrics are particularly useful for evaluating performance in scenarios with imbalanced data distributions, ensuring a robust assessment of the model’s capabilities.

The JSON schema served as the foundation for structuring the extracted data, ensuring consistency and alignment with key patient attributes. By adhering to this schema, the model’s outputs were systematically organized, facilitating both evaluation and integration into downstream applications. This structured approach not only streamlined the extraction process but also enabled a clear and standardized framework for assessing performance across diverse categories.

By using these metrics and leveraging the JSON schema, our evaluation offers a detailed understanding of the model’s performance, highlighting its strengths and areas for improvement in extracting and structuring data from medical reports. While fine-tuning presents a promising avenue for further performance gains, our zero-shot approach provides a scalable and flexible solution for medical information extraction, particularly in scenarios where annotated training data are limited.

Ethical Considerations

This study was approved for development by the Research Committee of the School of Doctoral Studies and Research at Universidad Europea (approval number 2025-637). The study used anonymized clinical cases, ensuring that no personally identifiable information was included. As the dataset comprised fully deidentified cases prepared in accordance with institutional guidelines, no additional ethics review board approval was required. The anonymization process strictly followed established protocols to guarantee privacy and confidentiality, upholding the highest ethical standards for research involving secondary analysis of medical data.

Results

Performance Metrics

The evaluation of the models is presented in Table 1, which summarizes their performance across specific medical data categories: names, ages, diagnoses, tests, and medication. Key metrics such as accuracy, precision, recall, and F_1-score are provided, alongside an overall average (Avg) calculated across all categories.

XSL•FO

As noted in the Evaluation section, the ground truth was established through manual annotation, and the distribution of entities varied significantly across categories. For instance, diagnoses and tests had a higher frequency of positive instances, while names and ages were less frequent. This imbalance underscores the importance of relying on metrics such as precision, recall, and F_1-score, which provide a more nuanced understanding of model performance than accuracy alone.

Observational Assessment

An analysis of the results revealed significant variations in performance both between models and within individual categories. For instance, GPT-4o demonstrated outstanding overall performance, with an average accuracy of 0.914 and an F_1-score of 0.813. However, it performed notably poorly in the names category, achieving an F_1-score of 0.222, suggesting that the model struggles to process textual entities that are complex or inconsistent.

In contrast, Gemma 2 excelled in categories such as diagnoses, achieving an F_1-score of 0.995, and tests, with an F_1-score of 0.990, showing high consistency in these critical areas. Nevertheless, its low performance in names, with a precision of 0.167, indicates a lack of balance across categories, which may limit its application in scenarios requiring the extraction of diverse types of sensitive data.

Models such as Llama 3 and Llama 3.1 exhibited similar patterns: relatively stable performance in diagnoses and tests but marked deficiencies in names and ages. For instance, Llama 3 achieved an F_1-score of just 0.137 in names, while reaching an F_1-score of 0.850 in diagnoses. This imbalance suggests that these architectures are less effective across all categories, potentially due to biases in training data or inherent limitations in their model design.

An interesting case is Qwen 2.5, which achieved a competitive average F_1-score of 0.730 and strong performance in diagnoses, with an F_1-score of 0.990, and tests, with an F_1-score of 0.964. However, its performance in names (F_1-score: 0.125) highlights a common trend across the evaluated models: significant challenges in this category, potentially due to the complexity and variability of names in medical contexts.

These results reflect the challenges posed by a zero-shot prompting approach, in which the models were tasked with extracting structured information without prior task-specific fine-tuning. While this method demonstrates the flexibility and adaptability of the models, it may also exacerbate limitations in categories requiring more nuanced understanding or specialized training, such as names and ages.

Overall, while the average metrics provide a general view of performance, the discrepancies across specific categories underscore the need for more specialized approaches to ensure consistent performance in medical applications. This analysis emphasizes the importance of optimizing both the models and prompting strategies to address the identified weaknesses and ensure reliability in real-world scenarios.

For the category of names, the datasets used in this study did not include actual personal identifiers due to anonymization. Instead, references to the absence of names (eg, “not available”) or generic mentions of a person were included. The consistently poor performance of the models in this category indicates a limitation in recognizing or interpreting such generic references within the text. This suggests that the models struggled with the ambiguity and variability introduced by the anonymized data.

Discussion

Principal Findings

Among the evaluated models, GPT-4o demonstrated the highest overall performance, achieving an average score of 91.4% across all assessed categories. Each individual category score exceeded 80 points (out of 100), highlighting the model’s consistency and robustness. In particular, GPT-4o excelled in accuracy, precision, and F_1-score, particularly in extracting age, diagnosis, and tests information. However, its recall, while satisfactory overall, was not as high as its other metrics, with Gemma 2 demonstrating superior recall rates in some categories.

A deeper analysis revealed that tasks such as name extraction posed challenges for all models, particularly due to the anonymization of the dataset, which used placeholder or fictional names. This led to true negatives rather than errors, reflecting a limitation inherent to the dataset design rather than a failure of the models. Tasks such as medication and diagnosis extraction, on the other hand, benefited from consistent terminologies and clearer patterns in the data, enabling models such as GPT-4o and Gemma 2 to achieve near-perfect precision and recall in these areas.

The anonymization of patient narratives in this study presented a unique challenge for the models in the names category. Rather than extracting explicit names, the models were tasked with

XSL•FO
RenderX

identifying placeholders or generic references. This experimental setup, while necessary for data privacy, may not fully represent real-world scenarios where explicit personal identifiers are often present. Consequently, the results in this category should be interpreted with this limitation in mind.

From an ethical and legal perspective, privacy is a fundamental concern when handling medical data. Privacy can be interpreted as intrinsic to the right to property, which extends beyond tangible assets to include personal data, such as health, economic, social, and nutritional information. Individuals often seek to control the extent to which external entities can access their personal data, particularly in sensitive domains such as health care.

However, scientific and technological research faces a significant dilemma. While the right to privacy must be rigorously defended, the trial-and-error phases inherent in advancements in fields such as computer science, medicine, and pharmacology often require experiments with real-world data. This tension underscores the importance of strategies such as anonymization and pseudonymization, which allow researchers to work with sensitive data while protecting individual identities.

Despite the benefits of open data for research and innovation, there is a lack of understanding about these strategies and the potential of open data to enhance scientific progress. Not all hospitals or institutions have open records suitable for experimentation, and ethical considerations often limit the availability of medical data for research purposes. In this study, the dataset of 100 Spanish medical reports was carefully anonymized to ensure compliance with ethical standards while enabling meaningful analysis. The decision to use anonymized data, rather than making the dataset publicly available, reflects the need to balance the advancement of medical research with the protection of patient privacy.

Gemma 2 followed closely behind GPT-4o, with an average score of approximately 80%. Its performance was particularly notable in the diagnosis and tests categories, where it achieved recall rates of 1.000 and near-perfect accuracy. This suggests that Gemma 2 is well-suited for tasks requiring exhaustive retrieval of relevant information. However, its precision in the name category remained low, reflecting ongoing challenges in handling anonymized or placeholder data.

Llama 3 and Llama 3.1 showed intermediate performance, with average scores of 62.8% and 62%, respectively. Both models showed relative strengths in extracting diagnostic and test-related information, achieving moderate recall and F_1-scores in these categories. However, their performance in extracting names and age data was weaker, likely due to variability in the data and limitations in their contextual understanding. The slight improvements in Llama 3.1 indicate potential benefits from iterative refinement in model architecture.

Qwen 2 and Qwen 2.5 demonstrated similar trends, with average scores of 64% and 77%, respectively. Qwen 2 excelled in tasks such as diagnosis and tests, achieving perfect precision, but struggled significantly in name extraction due to placeholder data. Qwen 2.5 improved on these results, particularly in recall for diagnosis and tests, highlighting its potential for more complex retrieval tasks. Nevertheless, both models require further development to address challenges in handling diverse data categories effectively.

Meta models exhibited acceptable accuracy for categories such as diagnosis, tests, and medications but faced difficulties in extracting names and age data. The significant class imbalance and variability in these categories adversely impacted their F_1-scores. These results underscore the need for additional fine-tuning or hybrid approaches to enhance their performance in scenarios involving diverse and unstructured medical data.

The variability in performance across categories reflects the inherent challenges of applying LLMs to a domain as diverse as clinical medicine. The dataset used in this study spans multiple medical specialties and includes a wide range of clinical conditions, medications, and terminologies. While this diversity enhances the generalizability of the findings, it also introduces complexities that may not exist in more homogeneous datasets. For example, categories such as medication and diagnosis benefit from the relative uniformity of medical terminology, while names and ages are inherently more variable due to anonymization and differences in reporting formats. Future efforts should explore the impact of dataset composition on model performance, particularly when applied to real-world clinical data.

From a broader perspective, these findings emphasize the adaptability of LLMs for extracting structured information from unstructured medical reports. Compared to traditional rule-based systems, LLMs provide greater flexibility and scalability, enabling them to handle a wide range of tasks and data formats. However, hybrid approaches that combine rule-based methods with generative capabilities could address some of the current limitations, particularly in high-stakes tasks such as name extraction.

The use of semantic chunking and RAG in this study demonstrates the effectiveness of context-preserving techniques in minimizing hallucinations and improving result relevance. By integrating retrieved data directly into the prompt, the models were able to generate structured outputs aligned with the predefined schema. This approach highlights the importance of carefully designed preprocessing steps to ensure consistent and reliable outputs.

The implications for clinical workflows are significant. By automating the extraction of critical patient information, LLMs reduce the cognitive load on health care professionals, streamline clinical workflows, and enable faster decision-making. These advantages are particularly evident in time-sensitive scenarios, where efficient information retrieval can make a substantial difference. However, the practical scalability of these solutions in resource-constrained environments remains an open question. Future work should investigate how these models can be adapted for deployment in settings with limited computational resources, ensuring their broader applicability and impact.

Despite these strengths, several challenges persist. Future research should focus on addressing edge cases, such as ambiguous or inconsistent data, and on optimizing models for

XSL•FO
RenderX

tasks requiring entity-specific recognition. In addition, expanding error analysis to cover more granular categories and integrating domain-specific fine-tuning can further enhance the applicability of LLMs in health care settings.

This approach highlights the challenges of working with sensitive data in health care research and underscores the importance of developing robust frameworks for data anonymization and access control. Future work should focus on creating standardized protocols for data sharing that prioritize both innovation and ethical responsibility.

Conclusions

This study explored various SCHEMA-TO-JSON strategies, leveraging the capabilities of LLMs to organize and extract information from medical reports based on a JSON schema framework implemented using *PyDantic*. This approach aimed to systematically structure clinical data, transforming unstructured narratives into a standardized format. The methodology proved effective in organizing domain-specific health care information, laying a robust foundation for the development of tailored data models.

The experimental results demonstrate that the LLMs used can effectively extract relevant information from medical histories. The high scores achieved in categories such as diagnoses and pharmacological data underscore the potential of these models to handle complex medical information. This aligns with findings in related studies, such as syntactic network analysis and KG frameworks, confirming the utility of advanced NLP techniques in the medical domain.

However, the study also highlights the following key areas for improvement:

- Challenges with personal details. OpenAI's models, despite their high overall performance, show inconsistencies in extracting specific details such as names and ages. These limitations are amplified in anonymized or pseudonymized contexts, where implicit or indirect references add complexity.
- Model variability. Models such as Gemma 2 and Qwen 2.5 exhibit strong performance in diagnostic and pharmacological categories but share similar challenges in handling personal details. Meta's models require substantial improvement across multiple categories, suggesting a broader scope for refinement.

These findings emphasize the need for further optimization of LLMs in domain-specific applications, particularly when addressing sensitive or nuanced categories of data. Incorporating additional training focused on these challenges or integrating external knowledge sources, such as KGs, may enhance the precision and adaptability of these models.

This work underscores the importance of deploying advanced NLP strategies to improve information retrieval and analysis in the medical domain. By addressing the inherent challenges of structured and unstructured data, this study contributes to the ongoing development of models capable of navigating and interpreting complex clinical information more effectively. Future work will focus on refining the extraction of sensitive details and exploring the integration of complementary techniques to enhance the overall robustness and reliability of these systems.

Data Availability

The data used in this study consist of anonymized clinical cases sourced from reputable organizations, including the Spanish Society of Internal Medicine [34], the Asturian Society of Family and Community Medicine [35], the Spanish Society of Cardiology [36], and the Faculty of Medicine at Francisco Marroquín University [37]. Given the sensitive nature of the data and their anonymization, they are not publicly available. However, further details about the data sources or methodologies used for anonymization can be provided upon reasonable request to the corresponding author.

Abstract

Background: Large language models (LLMs) have demonstrated the ability to perform complex tasks traditionally requiring human intelligence. However, their use in automated diagnostics for psychiatry and behavioral sciences remains under-studied.

Objective: This study aimed to evaluate whether incorporating structured clinical assessment scales improved the diagnostic performance of LLM-based chatbots for neuropsychiatric conditions (we evaluated autism spectrum disorder, aphasia, and depression datasets) across two prompting strategies: (1) direct diagnosis and (2) code generation. We aimed to contextualize LLM-based diagnostic performance by benchmarking it against prior work that applied traditional machine learning classifiers to the same datasets, allowing us to assess whether LLMs offer competitive or complementary capabilities in clinical classification tasks.

Methods: We tested two approaches using ChatGPT, Gemini, and Claude models: (1) direct diagnostic querying and (2) execution of chatbot-generated code for classification. Three diagnostic datasets were used: ASDBank (autism spectrum disorder), AphasiaBank (aphasia), and Distress Analysis Interview Corpus-Wizard-of-Oz interviews (depression and related conditions). Each approach was evaluated with and without the aid of clinical assessment scales. Performance was compared to existing machine learning benchmarks on these datasets.

Results: Across all 3 datasets, incorporating clinical assessment scales led to little improvement in performance, and results remained inconsistent and generally below those reported in previous studies. On the AphasiaBank dataset, the direct diagnosis approach using ChatGPT with GPT-4 produced a low F_1-score of 65.6% and specificity of 33%. The code generation method improved results, with ChatGPT with GPT-4o reaching an F_1-score of 81.4%, specificity of 78.6%, and sensitivity of 84.3%. ChatGPT with GPT-o3 and Gemini 2.5 Pro performed even better, with F_1-scores of 86.5% and 84.3%, respectively. For the ASDBank dataset, direct diagnosis results were lower, with F_1-scores of 56% for ChatGPT with GPT-4 and 54% for ChatGPT with GPT-4o. Under code generation, ChatGPT with GPT-o3 reached 67.9%, and Claude 3.5 performed reasonably well with 60%. Gemini 2.5 Pro failed to respond under this assessment condition. In the Distress Analysis Interview Corpus-Wizard-of-Oz dataset, direct diagnosis yielded high accuracy (70.9%) but poor F_1-scores of 8% using ChatGPT with GPT-4o. Code generation improved specificity—88.6% with ChatGPT with GPT-4o—but F_1-scores remained low overall. These findings suggest that, while clinical scales may help structure outputs, prompting alone remains insufficient for consistent diagnostic accuracy.

Conclusions: Current LLM-based chatbots, when prompted naively, underperform on psychiatric and behavioral diagnostic tasks compared to specialized machine learning models. Clinical assessment scales might modestly aid chatbot performance, but more sophisticated prompt engineering and domain integration are likely required to reach clinically actionable standards.

Introduction

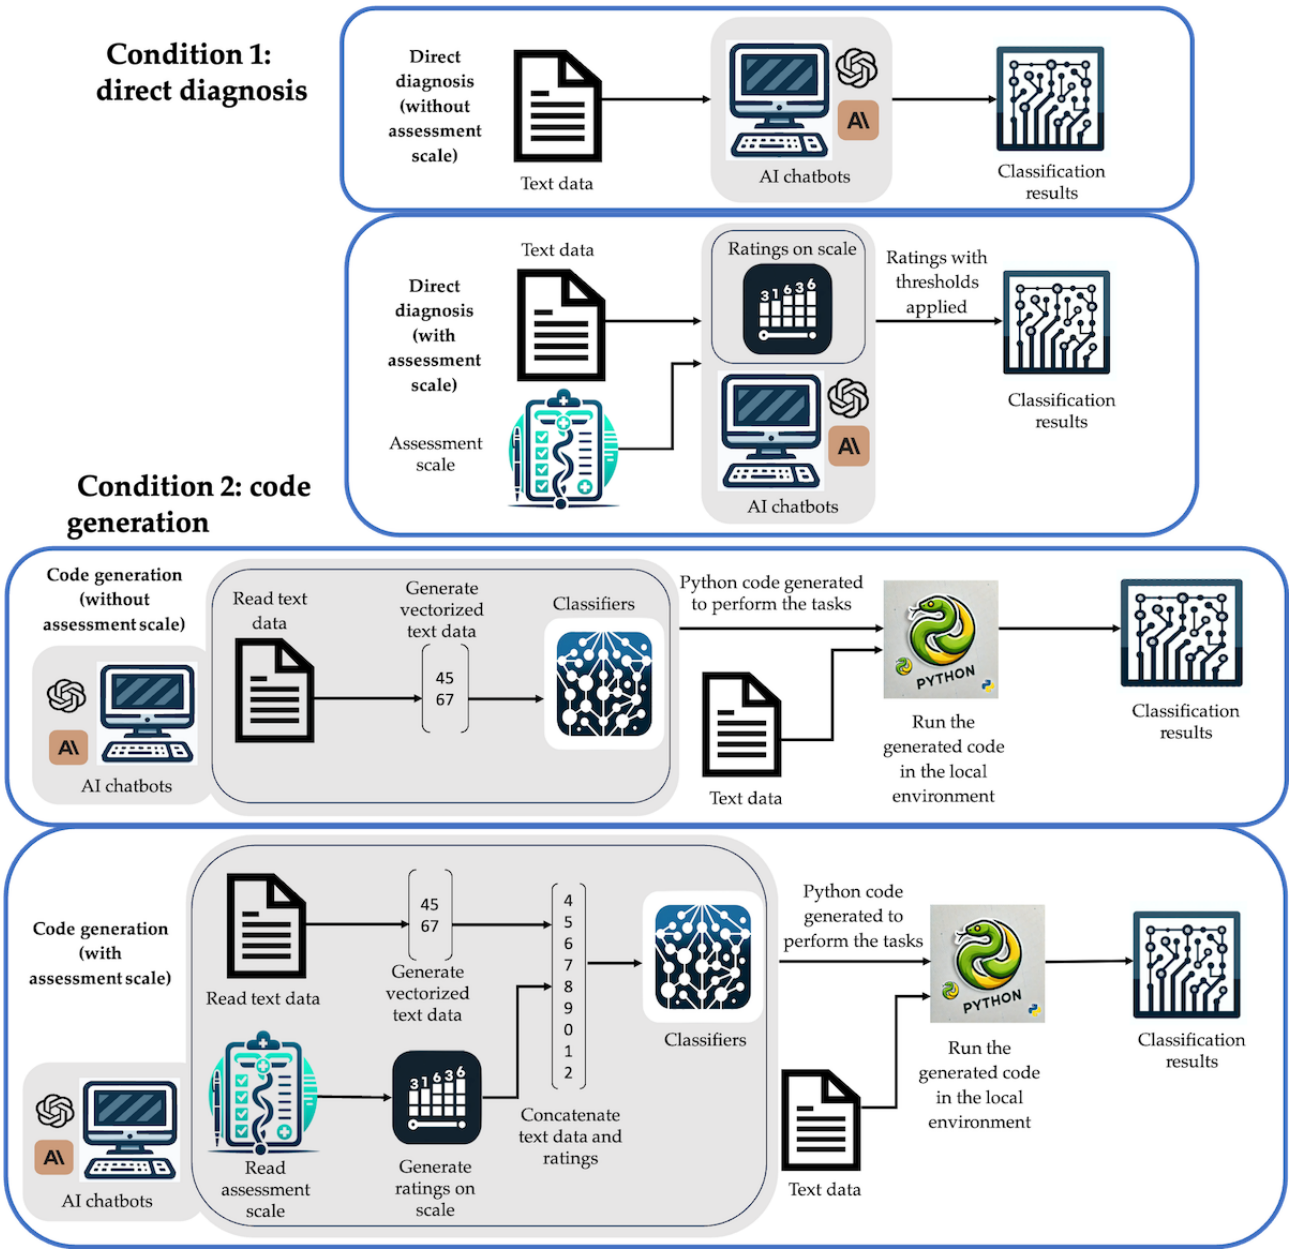
Background

Large language models (LLMs) have recently demonstrated capabilities that closely approximate or exceed human cognitive functions in various domains [1-3]. Given their efficacy in executing complex tasks, there is a burgeoning interest in exploring the potential applications of LLMs in clinical settings, including in areas such as providing emotional support [4,5] and mental health diagnoses [6-10]. The diagnostic process for neurobehavioral conditions typically encompasses comprehensive clinical assessments and longitudinal behavioral observations [11,12]. The integration of LLMs (as well as other machine learning [ML] models) into this process could potentially streamline this complex and time-consuming diagnostic procedure by facilitating automated screening processes [13,14]. While some research highlights some of the potential challenges of using LLMs for these tasks [15-18], they are emerging as a promising avenue for developing scalable and accessible screening services.

ChatGPT [19], Gemini [20], and Claude [21], prominent LLM-based conversational agents, have been the subject of evaluation for their potential in digital neurobehavioral diagnostics. Previous studies have indicated that the capabilities of chatbots for neurobehavioral classification remain limited even when assessing specific conditions or smaller patient cohorts [10,22,23]. In response to these findings, subsequent research efforts have focused on enhancing ChatGPT's performance in this domain [6,22], typically using varied prompting strategies such as the formulation of precise inquiries and the provision of relevant contextual information.

Objectives

Building on these foundational works, we aimed to evaluate the use of LLM-based chatbots to aid in automated diagnostics for neuropsychiatric conditions using assessment scales. We evaluated two paradigms: (1) directly deriving diagnoses from textual data and (2) chatbot-generated code executed in a local environment for diagnostic classification. As an attempt to reach clinical relevance, we instructed the chatbots to either provide ratings on standardized clinical assessment scales which were then used to derive a final diagnosis or to incorporate these ratings into their diagnostic decision making. This approach aimed to leverage established clinical approaches to diagnosis while harnessing the analytical capabilities of LLMs. We hypothesized that offering this clinically grounded method for automated diagnosis would lead to improved diagnostic performance.



Methods

Overview

We implemented 4 distinct methodologies to evaluate the diagnostic capabilities of the chatbots (Figure 1). In the direct diagnosis approach without assessment scales, we directly input data into the conversational artificial intelligence (AI) model, which then generated classification results. This process involved providing the chatbot with the processed dataset as input data and defining its primary task as providing neurobehavioral classification results for the condition of interest. We instructed the chatbot to derive diagnostic classifications for all participants using the text data from the entire processed dataset. If the chatbot indicated an inability to perform this task and requested to run in our environment, we directed it to use its pretrained knowledge to complete the task (see Multimedia Appendix 1 for the detailed prompts of each condition).

XSL•FO
RenderX

Figure 1. The 4 methods we explored in this study. The top 2 panels illustrate the direct diagnosis approach with and without the use of assessment scales, which require the chatbots to directly provide predictions or ratings on assessment scales. The bottom 2 panels, consisting of the code generation approach with and without assessment scales, require the chatbots to generate code that is subsequently executed in a Python environment.

The direct diagnosis approach using assessment scales involved inputting both data and a clinical assessment scale into the model; the model was subsequently tasked with rating items on the scale and providing these ratings as output. We then applied predefined thresholds from the clinical assessment scales to each data subject's ratings to derive final neurobehavioral diagnoses.

For both direct diagnosis conditions, we performed zero-shot classification without conducting training and testing splits, as we aimed to evaluate the models' ability to generalize from their pretrained knowledge. This process was repeated 5 times for each condition, with results averaged across iterations to improve robustness.

In addition to direct diagnosis, we explored a code generation approach to determine whether LLM-based chatbots could perform automated neurobehavioral classification by externalizing their reasoning into executable models. The motivation for the code generation condition stemmed from the observation that LLMs such as ChatGPT often struggle with directly solving complex reasoning tasks (at the time of our experiments) but can excel at generating code that reliably solves these problems. A notable example is that while ChatGPT frequently fails to correctly solve math puzzles through direct reasoning, it can generate Python code that solves them efficiently when executed. Recent studies have examined this phenomenon, revealing that LLMs perform poorly on complex logic-based tasks when relying solely on their internal reasoning capabilities yet demonstrate improved performance when prompted to generate code that encodes the required logic [24,25]. This suggests that the reasoning and structure embedded in generated code may enable LLMs to circumvent some of the limitations they face during direct response generation. While the diagnostic processes under the code generation condition

XSL•FO
RenderX

differed fundamentally from those under the direct diagnosis condition, they offer a complementary perspective on the models' capabilities. Notably, the chatbots frequently produced executable code—even without explicit prompting—in our early pilot tests.

In the code generation approach without assessment scales, which served as a control condition, we fed the processed data as input into the conversational AI model. Following the data review, we instructed the chatbot to select what it deemed the most appropriate algorithm for the task and output the corresponding Python code. This code was subsequently executed in an external Python environment (Python Software Foundation). We tasked the chatbot with conducting stratified 5-fold cross-validation on the dataset, reporting F_1-score, specificity, sensitivity, and accuracy as performance metrics. To optimize results, we engaged in an iterative process with the chatbot, requesting performance improvements until the generated code produced results consistent with its previous 2 iterations.

The code generation approach using assessment scales began with providing the chatbot with the processed data as input followed by a standardized assessment scale. We then prompted the model to generate the code and apply established cutoff thresholds from these scales as output to determine the final diagnosis. However, observing that this often resulted in unsatisfactory classifications, we next encouraged the chatbots to incorporate these ratings into an ML algorithm of their own design. The chatbots produced the algorithm, which we then ran in our local environment. If no further performance improvements from the condition without assessment scales were observed, we directed the chatbot to revert to the algorithm used in the condition without the assessment scale and integrate the assessment scale ratings into the training procedures. This methodology facilitated a direct comparison of performance between 2 code generation approaches, making any potential improvements attributable to the assessment scale approach. (see Multimedia Appendix 2 for an example of generated code).

Table 1 shows the final algorithm used in each code generation condition. We ensured that the chatbots incorporated the assessment scale ratings into their algorithms, requesting integration if they were initially omitted. The iterative process for each condition continued until the performance of the generated code reached a plateau with no significant improvement observed over 2 consecutive iterations.

Table 1. Machine learning algorithms produced by the chatbots in the 2 code generation conditions.

Approach	Algorithms		
	AphasiaBank	ASDBank	DAIC-WOZ[a] database
Code generation—no assessment scale			
GPT-4	TF-IDF[b]+LR[c]	TF-IDF+LR	CountVectorizer+LR
GPT-4o	Word Count	CountVectorizer+LR	TF-IDF+XGB[d] classifier
Claude 3.5	Word Count	TF-IDF+LR	TF-IDF+LR
GPT-o3	TF-IDF+LR	TF-IDF+LR	TF-IDF+LinearSVC
Gemini 2.5 Pro	TF-IDF+LR	TF-IDF+LinearSVC	Sentence embedding+LinearSVC
Code generation—assessment scale			
GPT-4	TF-IDF+LR	TF-IDF+LR	CountVectorizer+LR
GPT-4o	Word Count+LR	CountVectorizer+LR	TF-IDF+XGB classifier
Claude 3.5	Word Count+threshold	TF-IDF+RF[e]	TF-IDF+LR
GPT-o3	TF-IDF+LR	TF-IDF+LR	TF-IDF+LinearSVC
Gemini 2.5 Pro	TF-IDF+LR	—[f]	Sentence embedding+LinearSVC

[a]DAIC-WOZ: Distress Analysis Interview Corpus-Wizard-of-Oz.

[b]TF-IDF: term frequency–inverse document frequency.

[c]LR: logistic regression.

[d]XGB: extreme gradient boosting.

[e]RF: random forest.

[f]Not applicable.

To assess statistical significance, we conducted 1000-fold permutation tests on the F_1-score and accuracy to compare (1) direct diagnosis and code generation in non–assessment scale setups and (2) non–assessment scale and assessment scale setups. For comparisons between direct diagnosis and code generation, we aligned predictions by matching test sets across folds, comparing the performance on the same data points in both conditions and averaging the results across folds. For the checklist comparison, we ran permutation tests over all predictions from the respective conditions, also averaging across folds. Comparisons were omitted in cases in which the prediction patterns were apparently random or when performance in the latter condition was lower than in the former

(ie, assessment scale<non–assessment scale or code generation<direct diagnosis).

Datasets

We used 3 distinct databases, each focusing on a specific neurobehavioral condition. Two of these, ASDBank [26] and AphasiaBank [27], are sourced from TalkBank [28] and contain language samples for autism spectrum disorder (ASD) and aphasia, respectively, whereas the third database, the Distress Analysis Interview Corpus-Wizard-of-Oz (DAIC-WOZ) database [29], contains textual data from patients with depression, anxiety, and posttraumatic stress disorder.

AphasiaBank [27] is a repository containing multimedia language samples from both participants with aphasia and control participants. These samples were collected through standardized discourse tasks, including unstructured speech samples, picture descriptions, story narratives, and procedural discourse.

ASDBank [26] comprises a collection of language samples and interactions from individuals diagnosed with ASD. The data within ASDBank include transcribed audio and video recordings of clinical interviews and naturalistic interactions.

We used all available English-language transcripts from both AphasiaBank and ASDBank. Data processing was performed to consolidate all samples from a single participant into 1 data point. The resulting dataset comprised 715 aphasia data points and 352 control data points for AphasiaBank and 34 ASD data points and 44 control data points for ASDBank.

The DAIC-WOZ database [29] consists of semistructured interviews conducted by a simulated agent designed to identify symptoms of depression and posttraumatic stress disorder. These interviews include questions about personal experiences, quality of life, and emotions. We consolidated all samples from a participant, including the interviewer's input, into a single data point. The DAIC-WOZ database includes 56 patient data points and 133 control data points.

Table 2 provides a summary of the diagnosis distribution across each dataset.

Table 2. The number of control and patient data points in each of the datasets we evaluated.

Database	Number of control data points	Number of data points for condition of interest
AphasiaBank	352	715
ASDBank	44	34
DAIC-WOZ[a]	133	56

[a]DAIC-WOZ: Distress Analysis Interview Corpus-Wizard-of-Oz.

Aphasia, depression, and ASD each manifest distinct linguistic characteristics that are both overlapping and unique. Aphasia, typically resulting from brain damage, is characterized by impaired language production and comprehension, often including repetitive language and the frequent use of filler words as individuals struggle to retrieve or organize words effectively [30]. Depression, while primarily a mood disorder, affects language through reduced verbal output, monotone speech, and a preference for negative or self-critical language patterns. Depressive language, such as expressions of negativity, can be a key symptom of the condition. Another characteristic linguistic feature is an excessive number of sighs, reflecting physical or emotional fatigue. ASD is marked by unique communication challenges, including delayed speech development, echolalia (repetition of phrases), difficulty with pragmatic language (eg, understanding sarcasm or social cues), and overly literal or formal speech. Individuals with ASD may also exhibit fragmented sentences and frequent use of filler words, reflecting challenges in organizing thoughts or navigating social interactions [31].

Many previous studies have leveraged the datasets we used in our research. However, much of the existing work has focused on advanced tasks such as multimodal detection or severity classification rather than simpler text-based binary classification using chatbots. These studies have often achieved strong (although not clinically translatable) performances, frequently exceeding 80% in F_1-scores or accuracy. For example, Dinkel et al [32] applied a text-based multitask network to the DAIC-WOZ dataset, achieving an F_1-score of 0.84 for binary detection. Similarly, Agrawal and Mishra [33] used a fused bidirectional encoder representation from transformers–a bidirectional long short-term memory model integrated with Extreme Gradient Boosting to perform binary classification, achieving an F_1-score of 91%.

For the AphasiaBank dataset, most previous studies have focused on severity classification, making direct comparisons with our binary classification study challenging. The only relevant work, conducted by Cong et al [34], found that using LLM-derived surprisal features facilitated detection, achieving 79% in both accuracy and F_1-score. Similarly, studies involving the ASDBank dataset are limited, partly due to its recent development. Chu et al [35] included another dataset, the Child Language Data Exchange System, as a source of healthy control data. By extracting a few linguistic features from these 2 datasets, their binary classification approaches reached an F_1-scores of over 80% [35].

These studies suggest that LLM-based models directly diagnosing from the datasets used in this study should achieve high performance if chatbots exhibit comparable classification capabilities to those models in the previous studies.

Models

We evaluated 2 approaches using 3 types of state-of-the-art conversational AI models: ChatGPT with GPT-4, ChatGPT with GPT-4o, and ChatGPT with GPT-o3 (OpenAI); Gemini

XSL•FO
RenderX

2.5 Pro (Google AI); and Claude 3.5 Sonnet (Anthropic). These models were selected because they are some of the most widely used modern LLMs and because their efficacy in neurobehavioral classification tasks remains underexamined in the current literature. Notably, models such as Gemini 2.5 Pro and ChatGPT with GPT-o3 incorporate built-in prompting strategies such as chain-of-thought reasoning, allowing us to examine how such strategies influence performance. We excluded open models such as Llama because they do not support file input and including them would require a different approach from that used for the other models we tested.

Assessment Scales

We incorporated 3 widely recognized assessment scales and checklists used in clinical settings. We selected scales that assess behaviors at least tangentially related to language and that do not require extended observation periods. For example, the Autism Spectrum Quotient evaluates traits such as social preferences ("S/he prefers to do things with others rather than on her/his own"), behavioral patterns ("S/he prefers to do things the same way over and over again"), and attention capabilities ("have difficulty sustaining attention in tasks or fun activities"). The rating system for this checklist—*definitely disagree*, *slightly disagree*, *slightly agree*, and *definitely agree*—does not necessitate longitudinal observation, unlike scales that use time-sensitive ratings such as *rarely*, *less often*, *very often*, and *always*.

The assessment scales and checklists included in our study were as follows: (1) the fluency test in the Western Aphasia Battery–Aphasia Quotient (AphasiaBank) [36], (2) the Autism Spectrum Quotient (ASDBank) [37], and (3) Burn's Depression Checklist [38] (DAIC-WOZ database).

In the 2 direct diagnosis conditions, we conducted the experimental procedure 5 times and obtained results based on the entirety of each dataset. We did not perform a training and testing split for these conditions, opting instead for a zero-shot classification approach to assess the models' ability to generalize from their pretrained knowledge. However, in the code generation conditions, we instructed the chatbot to perform stratified 5-fold cross-validation on the entire dataset. The training and testing split ratio during each fold was 4:1. Results were evaluated based on the test sets generated during each fold and subsequently averaged.

Ethical Considerations

This study did not involve the recruitment of human participants or the collection of new data. All analyses were conducted on publicly available, deidentified datasets—AphasiaBank, the DAIC-WOZ database, and ASDBank—that are widely used in research and do not contain personally identifiable information. As such, no application for ethics review was submitted. This approach is consistent with institutional and regional guidelines that exempt studies using publicly available, deidentified data from human subjects review.

Results

Core Results

Tables 3 to 8 present the cross-validation results of the 2 approaches applied to each dataset, reporting accuracy, F_1-score, specificity, and sensitivity. Performance under the direct diagnosis conditions varied across datasets.

Table 3. Results of 4 approaches on the AphasiaBank dataset in the direct diagnosis condition.

	Accuracy	F_1-score	Specificity	Sensitivity
Results from Cong et al [34]	0.79	0.79	—[a]	0.79

[a]$P<.001$ for GPT-4 accuracy; $P<.001$ for GPT-4 F_1-score; $P<.001$ for GPT-4o accuracy; $P<.001$ for GPT-4o F_1-score; $P<.001$ for GPT-o3 accuracy; $P<.001$ for GPT-o3 F_1-score (direct diagnosis versus code generation in non–assessment scale setups when marked in the "No assessment scale" section)

[b]No test conducted.

[c]$P=.80$, $P=.60$ for GPT-4 accuracy and F_1-score; $P=.30$, $P=.20$ for Claude 3.5 accuracy and F_1-score (assessment vs non-assessment).

Tables 3 and 4 [34] compare approaches on the AphasiaBank dataset against a baseline performance of 79% across metrics in the study by Cong et al [34]. All of our direct diagnosis conditions yielded a lower performance than this baseline. Our code generation conditions improved results significantly, with ChatGPT with GPT-o3 achieving the highest F_1-score (0.865) and balanced specificity (0.92) and sensitivity (0.793), surpassing the baseline by Cong et al [34].

The results on the ASDBank dataset were compared against the baseline results from Chu et al [35], who achieved an F_1-score of 0.85 and a high sensitivity of 0.94, although specificity was notably low at 0.2. Our direct diagnosis approaches struggled in comparison, with ChatGPT with GPT-4 and ChatGPT with GPT-o3 producing lower F_1-scores (0.598 and 0.575, respectively) and poor specificity. The code generation condition significantly improved overall performance, with Claude 3.5 achieving the highest accuracy (0.68) and F_1-score (0.6). The other models also showed improvement, but their performance on specificity and sensitivity was less consistent. Gemini 2.5 Pro was unable to provide ratings on the checklist due to content restrictions related to ethical guidelines.

For the DAIC-WOZ dataset, the studies by Dinkel et al [32] and Agrawal and Mishra [33] established strong baselines, achieving F_1-scores of 0.84 and 0.91, respectively, along with high accuracy and sensitivity. In comparison, our direct diagnosis approaches showed inconsistent performance, with ChatGPT with GPT-4o and ChatGPT with GPT-4 achieving the highest accuracy (0.623) and F_1-score (0.452)—notably low values—with even poorer results on the other metrics. While the code generation approaches yielded higher accuracy in some cases, they did not meaningfully improve overall performance as their F_1-scores were significantly lower than those of the direct diagnosis condition.

We also note that most comparisons between assessment scale and no assessment scale conditions did not yield statistically significant differences except for ChatGPT with GPT-o3 and Gemini 2.5 Pro in the AphasiaBank direct diagnosis condition, which showed significant improvements in both accuracy and F_1-score.

Overall, our findings reveal a substantial gap when using the 2 different approaches: code generation and direct diagnosis. While code generation and newer models seem to have improved performance compared to direct prompting, they still did not reach the levels reported in previous studies in most cases. Both approaches fell short of established benchmarks, underscoring the limitations of current LLM-based diagnostic methods that rely solely on prompting without model fine-tuning.

Error Analysis

Overview

We first address the errors in the direct diagnosis approach, which did not appear to work well. We observed that most rounds of classification yielded close-to-random performances, especially for older models (ChatGPT with GPT-4 and ChatGPT with GPT-4o). Interestingly, we noticed patterns in the classification ratings produced, such as digits limited to only multiples of 3 or repeating sequences (eg, 3, 2, 1, 0, 3, 2, 1, 0). We present the percentage of rounds over 5 rounds of classification that followed such patterns in Table 9. This demonstrates that a direct diagnosis prompting strategy does not work well if models are presented with the entire dataset at once.

[a]Not applicable.

[b]DAIC-WOZ: Distress Analysis Interview Corpus-Wizard-of-Oz.

For the code generation approach, we found some examples of text archetypes (ie, typical examples) that were frequently misclassified. These archetypes often reflect characteristics of the conditions. Common errors we observed are described in the following sections.

Repetitive Language and Filler Words (Aphasia)

The presence of repetitive language patterns and an increased frequency of filler words led to misclassification as a high proportion of false positives for aphasia. Control participants' responses typically exhibited minimal repetition and filler word use. However, even a slight elevation in these linguistic elements frequently resulted in misclassification, with the chatbots erroneously classifying control participants as positives. Notably, misclassified false positives from almost all the chatbots contained these features.

Fragmented Sentences and Filler Words (ASD)

Transcripts containing filler words or fragmented sentences were misclassified in almost 100% of cases as false positives originating from individuals with ASD. With generative pretrained transformer models, this archetype was observed in most false-positive data points, indicating a consistent misclassification pattern. In contrast, Claude 3.5 exhibited a different trend because most misclassified points were false negatives. Claude 3.5 did not appear to excessively use the linguistic feature characteristic of this archetype.

Lack of Depressive Language (Depression)

Text lacking overt depressive indicators and conveying generally positive sentiments accounted for a large amount of false negatives. For instance, statements such as "uh I'd say maybe the fact that it's a lot different than it was about ten years ago" and "I am pretty happy with the level of education I've gotten" often led to false negatives.

Excessive Amount of Laughter (Depression)

Texts containing instances of laughter were classified as false negatives in >70% of cases originating from control participants rather than individuals with depression.

Excessive Number of Sighs (Depression)

Texts containing references to sighing were categorized as false positives originating from individuals with depression. Over 30% of false-positive cases included this feature, indicating its disproportionate influence on the classification process.

Frequency of Occurrence of Archetypes

Table 10 details the frequency of occurrence of these archetypes. The observed misclassifications highlight the inherent constraints of relying on text-based methods for neurobehavioral diagnosis.

Discussion

Principal Findings

This study reveals the limitations of using LLMs for automated neurobehavioral classification. In both direct diagnosis conditions, we encountered significant limitations with these models, which tended to generate random or close-to-random predictions. The models occasionally refused to offer diagnoses, and when compelled to complete the tasks, the resulting classifications were not accurate. These challenges were even more pronounced with Claude 3.5 and Gemini 2.5 Pro, with which we faced difficulties generating any classification results or ratings in some conditions. The inclusion of assessment scales did not substantially improve performance as the ratings on scale items also appeared to be randomly assigned in most situations. Notably, in many of these conditions, we observed a concerning trend in which assessment scale ratings were often identical across participants regardless of individual differences in their text data.

It is important to note that previous studies have successfully achieved F_1-scores of 70% to 80% using subsets of the ASDBank dataset and high performance (F_1-scores of 80%-90%) using various methods on at least portions of the other 2 datasets [32-35]. In contrast, our results indicate that most direct diagnosis approaches and the code generated by these models were not able to attain similar results to those of previous studies. This discrepancy suggests a gap between the performance that ML models can potentially achieve and the outcomes observed in our study. This may be due to our relatively straightforward methodological approach.

Regarding the code generation condition, our findings suggest that LLM-generated ML pipelines show promising potential for improving diagnostic performance. Notably, on the AphasiaBank dataset, ChatGPT with GPT-o3 produced code that outperformed results reported in previous studies, although the choice of learning algorithms sometimes varied across conditions and lacked a clear rationale.

In the code generation condition using assessment scales, we observed that the code from the chatbots did not apply diagnostic thresholds as defined by the assessment scales but, instead, directly incorporated the ratings as ML features. The rating methods were simplistic, and the chatbots frequently implemented a keyword-counting algorithm to provide ratings for ASDBank and DAIC-WOZ. These ratings were then concatenated with features extracted from the feature extractor. This direct concatenation of features without sophisticated integration of diagnostic logic may explain why the assessment scale conditions did not lead to improved performance. More effective integration of these ratings in the generated code may help enhance future model performance.

We also observed that models with built-in chain-of-thought reasoning capabilities such as ChatGPT with GPT-o3 and Gemini 2.5 Pro exhibited improved performance under certain conditions. For instance, in the code generation tasks on the AphasiaBank dataset, these chain-of-thought models consistently outperformed others. Permutation tests conducted on the test sets across 5 cross-validation folds revealed statistically significant differences between models that used chain-of-thought reasoning and those that did not (ChatGPT with GPT-4 vs Gemini 2.5 Pro: accuracy $P=.01$, F_1-score $P=.03$; ChatGPT with GPT-4 vs ChatGPT with GPT-o3: accuracy $P<.001$, F_1-score $P<.001$; ChatGPT with GPT-4o vs Gemini

XSL•FO
RenderX

2.5 Pro: accuracy P=.01, F_1-score P=.002; ChatGPT with GPT-4o vs ChatGPT with GPT-o3: accuracy P<.001, F_1-score P<.001). While this improvement was not observed across all datasets (ie, DAIC-WOZ and ASDBank), the integration of structured prompting strategies appears to be a promising direction for future research.

In previous studies, human-in-the-loop processes have demonstrated promise for diagnostic classification tasks [39,40]. However, in such approaches, the human must remain more involved in the computational diagnosis procedure than simply prompting the LLM to generate a direct diagnosis, clinical rating, or classification code. In prior work for autism diagnostics, for example, humans have extracted the behavioral features—a task that requires the ability to interpret relatively subjective human behavior—leaving the ML models to perform the simpler task of the final classification given the human-derived features [41,42]. It is likely that humans performing at least some level of analysis of the data will need to continue to achieve clinically useful performance, and future prompt engineering approaches should explore these ideas more thoroughly.

Limitations

We acknowledge several limitations of this study beyond the observed performance gaps.

First, the scope of our investigation was limited to 3 datasets, each representing a distinct neurobehavioral condition with relatively small sample sizes. This may constrain both the robustness and generalizability of our findings, as well as the models' capacity to learn effectively.

Second, another limitation lies in the selection and applicability of the clinical checklists used in the assessment scale approach. In many cases, the patient transcripts lacked sufficient information to reliably rate all items on the scales, potentially resulting in random or invalid scores. Future work may consider using longer or more comprehensive patient transcripts or choosing assessment tools that are more tolerant of limited inputs.

Third, additional prompting strategies warrant exploration. While we observed performance gains from models that incorporated chain-of-thought reasoning by default, other prompting techniques may also enhance diagnostic accuracy.

Finally, all input data were presented to the models at once in a single file. This may have hindered their ability to process the content effectively. Presenting the data incrementally one instance at a time could reduce noise and improve prediction consistency.

Conclusions

This study demonstrates that popular LLM-based chatbots remain inadequate for classifying neurobehavioral conditions from text transcripts even when prompted to incorporate clinical assessment scales into their evaluation strategy. We recommend that future research further investigate the limitations identified in this study and examine whether incorporating structured tools—such as assessment scales—can serve as a viable method to improve diagnostic accuracy for neurobehavioral conditions when using more sophisticated prompting strategies.

Acknowledgments

The authors gratefully acknowledge the grant support for the AphasiaBank project from the National Institutes of Health National Institute on Deafness and Other Communication Disorders (grant R01-DC008524; 2022-2027). The authors appreciate the permission to use ASDBank and the DAIC-WOZ database. In addition, the authors recognize the contributions of the ChatGPT (OpenAI) and Claude (Anthropic) large language models in editing the grammar and phrasing of the manuscript and generating some of the icons used in the figures, although the authors have further edited the outputs of these models. We also thank the Institute of Linguistics, Academia Sinica, for providing the research environment and for supporting the publication of this work.

Data Availability

The datasets analyzed during this study are available in the AphasiaBank [27], ASDBank [26], and DAIC-WOZ [29] repositories.

Authors' Contributions

In addition to PW, KL also serves as a corresponding author (limkhaiin@as.edu.tw).

Abstract

Background: The introduction of artificial intelligence (AI) in health care holds great promise, offering the potential to alleviate physicians' workloads and allocate more time for patient interactions. After the emergence of large language models (LLMs), interest in AI has surged in the health care sector, including within primary care. However, patients have expressed concerns about the ethical implications and use of AI in primary care. Understanding patients' perspectives on using AI in primary care is crucial for its effective integration. Despite this, few studies have addressed patients' perspectives on using AI in primary care.

Objective: This study aimed to synthesize qualitative research on primary care patients' perspectives regarding the use of AI, including LLMs, in primary care.

Methods: A qualitative systematic review, using thematic analysis, was performed in accordance with PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines. Databases, including PubMed, Scopus, Web of Science, CINAHL, and PsycINFO, were searched from inception to February 5, 2024. Eligible studies (1) used a qualitative interview research design, (2) explored primary care patients' perspectives on the use of AI in primary care, (3) were written in English, and (4) were published in peer-reviewed scientific journals. Quantitative studies, gray literature, surveys, and studies lacking depth in qualitative analysis were excluded. The Critical Appraisal Skills Program (CASP) checklist was used for quality assessment.

Results: Of 1004 studies screened, 6 were included, comprising 170 patients aged 13-91 years from 3 countries. Three themes emerged: "The Relationship with and Actions of AI Systems," "Implementing AI responsibly," and "Training Physicians and Artificial Minds." Patients acknowledged AI's potential benefits but advocated for clinician oversight, safety frameworks, and the preservation of patient autonomy.

Conclusions: This systematic review provides an understanding of patients' perspectives on AI in primary care. We identified heterogeneity in AI definitions across studies. Further research is needed on patients' perspectives across different countries. Notably, our synthesis revealed a significant research gap, as none of the included studies particularly explored patients' perspectives on LLMs, highlighting an important area for future research.

KEYWORDS

artificial intelligence; large language models; natural language processing; generative AI; machine learning; primary health care; patient perspectives; systematic review; qualitative meta-synthesis

Introduction

Background

The health care sector is facing challenges, with high administrative workloads and patients growing older and becoming more vulnerable. Primary care, often the first point of contact with health care, is especially vulnerable to these challenges [1]. Introducing artificial intelligence (AI) in primary care is suggested to free up time for patient contact and prevent physician burnout through the automation of administrative tasks [2,3].

Today, AI-assisted tools are widely used in various clinical settings and can successfully help predict mortality risks [4], improve therapy, and assist diagnosis [5]. Algorithms that are being used are already outperforming clinicians in spotting malignant tumors [6-9]. AI solutions are predominantly implemented in referral care settings, with limited use in primary care [10]. The most common AI applications in primary care include diagnostic decision support, treatment decision support, and data extraction [10].

Introducing AI in health care, however, is not without risks. Discrimination through biased training data, uncertainty regarding the division of moral and legal responsibilities, and questions of integrity and privacy are all concerns that may limit the implementation of AI in health care [10,11]. In addition, implementing AI in health care brings ethical obligations, as it both directly and indirectly impacts patient care [12].

Patient engagement is increasingly being recognized as vital to health care delivery, improving outcomes, safety, and reducing hospital admissions and costs [13]. Impactful organizations, including the World Health Organization (WHO) and the Organization for Economic Co-operation and Development (OECD), have identified patients as one of the main stakeholders in the development and assessment of medical AI applications [14,15]. For AI implementation to be successful, it is essential to consider the needs and perspectives of the end users. While studies have been conducted on clinicians' perspectives of AI in primary care [16-26], few studies exist on primary care patients' perspectives on AI [27-30].

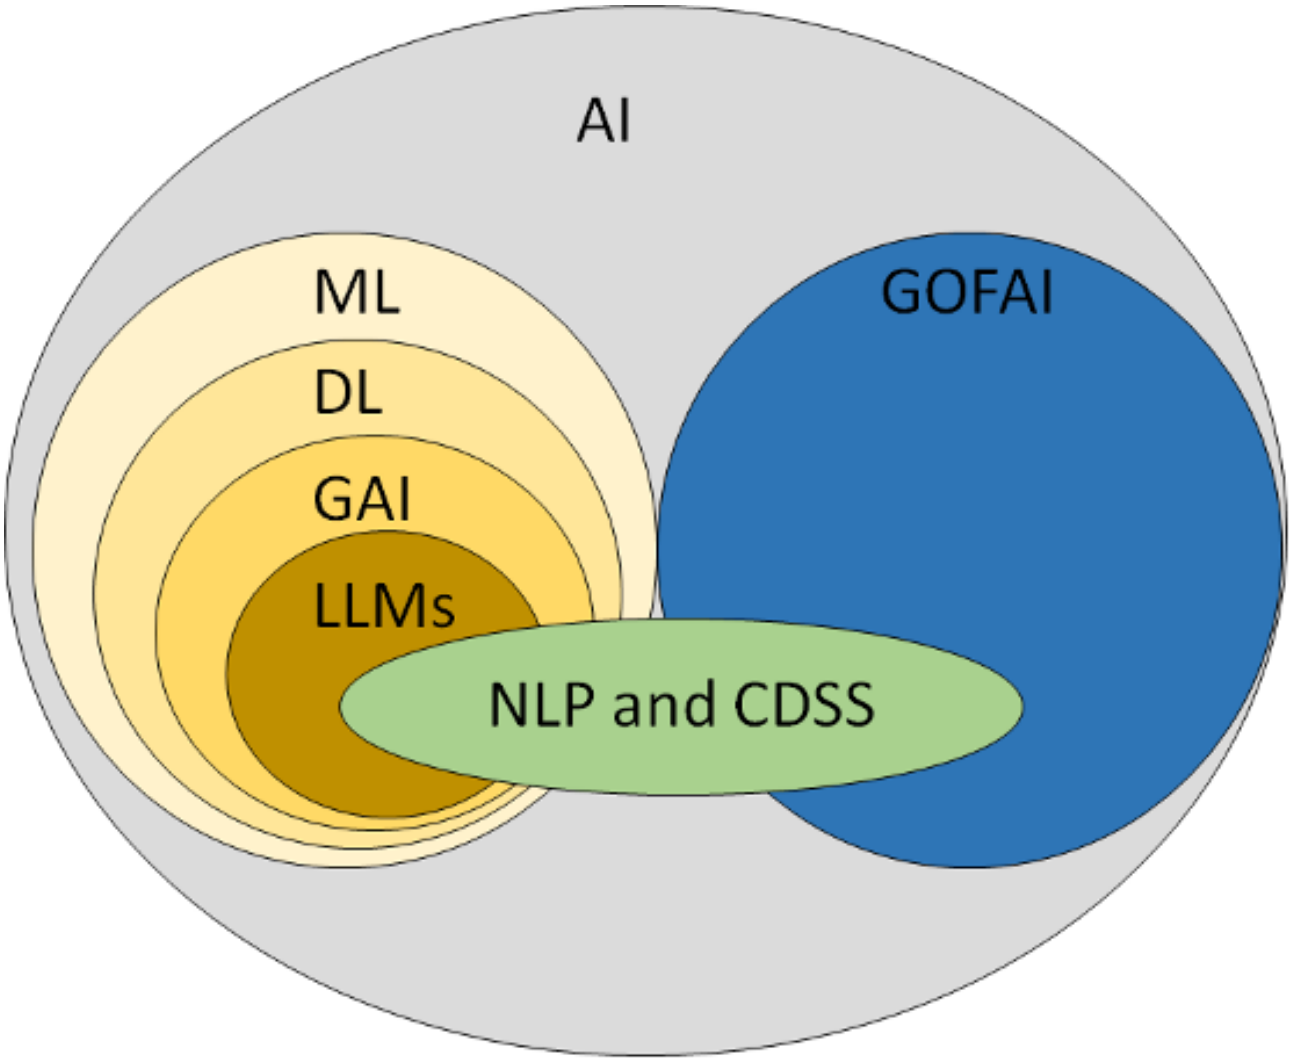
The emergence of large language models (LLMs) has significantly advanced the capabilities of AI systems, particularly in their ability to interpret and generate human language [31]. These models, such as ChatGPT (OpenAI), are built on deep learning (DL) and natural language processing (NLP) [31], and their conversational interfaces introduce new challenges and opportunities in health care [32,33]. In primary care, where the patient-doctor consultation is central, the integration of LLMs may influence communication, decision-making, and the overall care experience [34]. As LLMs become increasingly integrated into health care systems, it is important to consider how patients perceive and interact with these technologies. Understanding patients' perspectives on AI, including emerging forms, such as LLMs, is essential for responsible and effective implementation.

To our knowledge, this is the first qualitative meta-synthesis aiming to target primary care patient perspectives on AI and LLMs in primary care.

Aim

The primary objective of this qualitative meta-synthesis is to synthesize the current qualitative research on primary care patients' perspectives on the use of all types of AI, including the use of LLMs, in primary care.

Methods



AI Definitions

AI encompasses a diverse array of technologies rather than being just a single innovation [6]. The challenge in defining AI technology stems from the lack of a clear, consensus-driven definition. The types of technology associated with the term AI appear to shift over time, creating difficulties in capturing patients' perspectives [35]. One influential definition has been presented by the OECD: "An AI system is a machine-based system that, for explicit or implicit objectives, infers, from the input it receives, how to generate outputs, such as predictions, content, recommendations, or decisions that can influence physical or virtual environments. Different AI systems vary in their levels of autonomy and adaptiveness after deployment" [36].

The increasing integration of AI in health care has introduced various systems and models with overlapping and complex characteristics, as presented in Figure 1. To give context to the different types of AI technologies that may be relevant in primary care, we include short descriptions of key concepts, such as machine learning (ML), DL, NLP, LLMs, and clinical decision support systems (CDSS). These definitions are included to help the reader understand how patients might relate to different AI systems and to reflect how the field of AI is developing in health care. ML uses algorithms to learn patterns, and by training on large datasets, it can make predictions based on the training data. DL, a complex form of ML, can predict outcomes based on many different variables. NLP, based on ML (mostly DL), recognizes and analyzes texts and speech [6]. NLP allows computers to interpret and generate human language [37]. LLMs involve the use of NLP and DL to interpret and generate human language based on the input they receive [31]. LLMs may serve as foundation models for developing more sophisticated AI applications, such as ChatGPT (OpenAI). Further technical details and definitions of AI are provided in Multimedia Appendix 1 [6,37-42].

Study Design

This review was prospectively registered with the International Prospective Register for Systematic Reviews (PROSPERO; CRD42024505209) [43] and is reported in accordance with PRISMA (Preferred Reporting Items for Systematic Reviews and Meta‐Analyses) statement [44]. A completed PRISMA checklist is provided in Checklist 1.

This review used a systematic review methodology for qualitative studies, where the authors conducted a secondary qualitative analysis of the published quotes and supplementary information from the reviewed studies, allowing for a deeper exploration of underlying patterns and themes.

Search Strategy

Searches for peer-reviewed literature were conducted in PubMed and Scopus, with the assistance of a research librarian and research colleagues. Broader terms for “primary health care” and “artificial intelligence” ensured an inclusive search string. In PubMed, the search incorporated MeSH (Medical Subject Headings) terms and Boolean operators. The finalized search string was registered in PROSPERO before conducting the final search on February 5, 2024. After feedback from reviewers, an extended search was conducted in Web of Science, CINAHL, and PsycINFO on July 10, 2025. To ensure a comprehensive review, the reference lists of eligible studies were also screened to identify any studies that may have been missed in our initial searches. The search strings are listed in Multimedia Appendix 2.

Study Selection

The initial search results were imported into Rayyan (Rayyan Systems Inc) software [45] for duplicate removal, with all duplicates being manually verified and excluded from the review. Two authors, A Mundzic and RB, evaluated the studies for inclusion, independently screened the studies based on titles and abstracts, and performed a full-text evaluation. Any discrepancies during the inclusion process, whether in the title and abstract screening or full-text evaluations, were resolved through discussion. In this review, 6 studies [1,2,12,17,46,47] were included, with 4 studies [1,12,46,47] exclusively focusing on patients’ perspectives and 2 studies [2,17], including both patients’ and clinicians’ perspectives. Clinicians’ opinions were excluded during coding.

XSL•FO
RenderX

Inclusion and Exclusion Criteria

Inclusion criteria were defined using the SPIDER (sample, phenomenon of interest, design, evaluation, research type) framework [48]. Studies were eligible if they (1) used a qualitative interview-based design, (2) were written in English, (3) were published in peer-reviewed scientific journals, (4) were conducted in a primary health care setting, and (5) focused on patients' perspectives on the use of AI in primary care. For this review, "conducted in a primary health care setting," was defined as studies in which participants were recruited through primary care, had documented contact with primary care, or where the study context explicitly involved primary care (eg, general practice and family medicine). Studies were excluded if they were quantitative, survey-based, gray literature, or lacked sufficient depth in qualitative analysis. Consequently, studies lacking patient quotations (eg, survey-only or author-summarized reports) were excluded for not providing sufficient insight into participants' experiences.

Data Extraction and Quality Assessment

A Mundzic extracted all data from the eligible studies within the results and supplementary information that contained opinions and direct quotations from patients. A summary of the characteristics of the included studies was compiled by A Mundzic, and the second author, RB, reviewed the table for accuracy. The following data were extracted: number of participants, interview dates, explanation of AI, type of AI in the study, and emerging themes. In case of missing information relating to the study objectives, the corresponding authors of the respective publications were contacted.

The methodological quality of the chosen studies was assessed using the Critical Appraisal Skills Program Qualitative Research Checklist (CASP) [49]. The authors A Mundzic and RB, independently conducted the quality appraisal, after which they compared their findings and sorted out any discrepancies by discussion. In cases of disagreement, a discussion was held, and if consensus could not be reached, a third researcher, AE, was consulted to finalize the rating as "YES," "NO" or "Can't tell." In cases where information was missing, the authors answered, "Can't tell." The CASP checklist is present as Checklist 2.

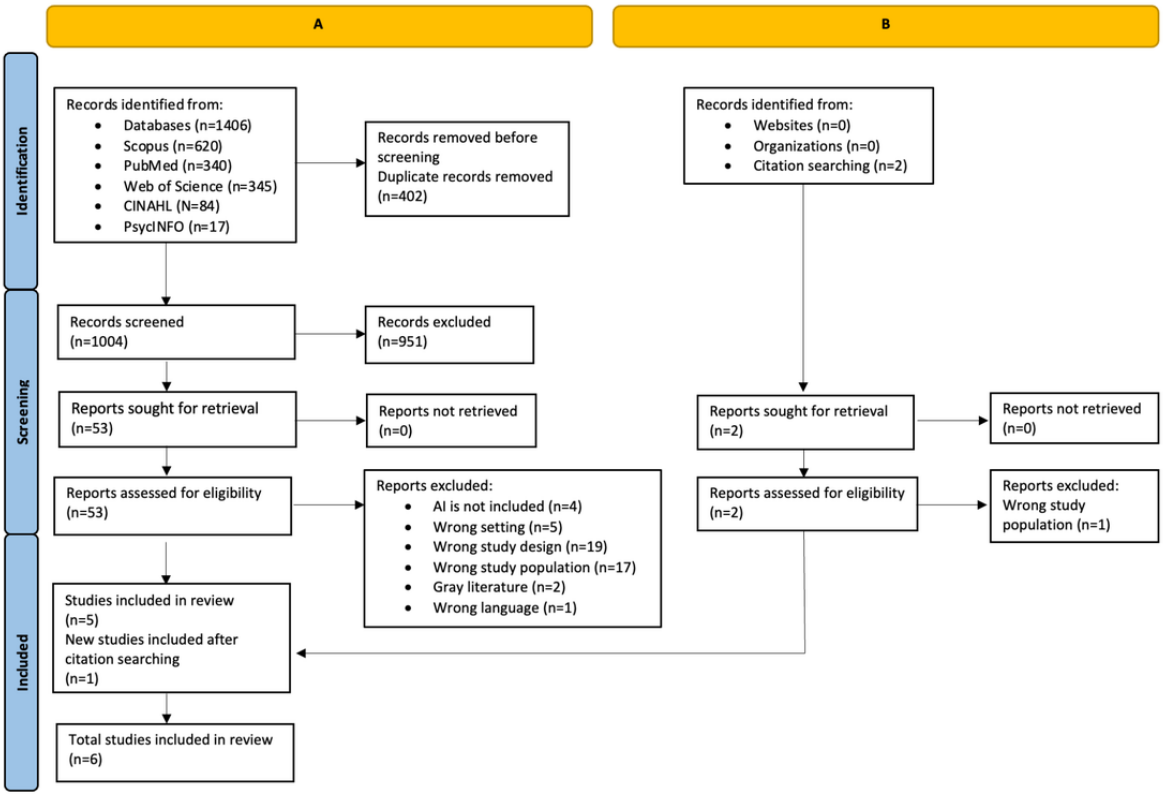
Data Analysis and Synthesis

Coding was performed in 2 steps. First, the 4 studies [1,12,46,47] focusing exclusively on patients' perspectives were coded. The remaining 2 studies [2,17], which included both patients' perspectives and clinicians' opinions, were coded separately. The emerging themes from these mixed studies were then compared to those from the studies focusing solely on patients to determine whether the presence of clinicians influenced the themes. No differences were found, and all the patients' perspectives are presented in this report.

The coding was conducted by A Mundzic, with RB double-checking the codes. Any discrepancies were resolved through discussion before proceeding. In cases of disagreement, a third researcher, AE, was consulted. Both authors independently grouped the codes and discussed emerging themes before finalizing them (see Multimedia Appendix 3 for the full codebook). NVivo 14 software (Lumivero) was used to generate initial codes, search for themes, and identify final themes. Thematic analysis was performed using an inductive approach, following Braun and Clarke's [50] 6-step method to identify latent themes. Inductive thematic analysis with a latent approach offers a flexible and in-depth data analysis [51]. Since patients' perspectives on AI in primary care are a relatively unexplored area of research [46], this method is suitable to answer the research question.

Ethical Considerations

Ethical approval is not required for this systematic review, as it is based solely on previously published studies. All included studies received ethical approval, except for the study conducted in Denmark, where ethical approval was deemed unnecessary according to Danish national regulations, as it involved self-reported data.



Results

Search Results and Selection

A total of 1406 records were retrieved from the electronic databases. After removing duplicates, 1004 studies remained for abstract and title screening. Following title and abstract screening, 53 full-text studies were screened, with 1 additional study identified from reference screening of the included studies. In this review, 6 studies [1,2,12,17,46,47] were included. Among them, 4 studies [1,12,46,47] exclusively focused on the patients' perspectives, and 2 studies [2,17] included the perspectives of patients, where clinicians' opinions were present. The process of the study selection is shown in Figure 2.

XSL•FO
RenderX

Figure 2. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart of study selection. AI: artificial intelligence. (A) Identification of studies via databases and registers. (B) Identification of studies via other methods.

Study Characteristics

The characteristics of the 6 included studies [1,2,12,17,46,47] are visualized in Table 1, and additional information is presented in Multimedia Appendix 4.

Four [12,17,46,47] of the included studies were conducted in the United States, and one each was conducted in Denmark [1] and Canada [2]. Two studies [12,46] were conducted by the same authors and appear to include the same participants but with different research questions. The ages of participants ranged from 13 to 91 years. Interviews were held between October 2019 and January 2022. The publication dates of the included studies ranged from September 21, 2021 to January 6, 2024. A total of 170 unique participants were included, excluding those who overlapped across studies.

The 6 included studies [1,2,12,17,46,47] had different approaches to how AI was defined to the participants. In 2 of the studies [12,46], participants were given a brief definition of AI and case studies focused on using AI for image analysis, optimizing preventative health, in-patient monitoring, diagnostic support, and engagement with patients during primary care appointments. In 1 study [1], participants had little knowledge about AI. Different scenarios were used to explore patients' opinions. In another study [47], questions were asked to explore participants' perspectives on teleophthalmology, AI-based image interpretation, and virtual care. In the study [47], teleophthalmology was implemented as a part of a federally qualified health center's primary care services, and the technology was used in routine diabetes care. The intervention was regarded as an extended service of general practice and therefore fell within the scope of the review. In the study by Davis et al [17], AI was described as integrating data from electronic health records and smartphones to predict suicide risk. In the last study [2], AI was described to participants as a technology that automates tasks typically requiring human intelligence, such as processing information, reasoning, learning, planning actions, and communicating in natural language, and presented as a general-purpose prediction technology that estimates missing information from available data.

[b]PCP: primary care physician.

Quality of Included Studies

Based on the quality assessment, all included studies were considered high quality, as they met most of the CASP criteria, with 1 study [47] fulfilling all the criteria. Many of the included studies [1,2,12,17,46] provided limited or no information regarding the CASP 6 item.

Main Findings

The thematic synthesis resulted in 3 main themes (Textbox 1): "The Relationship with and Actions of AI Systems," "Implementing AI Responsibly," and "Training Physicians and Artificial Minds."

XSL•FO
RenderX

Textbox 1. Analytical themes and descriptive themes.

The Relationship With and Actions of Artificial Intelligence (AI) Systems

- Accessibility
- Nonverbal communication
- The changing patient-physician relationship
- AI and clinician collaboration

Implementing AI Responsibly

- Data safety
- Data sharing
- Implementation of AI
- Regulations for AI

Training Physicians and Artificial Minds

- Bias
- Diversity in data
- Inaccurate data
- Reinforcing prejudice

Theme 1: The Relationship With and Actions of AI Systems

The included studies highlight patients' attitudes toward the changing patient-physician relationship, nonverbal communication, AI and clinician collaboration, accessibility, AI accuracy, efficiency, and priority applications of AI in primary care.

Many participants asserted the importance of an emotional connection with their physician [1,47], noting that body language helped them feel supported [2,47] and trust their physicians' advice more [47]. Concerns were raised about AI's assumed inability to perceive emotions, potentially affecting care quality when relying solely on nonemotional health data [2,47], highlighting physicians' unique ability to identify underlying issues that patients might not verbally express [47]. Some patients expressed that AI could enhance emotional comfort during times of difficult health challenges and contribute to acceptance [12].

Accessibility was a common concern [1,2,12,46,47]. Many patients considered AI to be beneficial in rural areas [12]. Patients expressed concerns regarding the accessibility of AI in health care, particularly for individuals with unique characteristics, such as those who use sign language, have strong accents, or have atypical sensory processing [12]. Some thought AI could increase health care costs [46], and overdiagnosis was mentioned as a reason [1].

Patients expressed trust in the health system and their physicians [1,12,47]. In 1 study [47], all participants said they would follow their physician's screening recommendations. Primary care physicians were considered authoritative figures [1], and many patients trusted them more than AI [2,47], citing a general distrust of technology and the belief that a trustful relationship isn't possible with a machine [47]. Patients believed physicians aimed to avoid mistakes that could harm their professional reputation [47]. However, concerns have been raised that health care providers might become overly dependent on AI [2,46], potentially replacing physicians and weakening the patient-physician relationship [1]. Another concern was that primary care physicians could shift from being health care providers to mere data collectors if AI gained too much influence [1].

Opinions on the accuracy of AI systems varied. Some noted that AI's access to vast medical data could enhance accuracy, stating that machines are more accurate than physicians [12,47], while others questioned its ability to understand nuanced symptoms [12]. Many patients doubted that AI could replace physicians, especially in decision-making, believing the patient-physician relationship is inherently human and essential to patient-centered care [2]. While some admitted AI's superior accuracy, they still preferred human involvement in treatment [47] and viewed AI as a helpful support tool [2,47].

Patients also discussed AI's capacity to manage large datasets and hoped it could use existing information effectively. They emphasized the importance of having as much data as possible when making decisions [12]. Suggested key AI applications in primary care included clinical documentation, practice operations, risk identification, and triage, with the potential to reduce administrative tasks and enhance physician efficiency [2].

Theme 2: Implementing AI Responsibly

Patients expressed opinions on regulations for AI, implementation of AI, data sharing, and data safety.

Participants called for AI regulations to prevent potential harm. Many patients viewed physicians as responsible for their care and preferred that physicians ensure the safety of AI. Patients wanted their physician to make treatment decisions and oversee

XSL•FO
RenderX

ongoing care [46]. Patients believed they should have the right to decide if AI tools are used in their care [1] but also to correct their recommendations if they believed them to be inaccurate [46]. Patients were uncomfortable relying entirely on AI-generated recommendations without the ability to independently assess the reasoning behind those suggestions [17,46]. While some opposed AI acting autonomously, others were open to it, provided their physician verified its recommendations [2,46].

An urge for carefulness was described when implementing AI in health care. According to patients, the AI tools should be well tested and accurate before being used [46]. Patients acknowledged that AI would not be acceptable to all [17], but that acceptance of new technology comes gradually [1,12].

Patients' views on health care and non-AI health technology were shaped by their social context, including identities, communities, and experiences with past illnesses. They supported AI if it aligned with medicine's goal of curing illnesses [12] and if the design, implementation, and use of AI should preserve or strengthen the patient-physician relationship [2].

Ethical concerns were raised, such as AI's ability to detect future illnesses, which could increase anxiety and hinder living in the present [1]. Other concerns involved the influence of business interests on the development of AI. One patient noted that health care systems have commercial interests, and companies seek to profit from their data [12]. Opinions on technological advancements were mixed, with some feeling it was beyond their control and a few expressing discomfort with technology, avoiding cell phones or the internet as long as possible [12].

Concerns about data safety included technological failures, hacking risks, and the possibility of data being reidentified after anonymization [46]. Patients identified factors that would make them more comfortable sharing data, including having unremarkable medical records, assurance of anonymization, and trusting their primary care physician as an authority. The purpose of data sharing was also important [1].

In one study [1], all patients expressed willingness to share data for AI implementation and the use of AI in general practice. However, sensitive data, such as mental illness or early retirement information, made them more skeptical about data sharing. Patients feared data misuse by insurance companies, potentially leading to monitoring or loss of liberty [8]. They desired transparency about what data were collected and wanted access to the data used for risk assessment [17].

Theme 3: Training Physicians and Artificial Minds

Perspectives on various aspects of training AI models, including bias, data diversity, risks of inaccurate data reinforcing prejudice, and the training of physicians in using AI, emerged among the included studies.

Patients expressed concerns about the risk of developers incorporating their biases into the datasets used to train AI [46]. Concerns were also raised that training AI with data that lacks diversity could harm certain social groups [12]. An example provided was when medical records contain errors, thereby creating a risk that AI might use incorrect information [46].

Participants acknowledged that implementing AI in health care could impact different populations unevenly, potentially reinforcing stigma or restricting access. Some shared instances where they or someone they knew faced discrimination due to mental illness, alcoholism, weight, or profession. They expressed ideas about AI exacerbating or alleviating these stigmas [12].

A fear was described, entailing that future generations of physicians might lack essential skills if AI applications or training fail to preserve the core competencies necessary for patient safety and patient-centered care. One patient wondered how AI would be monitored, how physicians would be trained, and how we would ensure that patients still benefit from experience and knowledge, rather than just dependency on AI [2].

Discussion

Principal Findings

This review presents newly emerged concepts derived from a synthesis of evidence across several studies, all using different approaches but set in a primary care context. The theme "The Relationship with and Actions of AI Systems" explored changes in the physician-patient relationship, nonverbal communication, AI-physician collaboration, accessibility, AI accuracy, efficiency, and key AI applications in primary care. Through the analysis, it became evident that patients are concerned about the prospect that AI might change the dynamics of the physician-patient relationship and that trusting AI is different from the trust placed in physicians. The part of trust placed in physicians is based on the emotional connection between patient and physician [1,2,47], but also on the knowledge that physicians have something to lose (ie, their professional reputation [47]. It is not obvious how this sense of trust nor the delegation of responsibility for one's health could be transferred from physician to AI systems, which is why this should be carefully considered by AI developers and health care organizations implementing AI into clinician workflows. Moreover, many patients expressed feeling supported by seeing their physicians' body language [2,47], something that may be hard to replicate using AI. Patients shared their views on AI regulations, implementation, data sharing, and data safety under the theme "Implementing AI Responsibly." This theme illustrates the varied views patients hold concerning the implementation of AI. Some patients reported that they considered it necessary for health care providers to inform them about the use of AI [1], which is not routinely done in current health care. For many years, physicians have received computationally automated decision support on a daily basis, such as when ordering an electrocardiogram for the analysis of heart-related conditions [52]. Consequently, physicians and health care providers should be aware of the discrepancy between current practice and patients' expectations and consider that patients' preferences may differ depending on their social context, identity, and lived experience [12]. The last theme, "Training Physicians and Artificial Minds," studies highlighted perspectives on training AI models, focusing on issues such as

XSL•FO
RenderX

bias, data diversity, the risk of inaccurate data reinforcing prejudice, and the training of clinicians in AI use. A knowledge gap was identified, as none of the included studies specifically addressed opinions on LLMs.

Comparison With Prior Work

Patients expressed trust in the current health care systems and valued their relationships with their physicians. Trust in physicians stemmed from their professional reputation and experience, qualities that patients felt a machine could not provide. Earlier studies have shown great trust in primary care physicians, aligning with our findings [53-58].

While AI as a diagnostic and decision support tool was well-accepted by patients, they strongly preferred that physicians be involved in the process. A similar sentiment was observed in a study representative of the Dutch population, where 78% of women did not fully support independent use of AI-based diagnostics in screening mammography without the involvement of a radiologist [59]. Another study found that patients preferred physicians over AI for all clinical tasks except for treatment planning based on current scientific evidence. When there was a disagreement between physicians and AI regarding diagnosis and treatment planning, most patients favored the physician's judgment. AI was considered more acceptable when supervised by a physician, especially in diagnosis, than when used independently [60].

Patients emphasized the importance of establishing an emotional bond with their physician, which made them feel recognized and supported, thus building trust and easing decisions about whether to trust their physician. However, concerns were raised about AI's inability to recognize emotions and how this limitation could impact care, especially when it depends solely on nonemotional health data. Concerns about the lack of human touch in AI have been mentioned in previous studies [61,62]. On the contrary, a study comparing physician and AI chatbot responses showed that chatbot responses were rated as more empathetic and of better quality than physician responses [63]. In this systematic review, we found that some participants viewed health care AI as a source of relief or hope in cases where a clear diagnosis has been elusive or where standard treatments have failed, a seemingly unique finding.

Patients were concerned that using flawed data for training AI systems could harm certain social groups and lead to unequal care. Evidence of racial bias has indeed been observed in previous studies. One such study found that, despite being assigned the same risk levels by an algorithm, Black patients were actually sicker than their White counterparts, a bias resulting in over half of Black participants being overlooked for additional care [64].

Our findings complement previous work, such as the scoping review by Moy et al [65], which broadly mapped patients' perspectives on AI across various health care settings and study designs. While their review provides a valuable overview, our meta-synthesis offers a more focused contribution by synthesizing qualitative interview studies conducted specifically in primary care. This narrower scope enabled a deeper exploration of context-specific themes and patient experiences within primary care. Furthermore, our synthesis identified a notable gap, where none of the included studies addressed LLMs, highlighting an area for future research as these technologies become increasingly integrated into primary care workflows.

Strengths

To our knowledge, this is the first qualitative meta-synthesis that synthesizes primary care patient perspectives on AI.

To ensure the study's quality, two authors independently handled the selection, quality assessment, and coding. Thematic analysis was conducted in such a way as to identify if nonpatient perspectives influenced the results.

During the inclusion and exclusion process, discussions emerged regarding the definitions of AI and how it was explained to patients in different studies. The varying definitions of AI presented challenges, as the authors' interpretations influenced the selection of studies and the summaries of the types of AI used. To maintain an inclusive approach, we aimed to include studies focusing on all types of AI. In some cases, studies addressed AI in health care more broadly. In these instances, inclusion was based on whether the recruitment and thematic framing were anchored in primary care. For example, studies that recruited patients following a recent primary care visit and analyzed their perspectives in that context were considered eligible. This approach ensured relevance to primary care while acknowledging the interdisciplinary nature of AI applications in health care.

Limitations

A major limitation of this review is that none of the included studies explicitly addressed primary care patients' views on LLMs, highlighting a gap in the current qualitative research on this highly relevant subject. Another limitation of this study is that the initial search included only 2 databases, PubMed and Scopus. These were selected based on the assumption that they would cover relevant literature within the study's scope. To ensure that no eligible studies were overlooked, we later conducted an expanded search on July 10, 2025, including Web of Science, CINAHL, and PsycINFO covering publications from inception up to February 5, 2024. The extended search did not identify any additional relevant studies, which supports the comprehensiveness of the original search strategy. The initial PRISMA flowchart of study selection is listed in Multimedia Appendix 5.

The definition of primary care varies globally. In Scandinavia, it primarily refers to appointments with general practitioners, while in the United States, it encompasses all non-emergency care. The results might have differed if more studies from general practice clinics were included. However, it is reasonable to assume that patients in general practice clinics share similar views about AI as those in primary care settings, as these clinics also provide care akin to primary care.

The inclusion of teleophthalmology as part of primary care may raise questions about scope. However, in the Pelayo et al [47] study, the service was embedded in a primary care setting and used to support chronic disease management. We therefore

XSL•FO
RenderX

considered the patients' perspectives on this AI-supported referral process to be relevant to primary care broadly.

A subgroup analysis of the results was not possible due to missing information about sexes and ages linked to specific quotations. Only 1 study by Upshaw et al [2] provided age-related information alongside participant quotes. The number of studies was insufficient to support comparisons by country.

Two of the studies conducted by Richardson et al [12,46] appeared to have overlapping study participants, which is a potential source of bias. However, when extracting patient quotes and comparing the material, the quotations in the 2 papers were not identical, and the studies focused on different research questions. In qualitative research synthesis, all quotations are considered valuable and important. Repetition of similar statements does not make a particular quote more important than another. Therefore, the risk of bias in this case is expected to be low.

Many of the included studies [1,2,12,17,46] provided limited or no information regarding CASP 6 item "Has the relationship between researcher and participants been adequately considered?" In contrast to quantitative research, where methodological details, such as double-blinding are commonly reported, qualitative studies less frequently describe the relationship between the interviewer and participants. Our interpretation is that this reflects a general reporting tendency rather than a lack of quality. A "Can't tell" rating does not imply that a study is of poor quality but rather that the relevant information was vague.

Future Directions

Understanding patients' perspectives is crucial as AI becomes more integrated into primary care. Future research could investigate how patients interpret various AI concepts and compare their opinions on AI across different health care settings, such as general practice clinics and primary care environments. Conducting studies in diverse countries and cultures is necessary to capture a broad range of patient attitudes toward AI in primary care, acknowledging that cultural and systemic differences may influence perceptions.

Patients have expressed concerns that machines can make mistakes and lack the authority and reputation that physicians possess. These opinions may be consciously or unconsciously influenced by a preference for social status. This raises an intriguing question: Could AI eventually achieve a form of social status and earn professional credibility? This is an important factor in determining patients' perspectives regarding responsibility and accountability if autonomous AI commits medical malpractice. Currently, no studies have investigated this topic, highlighting a valuable avenue for future research. Finally, a notable gap remains in the literature, as few studies [27-30] have explored patient perspectives on AI in general practice settings, and none have specifically addressed LLMs.

Conclusions

Primary care patients recognize that AI can enhance efficiency in primary health care by assisting physicians with administrative tasks and offering decision support through access to comprehensive and accurate medical data. Patients value the human elements in their relationship with physicians, considering these essential for patient-centered care. Although some acknowledge AI's superior accuracy, they still prefer human involvement in treatment. Many patients trust their physician more than AI and doubt that AI can replace physicians. Patients advocate for physicians to ensure AI safety and promote robust frameworks for its implementation. They emphasize the importance of preserving patient choice and autonomy. Understanding patients' perspectives and needs is vital for designing effective and user-friendly AI solutions. Understanding the risks associated with AI is essential to ensure its safe and ethical implementation in health care settings.

Acknowledgments

We would like to extend our gratitude to Rasmus Arvidsson for his valuable input throughout the process of this study. ChatGPT (OpenAI) was used to proofread and suggest improvements in wording and grammar for this manuscript.

Funding

This study was funded by Region Västra Götaland (reference 2024-00520) and the Swedish Research Council (reference 2023-05744).

Authors' Contributions

AE, A Mundzic, RB, DS, and RG contributed to conceptualization. AE, A Mundzic, RB, DS, RG, and RA developed the methodology. A Mundzic and RB conducted the investigation and data curation. A Mundzic handled writing–original draft of the manuscript, and all authors participated in writing–review and editing. AE provided supervision. A Mundzic and AE acquired funding for the study. A Mundzic handled the visualization.

Conflicts of Interest

AE has been employed since September 1, 2024, by Tandem Health AB, developing artificial intelligence products for health care providers. Tandem Health AB had no role in conceptualization, methodology, investigation, data curation, writing, supervision, funding acquisition, project administration, or visualization.

Abstract

Background: Overcrowded emergency rooms might degrade the quality of care and overload the clinic staff. Assessing unscheduled return visits (URVs) to the emergency department (ED) is a quality assurance procedure to identify ED-discharged patients with a high likelihood of bounce-back, to ensure patient safety, and ultimately to reduce medical costs by decreasing the frequency of URVs. The field of machine learning (ML) has evolved considerably in the past decades, and many ML applications have been deployed in various contexts.

Objective: This study aims to develop an ML-assisted framework that identifies high-risk patients who may revisit the ED within 72 hours after the initial visit. Furthermore, this study evaluates different ML models, feature sets, and feature encoding methods in order to build an effective prediction model.

Methods: This study proposes an ML-assisted system that extracts the features from both structured and unstructured medical data to predict patients who are likely to revisit the ED, where the structured data includes patients' electronic health records, and the unstructured data is their medical notes (subjective, objective, assessment, and plan). A 5-year dataset consisting of 184,687 ED visits, along with 324,111 historical electronic health records and the associated medical notes, was obtained from Kaohsiung Veterans General Hospital, a tertiary medical center in Taiwan, to evaluate the proposed system.

Results: The evaluation results indicate that incorporating convolutional neural network–based feature extraction from unstructured ED physician narrative notes, combined with structured vital signs and demographic data, significantly enhances predictive performance. The proposed approach achieves an area under the receiver operating characteristic curve of 0.705 and a recall of 0.718, demonstrating its effectiveness in predicting URVs. These findings highlight the potential of integrating structured and unstructured clinical data to improve predictive accuracy in this context.

Conclusions: The study demonstrates that an ML-assisted framework may be applied as a decision support tool to assist ED clinicians in identifying revisiting patients, although the model's performance may not be sufficient for clinic implementation. Given the improvement in the area under the receiver operating characteristic curve, the proposed framework should be further explored as a workable decision support tool to pinpoint ED patients with a high risk of revisit and provide them with appropriate and timely care.

unscheduled return visit; machine learning; electronic health records; deep learning; clinical decision support system

Introduction

Background

Health care services are inherently risky, as they might involve unpredictable events. Risks may damage a health care provider's finances, patient safety, staff satisfaction, or liabilities. Risk management in health care is extremely important—as human lives are on the line—which consists of a complex set of clinical and administrative systems, processes, procedures, and reporting structures designed to monitor, identify, assess, mitigate, or prevent risks to patients.

The coordination between primary care providers and hospitals in Taiwan often lacks a streamlined and effective referral mechanism, contributing significantly to emergency department (ED) overcrowding. In Taiwan, patients often seek medical support from major medical institutions rather than local clinics. This tendency may be attributed to the structure of the national health care insurance system in Taiwan, where diagnostic fees

XSL•FO
RenderX

are similar between local clinics and large medical institutions. In the current system, patients with nonemergency conditions frequently bypass local clinics and primary care providers, opting to visit the ED directly. Moreover, primary care providers may fail to appropriately direct patients to specialized departments or hospitals due to limited communication channels, inadequate follow-up procedures, or the absence of clear referral protocols. Without a robust referral system, conditions that could be managed effectively in primary care settings are unnecessarily escalated to emergency care, further straining ED resources.

Premature self-discharge, where patients choose to leave the ED before completing their prescribed treatment or before being officially discharged by medical professionals, is a significant contributing factor to ED overcrowding in Taiwan. This behavior often stems from patients' subjective perception of their condition improving or from a lack of understanding of the importance of completing treatment. Cultural attitudes toward health and limited medical knowledge further exacerbate this issue, as patients may misinterpret temporary symptom relief as a full recovery. Such self-discharges frequently result in incomplete or interrupted care, which can lead to complications or the progression of the underlying medical condition. Consequently, these patients are likely to return to the ED when their symptoms reappear or deteriorate, thereby increasing the number of unscheduled return visits (URVs). This not only strains ED resources but also disrupts patient flow and increases the workload for health care providers. Additionally, premature self-discharge may be influenced by nonmedical factors, such as long waiting times, perceived inconvenience, or economic pressures, despite Taiwan's universal health care system. Patients who prioritize immediate symptom relief over long-term health outcomes may also undervalue the importance of follow-up care and professional medical advice.

Patients admitted to the ED often require timely health care resources. A growing number of ED patients in recent years demand more health care resources than ever [1]; overcrowded emergency rooms are a common phenomenon worldwide. According to Taiwan's ED statistical data [2], more than 6.1 million ED visits in 2022 contributed to a 13.6% increase compared with 2021. Among the ED admissions, patients with varying severity of diseases or comorbidities request even more health care services. Efficient use of ED services becomes a challenge for health care management, where the unexpected ED revisit rate is a common performance metric. The number of revisits could be reduced if a clinic support system assesses the revisit risk at a patient's initial visit to the ED.

Addressing the issue of ED overcrowding requires the implementation of long-term solutions aimed at optimizing health care resource allocation and improving patient flow management. While systemic changes, such as enhancing primary care accessibility and strengthening referral mechanisms, are critical, such reforms often require significant time and policy adjustments. To provide immediate and practical relief, this study focuses on the development of a clinical decision support system designed to predict the likelihood of patient unplanned revisits. By leveraging predictive analytics, the proposed clinical decision support system enables health care providers to identify high-risk patients and implement targeted interventions, such as personalized discharge planning and follow-up care. These measures not only improve patient outcomes but also help alleviate the burden on EDs, offering a scalable and effective tool to mitigate overcrowding while broader systemic solutions are pursued.

The applications of information technology to improve health care delivery have been appreciated for decades. To control risks and reduce clinical errors, health care organizations can learn from retrospective events. Health information technologies, such as electronic health records (EHRs), provide good access to retrospective patient information. With the expanding applications of machine learning (ML) on outcome prediction, these use cases have demonstrated the applicability of assessing patient risk from data repositories. Therefore, this study aims to develop an ML-assisted model that predicts URVs in the ED and anticipates that such an application could improve patient safety and reduce medical costs by decreasing the frequency of URVs.

Related Work

It is critical for emergency clinicians to determine high-risk patients who might return in worse conditions or even die. A study [3] on predictors of 30-day ED revisits and 90-day functional decline or mortality concluded that age, sex, polypharmacy, and cognitive impairment were independent predictors of a 30-day ED revisit and that no effective clinical prediction model could be developed. Another study [4] analyzed multi-state ED revisit data. Within 3 days of an index ED visit, 8.2% of patients returned within 72 hours; 32% of those revisits occurred at a different health care institution. Revisit rates varied by diagnosis and by state. Research on ED revisits in different countries yielded varying findings. To differentiate patient risk groups, an analytic study [5] collected 10-year EHR data from multiple health care institutes and applied group-based trajectory modeling. Patients with behavioral diagnoses, injuries, alcohol and substance abuse, stroke, or diabetes had a higher risk of revisiting.

Several studies [6-8] analyzed ED revisit cases in Taiwan. The first study concluded the following findings: 5.47% of patients had a revisit within 72 hours; most revisits were related to illness; and abdominal pain was the most common presentation (55.7%). The second analysis, focusing on unplanned revisits with abdominal pain, demonstrated that older patients receiving multiple analgesics and laboratory tests had a high risk of URV. The third work summarized factors that may impact ED revisits, including blood pressure, pulse rate, fever, triage level, gender, and main illness, while old age was identified as a key factor. The fourth work investigated the risk factors of ED revisits among patients younger than 50 years and applied the decision tree (DT) to identify the variables capable of partitioning the groups into URVs and non-URVs. They found that the Charlson Comorbidity Index (CCI) scores for URVs are higher than those of non-URVs, and the triage levels of URVs are more severe than those of non-URVs.

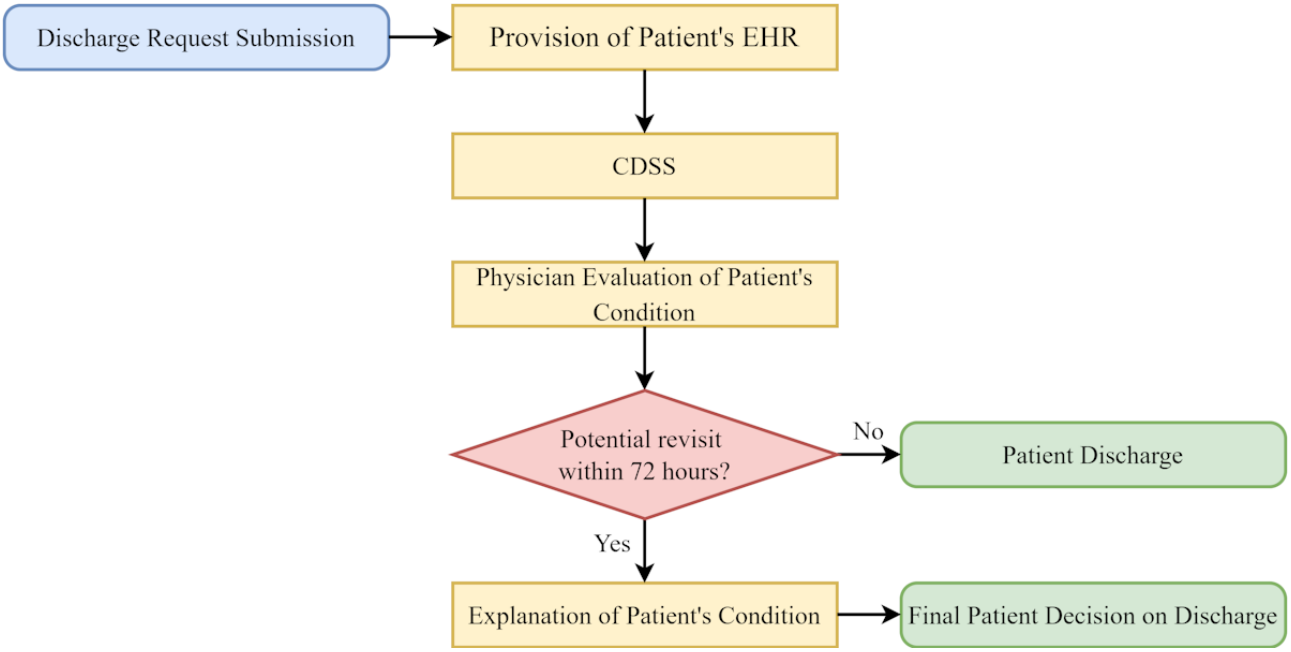
A prior study [9] analyzed 48-hour ED revisits in a hospital in Thailand. In addition to their revisits mostly being related to

XSL•FO
RenderX

gastrointestinal illness (28.76%), they observed the key predictive factors similar to Taiwan's previous research. The past work encouraged further study to evaluate the most common and critical causes of revisits to improve revisit prediction. Most of the past research analyzed URV cases, excluding non-URV cases, and then applied statistical approaches to determine the common factors of URV patients. Even though most ED patients were non-URVs, they might exhibit some similar clinical characteristics to URV cases. Modern ML models might be able to learn the correlations among those features.

A review study [10] explored the existing research that applied ML models to predict ED revisits. Logistic regression (LR) is the most widely used method, while extreme gradient boosting generally exhibits superior performance. Developing ML prediction models for ED URVs is feasible; however, improving the accuracy beyond 0.75 remains a challenge.

Vest and Ben-Assuli [11] applied a DT algorithm to predict the risk of 30-day ED readmissions. Social determinants of health measurements have poor discriminating ability, but the prediction performance improves with more patient information, including current triage and historical data. McCusker et al [12] designed a screening tool with 27 self-report screening questions to assess health risks in senior patients during the 6 months following their initial ED visits. Davazdahemami et al [13] adopted a deep neural network model to predict URVs to the ED. They applied the word embedding model (Doc2Vec) to encode unstructured physician notes and concluded that leveraging structured and unstructured EHR data improves prediction performance.



Methods

Study Population and Setting

Kaohsiung Veterans General Hospital (KVGH) is one of Taiwan's largest general hospitals serving the southern region of Taiwan and offering inpatient, outpatient, and ED health care services. This study analyzed the retrospective administrative medical data of outpatients who sought ED services at KVGH between January 2018 and December 2022. The studied data contains 2 parts, structured and unstructured data, where structured data refers to EHR data and unstructured data consists of subjective, objective, assessment, and plan notes.

Figure 1 outlines the workflow when a patient submits a discharge request. In the initial stage, the system retrieves the patient's medical records and analyzes them in the subsequent stage. The model then assesses the likelihood of the patient revisiting the ED within 72 hours based on their medical data. The prediction outcomes serve as decision support for physicians in the clinical assessment process. If no significant risk factors for readmission are identified, the discharge request is approved. However, if the model predicts a high probability of an unplanned revisit, physicians may advise the patient to stay and provide an explanation of their medical condition. Tables 1-3 outline the demographics of the studied dataset.

[a]TTAS: Taiwan Triage Acuity Scale.

[b]ED: emergency department.

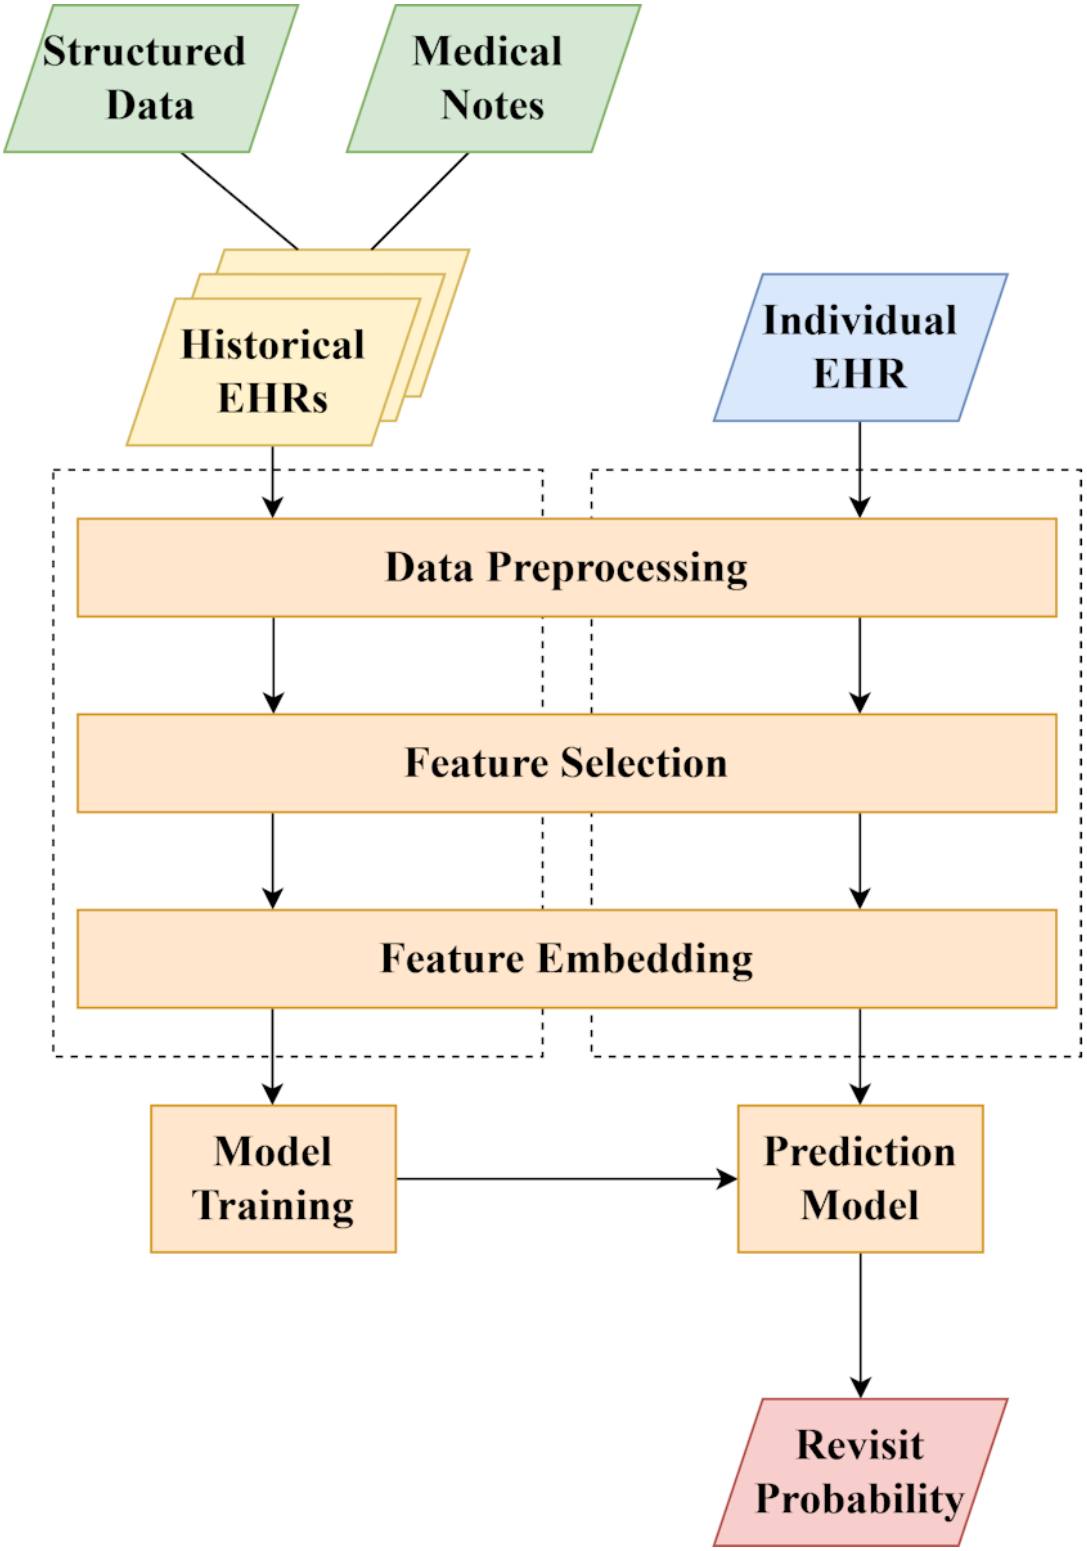
[c]*ICD-10*: *International Statistical Classification of Diseases, Tenth Revision*.

Prediction Target

The collected data were divided into 2 cohort groups: URV patients and non-URV patients. Our prediction target is a binary indicator of 72-hour URV (coded as URV/non-URV) in ED. Each visit is labeled with an associated indicator column to indicate whether the patient had an ED revisit within 72 hours.

Ethical Considerations

This study was conducted in accordance with the principles outlined in the Declaration of Helsinki and received approval from the Institutional Review Board (IRB) of KVGH with IRB certification number KSVGH23-CT5-04 (date of approval: October 31, 2023). The requirement for consent to participate was waived by the IRB of KVGH, as the research uses historical electronic medical records without any direct patient intervention. All data points have been deidentified, and no



XSL•FO
RenderX

specific individual can be identified from the data. The rights and interests of the patients are not harmed, and this study does not have any impact on patients' treatment and medication before and after analyzing the data.

Model Development

Figure 2 outlines the proposed system architecture consisting of the following modules: data preprocessing, feature selection, feature embedding, and prediction model. Each is explained in the following sections.

Figure 2. The architecture of the proposed framework. EHR: electronic health record.

XSL•FO
RenderX

Data Preprocessing

The studied data consists of 2 parts: structured and unstructured data. This module performs data cleansing and normalization tasks, removing missing fields and out-of-range data and subsequently normalizing data into a consistent range. Variable values within the same range avoid the problem of excessive weight on certain variable values and then improve the performance of model training. According to preliminary studies, *z* score standardization performs better than Min-Max normalization. This study applies *z* score standardization to normalize and redistribute all pathological feature values to the same interval.

Model Variable Selection

Model variables, aka features, provide information for the model, and ML algorithms can automatically determine feature weights during the training process. Typically, incorporating more variables can enhance performance. However, irrelevant variables may negatively affect prediction accuracy. Therefore, in real-world applications, feature selection or model variable selection is a critical process for identifying relevant ones to construct an effective prediction model. Without loss of generality, this research adopts the term feature to describe the model variable.

The studied dataset comprises 24 distinct features, including both structured and unstructured data. Structured data are derived from EHR, while unstructured data contents originate from clinicians' medical notes. To appropriately integrate unstructured data, subjective complaints recorded in medical notes are transformed into corresponding *ICD-10* (*International Statistical Classification of Diseases, Tenth Revision*) codes. This mechanism converts unstructured medical notes into structured data while preserving their original information.

This study defines 3 feature sets (FSs), denoted as FS_A, FS_B, and FS_C. FS_A contains all features in the dataset to evaluate model performance without applying any feature selection procedure. Based on preliminary experiments, features related to lab orders and medical orders were found to have no positive impact on the prediction model and were thus excluded from both FS_B and FS_C. To further analyze the effect of incorporating unstructured data on model performance, features derived from unstructured data were removed from FS_B. Table 4 provides a summary of the features in these 3 sets.

[a]FS: feature set.

[b]ED: emergency department.

[c]ICD-10: International Classification of Diseases-10.

[d]TTAS: Taiwan Triage Acuity Scale.

[e]HBP: high blood pressure.

[f]LBP: low blood pressure.

It is important to note that the patient ID is deidentified and serves to indicate a specific patient, while the case number is a serial identifier for an ED visit. Both features are excluded from the prediction model during training.

ED visits are listed in chronological order. For structured data, each visit is characterized by the following types of features: (1) basic ED visit record, (2) vital signs, and (3) care order information (as outlined in Table 4). The basic ED visit record includes gender, age, *ICD-10*, admission time, discharge time, visit disposition, and triage level coded as a categorical variable based on the type and severity of initial presenting signs and symptoms using the Taiwan Triage and Acuity Scale, ranging from 1 (resuscitation) to 5 (nonurgent). The vital signs include body temperature, respiratory rate, pulse, high blood pressure (HBP), low blood pressure, mean arterial pressure, and oxygen saturation. The care order information includes laboratory tests and medication-related information.

XSL•FO
RenderX

Past studies have revealed that patients with multiple diseases have high risks of ED visits, where such information typically is recorded in unstructured medical notes during the diagnosis. To improve prediction performance, this study extracts diseases from unstructured subjective, objective, assessment, and plan notes, along with the *ICD-10* from EHR, and then calculates the CCI score [14] to indicate the patient's condition.

Feature Embedding

Inputs to ML models must be numerical, and therefore, nonnumeric features usually need to be encoded or embedded before feeding them into the model. Feature embedding or feature encoding serves as a bridge between raw data and model inputs, enabling algorithms to operate efficiently on transformed data. Since feature embedding is as critical as feature selection for building an efficient model, this study designs 2 feature encoding schemes to evaluate the impact of feature embedding and to identify the most suitable one for the prediction model. Table 5 explains the studied feature encoding schemes in detail.

Table . Studied encoding methods.

Feature	Range	Description
Encoding E_A		
Age[a] (years)	0-5	0: <41; 1: 41-50; 2: 51-60; 3: 61-70; 4: 71-80; 5: >80

[d]LBP: low blood pressure.

[e]Based on Chen et al [16].

[f]SpO_2: saturation of peripheral oxygen.

[g]*ICD-10*: *International Statistical Classification of Diseases, Tenth Revision*.

The studied data contains a mix of numerical and categorical data. Even though the studied structured data is mostly numerical, its values represent different meanings. Vital signs are in numerical form but can be interpreted as categorical variables, as vital signs usually have a normal range. For example, HBP can be tiered into 3 levels—0 (low HBP), 1 (normal HBP), and 2 (high HBP)—as shown in the first encoding method of Table 5. On the other hand, for the ML model, low HBP and high HBP both imply the patient's HBP is not in the normal range, and there might not be much difference between too high and too low. Therefore, the HBP feature value can be interpreted as normal or nonnormal. As expressed in the second encoding method of Table 5, it is categorized into 2 types: 0 for normal HBP and 1 for HBP not in the normal range. Those numerical features not listed in the table are applied in their original numerical values to the ML models.

When working with categorical data, such as disease names, it is critical to convert them into a numerical format so that ML algorithms can understand them. One-hot encoding is commonly

XSL•FO
RenderX

used for encoding categorical variables. This study adopts an improved one-hot encoding scheme, which presents a group of related categories together, as illustrated in Figure 3.

Figure 3. Pandas' one-hot embedding method.

	Disease		Disease diabetes	Disease hypertension	Disease cardiovascular
Patient A	Diabetes		1	0	0
Patient B	Hypertension	→	0	1	0
Patient C	Hypertension		0	1	0
Patient D	Cardiovascular		0	0	1

Class Imbalance

Training an effective model requires a balanced or near-balanced class distribution. However, the datasets collected from real-world environments are typically imbalanced, as most ED visits are non-URV cases, which constitute the major class. Sampling is a process of resampling data to improve dataset distribution, whereas oversampling is a process of increasing the sampling rate of the minority class, while undersampling reduces the sampling rate of the majority class.

Oversampling techniques applied to the minority class, which are widely used to address data imbalance issues, may introduce several significant challenges, particularly in the medical domain. For instance, methods such as random duplication of existing data can lead to model overfitting, as the model may overly rely on a restricted subset of the input. Furthermore, approaches like SMOTE or other algorithms that dynamically generate synthetic data may pose ethical and legal concerns, as the generated data could be false or misleading, ultimately negatively impacting the prediction model. In contrast, random undersampling can effectively reduce a considerable number of non-URV records, resulting in a balanced dataset with minimal information loss.

Based on the aforementioned analysis, this study adopts random undersampling to achieve a balanced dataset while minimizing the risks associated with oversampling techniques. Given that oversampling may introduce model overfitting and ethical concerns due to synthetic data generation, random undersampling presents a more reliable approach by reducing the number of non-URV records without compromising data integrity. This method ensures that the dataset maintains a proportional distribution between classes, thereby enhancing the model's generalizability and mitigating bias.

Prediction Model

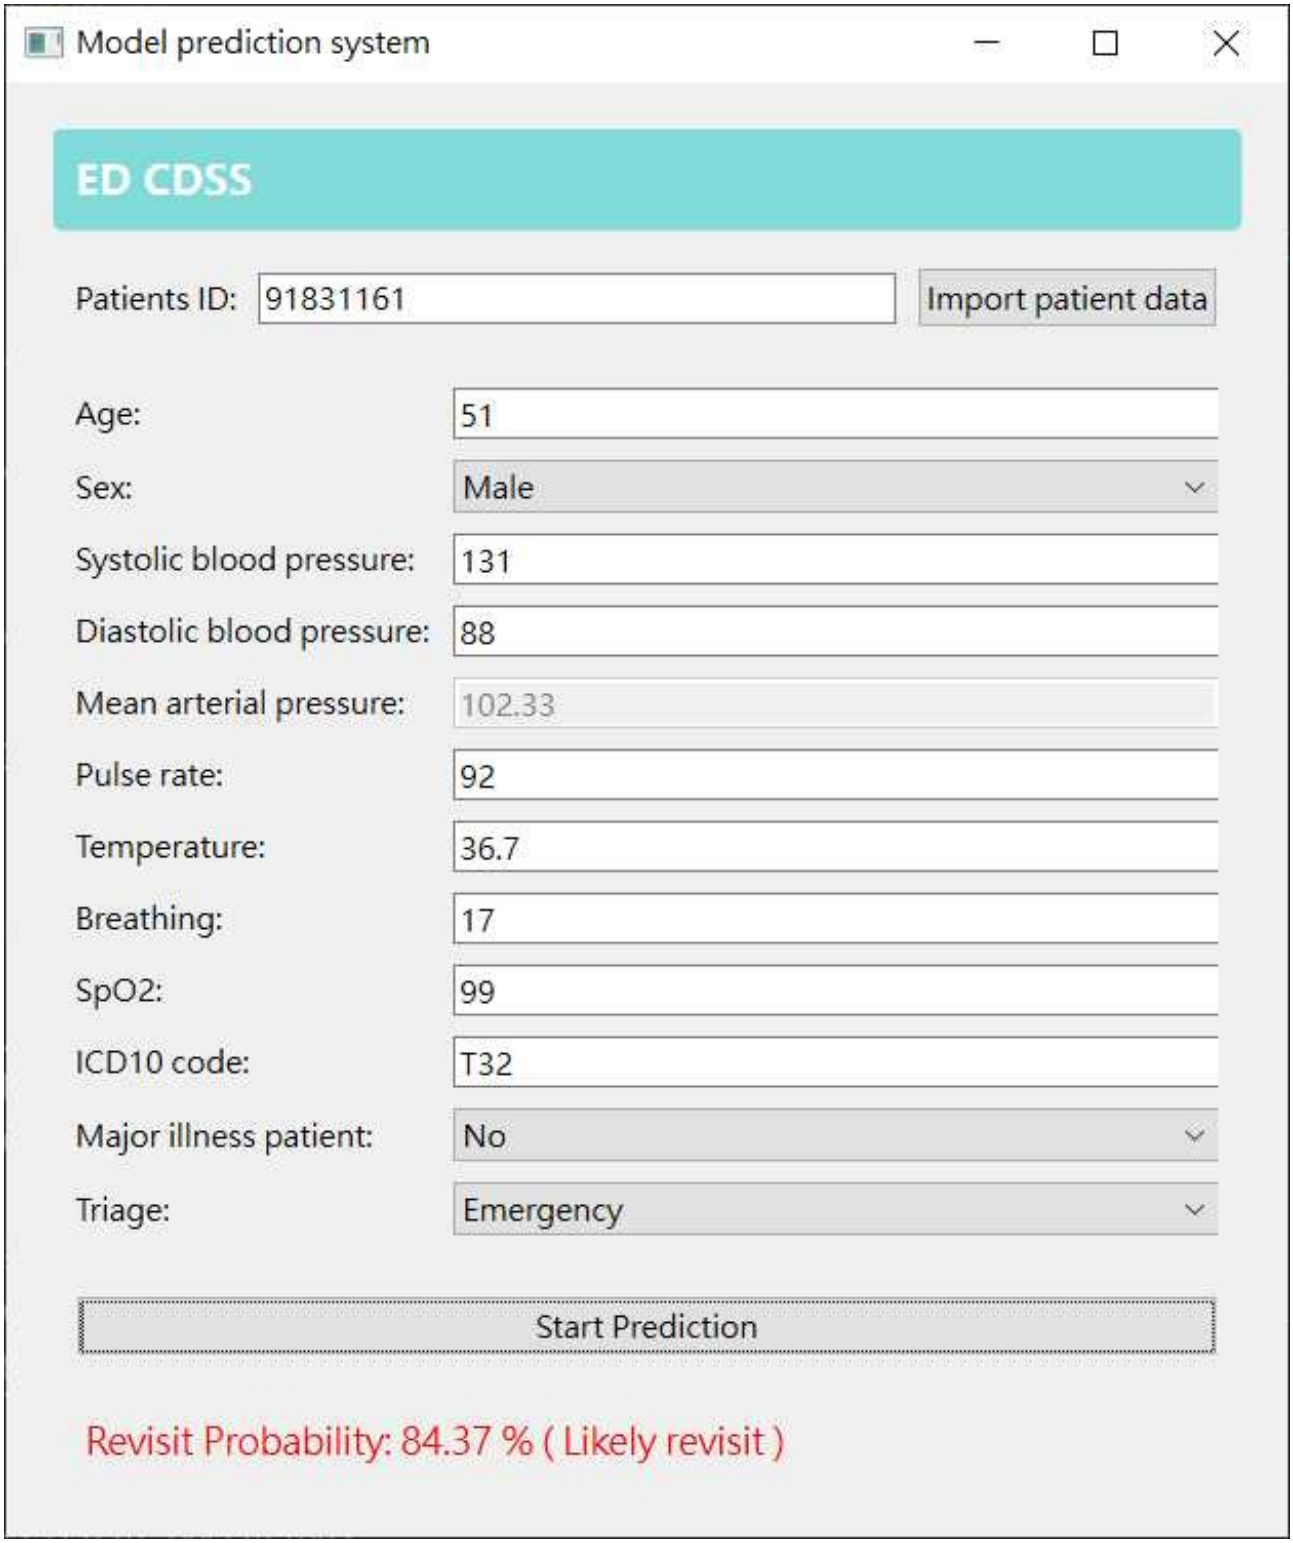
To identify the optimal ML algorithms tailored for the proposed framework, this study evaluates various classification algorithms commonly used in related literature. These include DT, LR, random forest (RF), support vector machine (SVM), one-class support vector machine (OCSVM), grid search cross-validation (GSCV), multilayer perceptron (MLP), convolutional neural network (CNN), tree-based pipeline optimization tool, and long short-term memory (LSTM).

Hyperparameter fine-tuning is a critical process that directly influences model performance. To determine the optimal hyperparameters for each algorithm, multiple combinations of hyperparameter sets are independently evaluated.

Additionally, the different FSs and feature encoding methods described earlier are assessed to construct an effective URV prediction model.

To develop and evaluate the prediction models, the dataset was randomly partitioned into training and testing sets with a ratio of 8:2. This process was repeated 10 times with different random splits, and the final performance metrics were reported as the average across these 10 runs to ensure robustness and reduce variance due to data partitioning.

System Interface



The proposed system is designed to provide a straightforward and user-friendly interface, enabling physicians to efficiently enter medical records, as illustrated in Figure 4.

The interface consists of 2 primary sections: the clinical data input section and the model output section. The clinical data input section includes structured data fields for entering numerical values, as well as dropdown menus for selecting categorical features. The use of dropdown menus minimizes potential input errors and reduces input time, thereby enhancing data entry efficiency. Once the required data are entered, they are fed into the pretrained prediction model upon submission. The prediction model then analyzes the clinical input data to determine whether a patient is at risk of revisiting the ED within 72 hours. The prediction output provides the likelihood of a revisit along with the model's decision, offering physicians a clear assessment of patient risk.

The intuitive design of the interface increases physician adoption and usability, facilitating seamless integration into clinical workflows. By streamlining data entry and automating risk assessment, the system improves decision-making efficiency while minimizing potential input errors. The straightforward structure ensures that physicians can quickly interpret and act upon prediction results, ultimately supporting more effective ED management.

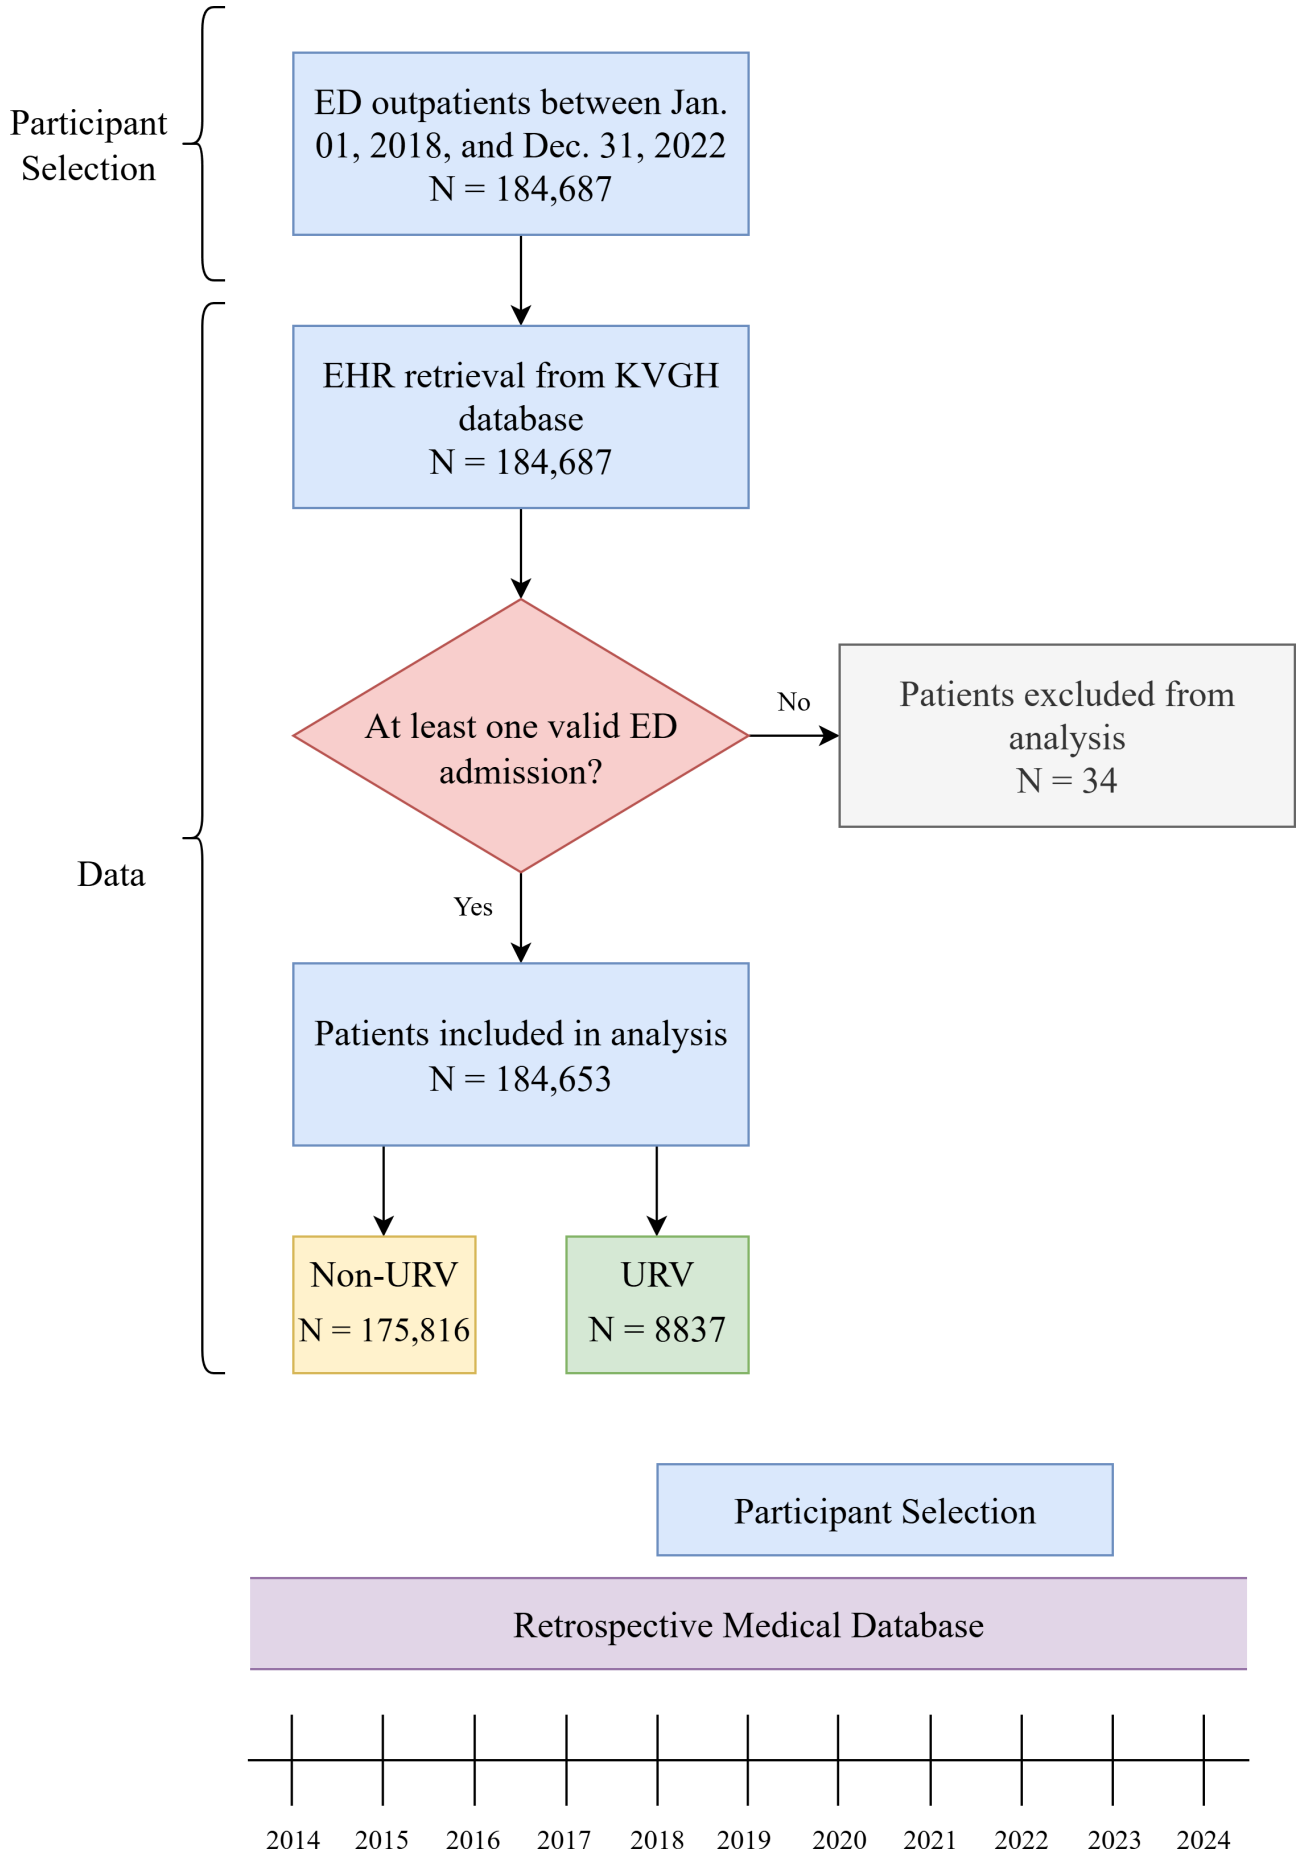
Results

Overview

According to past studies and our preliminary study, several factors might impact training efficiency. Therefore, this study conducts 2 experiments in order to obtain an efficient URV prediction model for ED by evaluating different ML models, FSs, and encoding schemes. The first experiment investigates the prediction performance of traditional and modern ML algorithms by applying 2 types of FSs (a complete set vs a subset of selected features), and the second experiment evaluates the impact of feature encoding.

Figure 5 illustrates the process of data selection, data filtering, and the study timeline for a retrospective medical study. The selection process begins with 184,687 ED patients treated between January 2018 and December 2022. EHRs were retrieved from the KVGH database for these patients. To ensure data validity, a screening criterion was applied, requiring at least

XSL•FO
RenderX



one valid ED admission. As a result, 34 patients were excluded, leaving a final study cohort of 184,653 patients for analysis.

All experiments were performed on a personal computing workstation configured with a 12th Generation Intel Core i7 CPU, 32 GB of RAM, an NVIDIA RTX 3060 dedicated GPU, and a 512 GB solid-state drive.

Performance Measurement

Model performance is evaluated using metrics such as accuracy, recall, and the area under the receiver operating characteristic curve (AUROC). AUROC is a widely used metric for assessing the effectiveness of binary classification models, as the receiver operating characteristic curve illustrates the trade-off between the true positive rate and the false positive rate across various decision thresholds. AUROC values range from 0.5 to 1.0, where a value of 0.5 indicates that the model performs no better than random chance in distinguishing between the 2 classes.

Certain models may achieve a high recall rate but low accuracy, while others may exhibit high accuracy but low recall. Neither type of model is suitable for reliable prediction. Since AUROC accounts for both aspects of classification performance, this study selects AUROC as the primary metric for evaluating prediction performance.

Performance Evaluation of ML Models for URV Prediction

This section investigates the predictive performance of various ML algorithms using different FSs: FS_A, FS_B, and FS_C. These ML algorithms iteratively learn important patterns from the input data and adjust feature weights accordingly. However, an excessive number of features can introduce noise and negatively impact model training, highlighting the necessity of a feature selection process during training. A carefully selected subset of key features may yield more effective performance. Therefore, in addition to evaluating various ML models, this experiment also examines the effectiveness of the selected features.

Table 6 summarizes the results, comparing 2 categories of ML models: traditional ML and modern ML. In terms of predictive modeling, modern ML algorithms generally require longer training times but produce better prediction models compared with traditional ML algorithms, with the exception of LSTM. The best-performing modern ML model (CNN) surpasses the best-performing traditional ML model (LR) and outperforms all other models, achieving superior performance with a reasonable training time.

[m]TPOT: tree-based pipeline optimization tool.

Among these combinations, LR with FS_A outperforms other traditional ML algorithms in terms of AUROC, which is indicative of overall model performance. The evaluated traditional ML models (DT, SVM, and OCSVM) exhibit diverse prediction performances, with some demonstrating high accuracy but low recall, while others show high recall but low accuracy. Notably, LR and RF deliver stable performance across both metrics.

In contrast, most modern ML models yield stable prediction performance, except for LSTM. While LSTM is highly suitable for time-series prediction, it is not appropriate for the current dataset, leading to the poorest performance among all modern ML and traditional ML models, except OCSVM with FS_B. Given that the studied dataset comprises only 24 distinct features, simpler algorithms such as DT and LR in traditional ML and CNN in modern ML outperform more complex models.

The superior performance of simpler models on this dataset can be attributed to the nature of the data. Complex algorithms, such as LSTM, typically require larger datasets with extensive FSs to effectively capture patterns and avoid overfitting. When applied to datasets with fewer features, these models are more prone to overfitting, leading to reduced generalization and poorer performance. In contrast, simpler algorithms, which rely on fewer parameters and are less prone to overfitting, can effectively handle smaller datasets, making them more suitable in such cases.

Impact of Feature Set on Model Performance

With respect to feature selection, the complete FS (FS_A) generally builds better prediction models compared with the subsets (FS_B and FS_C) according to the results in Table 6. The discrepancies in AUROC between FS_A and FS_C fall within ±1, suggesting that the subset contains critical determinants for URV prediction. Both FS_B and FS_C primarily consist of vital signs and age, indicating that these are key features for URV prediction. Moreover, FS_C incorporates medical notes and outperforms FS_B across all evaluation models, highlighting the

XSL•FO
RenderX

importance of unstructured data in enhancing predictive performance.

Comparison of Training Time Across ML Models

Regarding training time, traditional ML algorithms generally require less time to complete their training phases compared with modern ML algorithms. GSCV, for instance, requires at least 860 seconds to build a prediction model but does not achieve the best detection results. In contrast, CNN, which yields the best performance, completes its training phase in an average of 48 seconds, while MLP, the second-best algorithm, requires less than 15 seconds on average. As MLP is a simplified version of CNN, it is expected that CNN takes longer training time than MLP. Notably, both MLP and CNN outperform other models, with only minor discrepancies observed between their performances.

Performance Evaluation of ML Models With Different Feature Encoding

This section investigates the impact of feature encoding on model training. This experiment evaluates 2 encoding methods (E_A and E_B) on the 2 best prediction models (MLP and CNN) with the best FS (FS_A) obtained from the previous experiment and another feature subset (FS_C), since FS_C outperforms FS_B across all evaluation models. The studied encoding methods are described in the previous section and outlined in Table 5. FS_C includes FS_B and some other relevant features, as shown in Table 4, in order to investigate the encoding impact on different types of features.

Table 7 lists the evaluation results, where the boldface figure indicates the best of a given performance measurement. The results demonstrate that the encoding method has a certain impact on model training. A simplified encoding E_B performs better than E_A. That is, categorizing vital signs into 2 types (normal and abnormal) can better represent the meaning of the features than the 3 types (low, normal, and high); converting *ICD-10* into 22 categories defined by World Health Organization can better represent the meaning of the diseases; age classified into 3 categories (0: <41 years; 1: 41-65 years; 2: >65 years) is better than the 6 categories defined by CCI (0: <41 years; 1: 41-50 years; 2: 51-60 years; 3: 61-70 years; 4: 71-80 years; 5: >80 years).

[e]CNN: convolutional neural network.

Model Parameters

The CNN model architecture consists of a repeated block structure, composed of two 1D convolutional layers followed by a 1D max-pooling layer. This block is repeated 5 times, after which the output is passed to a fully connected layer and finally mapped to the probability of a URV.

Each convolutional layer uses 64 filters with a kernel size of 3 and uses the rectified linear unit as the activation function. The max-pooling layer is configured with a pool size of 2.

For model training, the number of epochs was set to 100, and an early stopping mechanism was implemented to prevent overfitting, with a patience value of 25. The model was optimized using the Nadam optimizer with a batch size of 256. A dynamic learning rate adjustment strategy was applied, where the learning rate was reduced by a factor of 0.5 if no improvement was observed for 5 consecutive epochs. The minimum learning rate was set to 1^{e-4}, with epsilon set to 0.0001.

Discussion

Principal Findings

This study proposes an ML-assisted system for predicting patients at risk of revisiting the ED, leveraging features extracted from both structured and unstructured medical data. The structured data consists of patients' EHRs, while the unstructured data includes medical notes. The findings indicate that the conventional trade-off between training time and prediction performance may not be universally applicable. While traditional ML models require significantly less training time, modern ML models demand at least twice as much, if not more. When computational resources or training time are constrained, traditional ML models such as LR can serve as effective prediction tools; however, when such limitations are not a major concern, CNN is recommended. Additionally, while incorporating a broad range of relevant features enhances predictive performance, a subset of key features may have a dominant impact on model outcomes. In particular, vital signs and age are identified as critical predictors for URV, and properly encoding features into the appropriate categories can further improve model efficiency.

In this study, 2 encoding strategies (E_A and E_B) were evaluated. The experimental results indicate that models trained on datasets encoded using the E_B approach consistently outperform those trained with the E_A approach. This performance difference can be attributed to the characteristics of the respective encoding methods. Although E_B uses a relatively simpler encoding scheme, it distinctly classifies variables into 2 well-defined categories: normal and abnormal. In contrast, E_A uses a 3-category system— "too low," "normal," and "too high." However, the categories "too low" and "too high" both represent abnormal conditions and may not be sufficiently distinguishable in practice. This lack of distinction could introduce ambiguity for the predictive model, thereby adversely affecting its performance.

For practical implementation, AUROC is used to represent the overall performance of a model. Models with higher AUROC values are associated with fewer false alerts while maintaining an acceptable true positive rate. According to the experimental results, among traditional ML models, LR demonstrates the best performance in predicting URV, achieving an AUROC of 0.636. Among modern ML models, CNN outperforms its counterparts in terms of AUROC values.

In scenarios where capturing all URV cases is prioritized, recall serves as a critical performance indicator. Among traditional ML models, DT achieves the highest recall rate of 0.908, while among modern ML models, LSTM achieves the highest recall value of 0.989. However, it is noteworthy that both DT and LSTM exhibit low accuracy values, indicating that these models tend to generate a considerable number of false alerts.

Limitations

A notable finding is that, although advanced CNN-based models such as LSTM typically outperform CNN in most ML applications, this advantage does not necessarily hold in URV prediction for ED visits. One possible explanation is that ED visits often lack prior knowledge of a patient's visit history, which limits the predictive capacity of sequential models like LSTM. Furthermore, the absence of sufficient medical history may constrain the overall performance of ML-based prediction models. Future research could explore the integration of patients' comprehensive medical histories to enhance predictive accuracy. Additionally, the diverse causes of ED revisits present a challenge for ML models, as they make it difficult to distinguish patterns among different revisit cases. Investigating ML-based predictions for specific revisit causes may further refine model performance.

Given the nonstandardized nature of medical notes, this study transforms the unstructured textual content into corresponding *ICD-10* codes. This structured representation has been shown to enhance the predictive performance of the model. However, medical notes possess a wide array of clinically relevant information beyond *ICD-10* codes, including chief complaints, prior treatments, and allergy histories. Therefore, the application of advanced natural language processing techniques may further improve predictive outcomes by enabling the extraction of richer features from unstructured clinical text.

Comparison With Prior Work

Previous studies mostly focused on general revisits, while studies specifically addressing ED revisits were relatively understudied. Most existing work (Vest and Ben-Assuli [11]) considered a long prediction window, such as 30 days, while revisit time frames are likely shorter, for example, 72 hours [12]. Most existing prediction models selected features from merely one type of EHR data, rarely considering both types of patients' medical data: structured EHR and unstructured medical notes. Prior studies [6-8] that applied ML prediction models primarily evaluated 1 or 2 models and rarely analyzed the performance of multiple prediction models or various FSs.

A similar study by Guo et al [8] on ED revisits incorporated both structured and unstructured medical records by converting them into semantic patterns and developing a customized bidirectional encoder representations from transformers (BERT) model, referred to as BlueBERT, to predict URVs. The issue of data imbalance, with URV cases accounting for only 2.22% of their studied dataset, was addressed using random undersampling techniques. Their experimental results demonstrated the superiority of BlueBERT compared with other models, such as KNN, RF, and XGB, in terms of AUROC.

To the best of our knowledge, our study is one of the few attempts to combine 2 types of patients' medical data (structured and unstructured) to identify unplanned revisits to the ED and is the first study that conducts a comprehensive performance evaluation of traditional as well as modern ML classification models, where the traditional ones include LR, RF, SVM, and OCSVM and the modern ones include GSCV, MLP, CNN, tree-based pipeline optimization tool, and an improved CNN LSTM. Furthermore, this study analyzes the importance of feature selection and the impact of feature embedding on the efficiency of model training.

XSL•FO
RenderX

Conclusions

This study evaluates both traditional ML and modern ML models for predicting the URVs in ED and examines the impacts of feature selection and feature encoding on model training. The evaluation concludes the following findings: (1) adopting an appropriate model is important for a targeted problem, (2) not all the MLL models are superior to traditional ML ones, (3) an advanced modern ML model might not yield better performance than a basic modern ML model (such as CNN) or a traditional ML (such as LR), (4) a complicated algorithm requiring long training time (such as GSCV) might not construct an efficient prediction model, (5) feature selection is relevant to build an efficient model, (6) finding key features is critical for interpreting the prediction results, (7) feature encoding affects the efficiency of model training, and (8) an encoding scheme which better represents the meaning of the features could yield a better prediction model.

Authors' Contributions

C-MC and W-CJ contributed to the conceptualization of the study. C-MC, Z-HY, and Z-XC developed the methodology. Z-HY was responsible for the software. W-CJ, C-MC, and Z-XC performed the validation. Z-HY and W-CJ collected the data. C-MC and Z-XC prepared the original draft of the manuscript. W-CJ reviewed and edited the manuscript. Z-XC and Z-HY created the visualizations. W-CJ and C-MC supervised the work. W-CJ managed the project administration.

Conflicts of Interest

W-CJ is an employee of Kaohsiung Veterans General Hospital and receives a salary from the institution. The other authors declare that they have no competing interests or financial support related to this study.

Abstract

Background: Recent advancements in Generative Adversarial Networks and large language models (LLMs) have significantly advanced the synthesis and augmentation of medical data. These and other deep learning–based methods offer promising potential for generating high-quality, realistic datasets crucial for improving machine learning applications in health care, particularly in contexts where data privacy and availability are limiting factors. However, challenges remain in accurately capturing the complex associations inherent in medical datasets.

Objective: This study evaluates the effectiveness of various Synthetic Data Generation (SDG) methods in replicating the correlation structures inherent in real medical datasets. In addition, it examines their performance in downstream tasks using Random Forests (RFs) as the benchmark model. To provide a comprehensive analysis, alternative models such as eXtreme Gradient Boosting and Gated Additive Tree Ensembles are also considered. We compare the following SDG approaches: Synthetic Populations in R (synthpop), copula, copulagan, Conditional Tabular Generative Adversarial Network (ctgan), tabular variational autoencoder (tvae), and tabula for LLMs.

Methods: We evaluated synthetic data generation methods using both real-world and simulated datasets. Simulated data consist of 10 Gaussian variables and one binary target variable with varying correlation structures, generated via Cholesky decomposition. Real-world datasets include the body performance dataset with 13,393 samples for fitness classification, the Wisconsin Breast Cancer dataset with 569 samples for tumor diagnosis, and the diabetes dataset with 768 samples for diabetes prediction. Data quality is evaluated by comparing correlation matrices, the propensity score mean-squared error (pMSE) for general utility, and F_1-scores for downstream tasks as a specific utility metric, using training on synthetic data and testing on real data.

Results: Our simulation study, supplemented with real-world data analyses, shows that the statistical methods copula and synthpop consistently outperform deep learning approaches across various sample sizes and correlation complexities, with synthpop being the most effective. Deep learning methods, including large LLMs, show mixed performance, particularly with smaller datasets or limited training epochs. LLMs often struggle to replicate numerical dependencies effectively. In contrast, methods like tvae with 10,000 epochs perform comparably well. On the body performance dataset, copulagan achieves the best performance in terms of pMSE. The results also highlight that model utility depends more on the relative correlations between features and the target variable than on the absolute magnitude of correlation matrix differences.

Conclusions: Statistical methods, particularly synthpop, demonstrate superior robustness and utility preservation for synthetic tabular data compared with deep learning approaches. Copula methods show potential but face limitations with integer variables. Deep Learning methods underperform in this context. Overall, these findings underscore the dominance of statistical methods for synthetic data generation for tabular data, while highlighting the niche potential of deep learning approaches for highly complex datasets, provided adequate resources and tuning.

Introduction

In recent years, Generative Adversarial Networks (GANs) and large language models (LLMs) have revolutionized the synthesis and augmentation of medical data [1-3]. These technologies have introduced methods for creating high-quality, realistic datasets, which are essential for advancing machine learning (ML) applications in the health care sector [4-6]. The ability to synthesize realistic medical data is particularly valuable in contexts where data privacy and availability are major concerns [7]. Medical data is often subject to strict regulations due to privacy laws and ethical considerations, which can limit the availability of comprehensive datasets for research and development. By using GANs and LLMs to generate synthetic data, researchers and practitioners can overcome these limitations, creating datasets that preserve the statistical properties and correlations of the original data while ensuring that individual patient identities remain protected.

However, despite the promising capabilities of GANs and LLMs, several challenges persist in leveraging these technologies effectively for medical data synthesis [8-11]. A key challenge is the ability of these models to accurately capture and replicate the intricate relationships within medical datasets. Medical data often exhibits complex interdependencies between features, such as the relationship among symptoms, diagnostic indicators, and treatment outcomes. Inaccurate representation of these correlation structures can result in synthetic data that fails to mimic the true variability and relationships found in real-world medical data [12]. The use of synthetic medical data also raises ethical concerns, particularly regarding the potential perpetuation or, in some cases, even amplification of biases inherent in the original datasets [13]. For instance, GANs tend to prioritize matching overall data distribution rather than subgroup-level details. Such representation issues can translate into new or stronger associations between sensitive attributes such as race and medical conditions [14]. If high data quality is promised based on such data because a particular metric performs well, ML methods may establish incorrect associations accordingly.

Focusing on pairwise correlation structures in medical data synthesis, despite their limitations in complex data environments, remains crucial for several reasons: (1) correlation analysis identifies primary dependencies as a starting point for understanding how variables interact; (2) if a ML model recognizes that certain variables are typically correlated, it can better simulate realistic scenarios, leading to more accurate predictions and insights; and (3) pairwise correlation structures provide a baseline for validating and comparing synthetic data. Even though they might not capture all forms of dependence, comparing correlations in synthetic data with those in real-world data can help assess the fidelity and quality of the generated datasets.

There have been several approaches addressing correlations in the context of Synthetic Data Generation (SDG), particularly for relational data [15]. Most methodological studies aim to capture correlation structures by extending existing techniques. For example, Vu et al [16] explored how to make the loss function of GANs correlation-aware but found no significant benefit. In contrast, Patel et al [17] demonstrated that incorporating a Correlational Neural Network can improve a GAN's ability to capture correlations, slightly outperforming the MedGAN model. Torfi and Fox developed realistic synthetic health care records by leveraging Convolutional Neural Networks to capture correlations between medical features, achieving comparable performance to real data in ML tasks while maintaining privacy and statistical fidelity [18]. Rajabi and Garibay [19] showed that effective consideration of correlations can enhance fairness in synthetic data. These works are noteworthy because the primary goal of advanced SDG methods is to capture the full dependency structure.

Despite the substantial body of work on validation and benchmarking in SDG, there is a notable gap in studies specifically assessing how the correlation structure of real data influences the effectiveness of SDG methods in replicating such relationships. Understanding whether faithfully reproducing correlation structures is critical for achieving high-quality results in downstream tasks remains an open question. This issue is particularly relevant given the increasing reliance on SDG methods across various domains. Simulation studies are well-suited to address these questions, as they enable controlled analysis of specific factors affecting model performance [20]. For instance, Strobl et al [21] demonstrated through simulations that Random Forest (RF) models tend to produce biased variable selection when predictors differ in scale or category count.

The aim of this study is to address the research gap by developing a simulation design and validating the results on 3 real-world medical datasets. We evaluate how effectively SDG methods can replicate the correlation structure of the original data and perform a classification task using RF. To provide a comprehensive analysis, alternative models such as eXtreme Gradient Boosting [22] and Gated Additive Tree Ensembles [23] are also considered. In addition, for one notable case, we assess whether the relevant variables are selected based on variable importance measures, as correlation matrix distances are often calculated in practice without addressing their impact. For this analysis, we use the following SDG approaches: Synthetic Populations in R (synthpop) [24], copula [25], copulagan [26], Conditional Tabular Generative Adversarial Network (ctgan) [27], Tabular Variational Autoencoder (tvae) [27], and tabula for LLMs [28,29], the latter of which per default uses DistilGPT-2 (distilled Generative Pretrained Transformer -2), a streamlined version of the english-language model GPT-2. The corresponding assessment will help practitioners in guiding their choice of SDG methods.

Methods

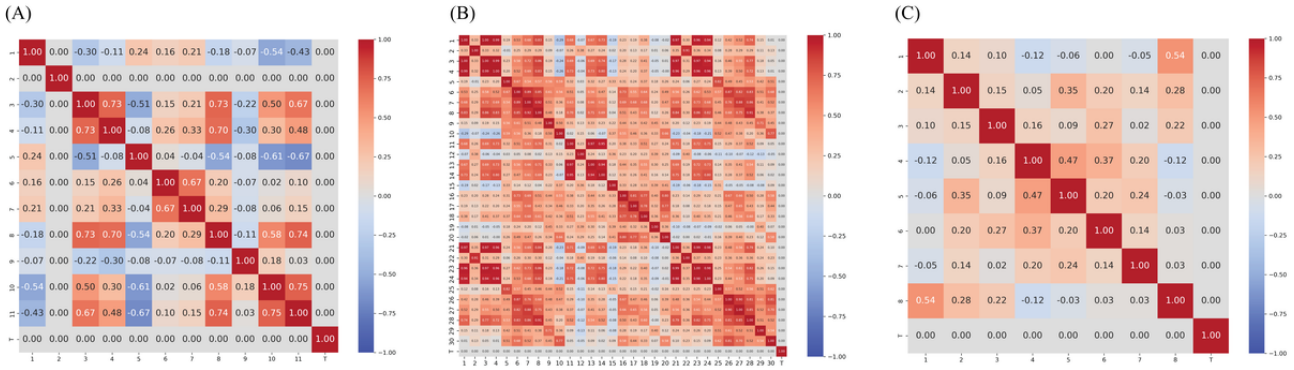
Overview

The schematic diagram in Figure 1 outlines the key steps in the methodology used in this study. The process begins with data generation, where simulated datasets were created using correlation matrix construction and target variable creation. Besides that, we selected 3 real-world datasets (Body Performance [BP], Breast Cancer [BC], and Diabetes [DB]). All datasets are then used to generate and evaluate various SDG methods.

Figure 1. Overview of the methodology workflow. BC: Breast Cancer Dataset; BP: Body Performance Dataset; ctgan: Conditional Tabular Generative Adversarial Network; DB: Diabetes Dataset; pMSE: Propensity Score Mean-Squared Error; SDG: synthetic data generation; tvae: Tabular Variational Autoencoder; VIMP: variable importance.

Datasets

Real-World Datasets



We selected 3 medical datasets from Kaggle – Body Performance (BP), Breast Cancer (BC), and Diabetes (DB) – that are commonly used in predictive modeling and data analysis tasks. All 3 datasets involve classification problems. The correlation matrices of these datasets are provided in Figure 2.

The BP dataset provides comprehensive data on physical fitness and body measurements, encompassing variables such as height, weight, age, gender, body fat percentage, and details of physical activity and fitness routines. It includes 13,393 samples with 11 numerical features and a categorical target variable that classifies individuals into four fitness categories: excellent, good, average, and poor. Among the features, age and sit-up count are recorded as integers.

The BC dataset comprises 569 entries, each with 30 numerical features extracted from digitized images of fine needle aspirates of breast masses. These features, representing the mean, standard error, and maximum value, quantify geometric and textural properties of cell nuclei, including radius, texture, perimeter, area, smoothness, compactness, concavity, concave points, symmetry, and fractal dimension. The dataset supports tumor classification as malignant or benign based on the nuclei features.

The DB dataset is tailored for predicting diabetes based on diagnostic measurements. It comprises 768 records of Pima Indian women aged 21 and older, with variables including the number of pregnancies, glucose levels, blood pressure, skin thickness, insulin levels, BMI, a diabetes pedigree function, age, and a binary diabetes outcome. All variables are numerical, representing physiological and diagnostic metrics critical to diabetes prediction.

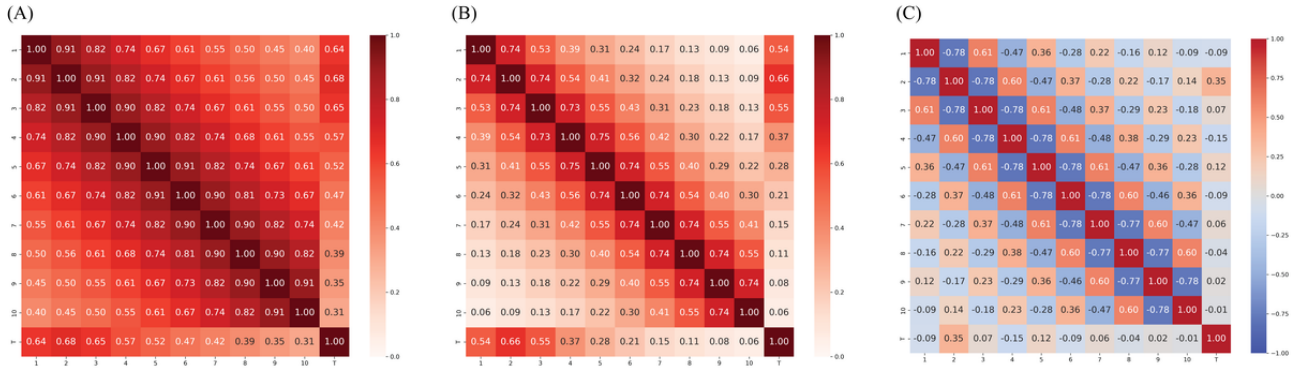
Figure 2. Correlation matrix for 3 real-world datasets: (A) BP: Body Performance Dataset, (B) BC: Breast Cancer Dataset, and (C) DB: Diabetes Dataset.

Simulated Datasets

In our simulation study, we first generate 10 Gaussian-distributed features and then impose distinct correlation structures using the Cholesky decomposition method [30]. A binary target variable is subsequently constructed based on 4 selected features. The process of defining the target variable is repeated across 3 different correlation structures, with the simulation executed at 3 distinct sample sizes (500, 5000, and 10,000). The use of varying sample sizes allows us to examine the effect of data volume on the robustness and stability of the correlation structures and the resulting relationships between features and the target variable.

To introduce correlations, we construct 3 types of correlation matrices based on 3 different exponential decay rates, corresponding to varying strengths and patterns of correlation: 0.1 for strong positive correlations, 0.3 for weaker positive correlations, and 0.25 for alternating correlations (positive and negative). The correlation between variables is defined using equation (1) for the 0.1 and 0.3 decay rates, where the exponential decay ensures that correlations decrease as the index distance increases:

XSL•FO
RenderX



Here, α represents the decay rate, controlling the speed at which correlations diminish as the distance $|i - j|$ between indices grows. Smaller values of (eg, 0.1) result in slower decay and stronger correlations over larger distances, while larger values (eg, 0.3) lead to faster decay and weaker correlations.

For the 0.25 alternating correlation, equation (2) is used, incorporating alternating signs to produce correlations that switch between positive and negative values with increasing index distance. In this case, α = .25 determines the rate of decay, while the alternating factor $(-1)^{|i-j|}$ introduces the sign changes in the correlations. The resulting correlation matrix, which must fulfill the condition of symmetric positive semidefiniteness, is then decomposed via Cholesky decomposition, allowing us to transform independent normal variables into correlated ones as defined by the specified structure. Examples of such generated correlation matrices are shown in Figure 3.

Figure 3. Correlation matrices used in the simulation study: (A) positive exponential decay rate of 0.1, (B) positive exponential decay rate of 0.3, and (C) alternating positive and negative exponential decay rate of 0.25.

The correlation between different types of variables is calculated through a structured process that accommodates binary, continuous, and mixed data types. For each pair of variables, the appropriate correlation metric is selected based on their data types. If at least one variable is binary, the Point-Biserial correlation coefficient is used [31]. The data with the correlated variables is then used to construct a binary target variable, which is defined as a linear combination of the first 4 features from the 10 generated variables, as shown in equation (3):

The remaining 6 variables $(X_5, \ldots, X_{10})$ do not contribute to Y and effectively act as noise variables in the dataset. These noise variables introduce additional complexity by creating scenarios where irrelevant features must be disentangled. This setup mimics real-world scenarios where datasets often contain features that are unrelated or weakly related to the target variable. Y is then used to define thresholds based on its median, with a range of SD 10% around the median. Values exceeding the upper threshold are assigned the binary label 1, while those below the lower threshold are assigned 0. For values within the threshold range, binary labels are assigned randomly. It should be noted that while the features X_1, X_2, X_3, X_4 remain continuous, the binary target variable is derived through this thresholding approach applied to the linear combination defined in equation (3).

The complexity in these simulated datasets arises from structured correlation patterns, where the strength, direction, and interplay of correlations among features significantly affect their relationships with the target variable. This correlational complexity can be understood at three levels:

1. Feature-target correlation: Variability in how individual features relate to the target, ranging from strong to very weak associations.
2. Feature-feature correlation: Associations among features that introduce complicate the disentanglement of their individual contributions to the target.
3. Global correlation structures: The overall arrangement of feature-target and feature-feature correlations, encompassing uniform (eg, consistent signs) or mixed configurations (eg, alternating signs).

Based on these levels, the datasets can be categorized into three complexity groups:

- Low complexity: Features exhibit rather strong relationships with the target, minimal or no correlations among features, and homogeneous global correlation.
- Moderate complexity: Feature-target relationships vary, ranging from strong to weak, with moderate feature-feature correlations, and consistent correlation signs.
- High complexity: Feature-target relationships are rather weak, with moderate feature-feature correlations, and alternating correlation signs (Figure 3C).

As complexity increases, the challenges in data analysis and modeling grow substantially. The correlation matrices of both simulated and real data reveal that BP most closely aligns with the 0.25 case (high complexity), BC with the 0.1 case (low complexity), and DB with the 0.3 case (low complexity).

Synthetic Data Generation Methods

We use a range of SDG methods to explore diverse approaches to data synthesis. Statistical methods include synthpop, a widely used statistical model that generates synthetic data by fitting individual features and their conditional distributions based on

XSL•FO
RenderX

the observed data structure. Synthpop is particularly well-suited for datasets with both continuous and categorical variables, as it applies models such as classification and regression trees that account for different data types. Another statistical method, copula, uses copula functions to model dependencies among variables, allowing for the generation of multivariate synthetic data by combining marginal distributions with a dependency structure. While copula-based methods are primarily designed for continuous variables, extensions or preprocessing techniques can be used to encode and incorporate categorical variables, such as one-hot encoding or ordinal transformations.

For more advanced generative approaches, we use copulagan, ctgan, and tvae, which are deep learning–based models designed to handle complex data synthesis tasks. Copulagan combines the dependency modeling capabilities of copulas with GANs. It learns the marginal distributions of real data columns and applies ctgan to model normalized data, improving the synthesis of mixed data types. Ctgan uses conditional GANs to address challenges in imbalanced and categorical data. It incorporates techniques like mode-specific normalization to handle high-cardinality categories, enabling precise modeling. Tvae captures complex, nonlinear relationships in tabular data by learning latent representations and generating high-quality synthetic data. In addition, we used the Tabula [29] LLM, which leverages LLMs such as a distilled Generative Pretrained Transformer-2 model, and encodes tabular data into natural language-style representations. This framework allows flexible data generation, incorporating domain-specific contexts and enabling synthesis from textual prompts. While not all models used qualify as LLMs (parameter sizes ≥1 billion), we used the term for simplicity.

For the implementation of copula, copulagan, ctgan, and tvae we used the Synthetic Data Vault library (SDV [32]). SDV (Andrew Montanez et al) integrates various methods into a unified framework, facilitating seamless experimentation and evaluation. Although adaptations of synthpop for Python (Sam Maurer et al) exist, we used the native R [24] environment, as it provides the most stable and comprehensive implementation.

Utility and Correlation Matrix Distance Measures

To evaluate the quality of the synthetic data, we use 3 key metrics. First, training on synthetic data and testing their performance on original data, using the F_1-score as a measure. The F_1-score is calculated using a classification probability cutoff of 0.5. This approach is often referred to as train-synthetic-test-real. The evaluation differs depending on whether the data is derived from real-world datasets or simulated datasets. For real-world datasets, the original data is split into training and testing sets with an 80/20 split. The 80% training split is used to train the SDG methods, and an equivalent amount of synthetic data (corresponding to the 80% training size) is generated. The quality of this synthetic data is then evaluated by testing it against the original 20% testing split from the real-world dataset. For simulated datasets, 100% of the "real" simulated data is used to train the SDG methods. To evaluate the quality of the synthetic data, a separate test set consisting of 100% newly generated synthetic data was created. The performance is then assessed by testing the synthetic simulated data against the "real" simulated data containing the full 100% of the samples. The F_1-score resulting from training on the original data is represented as a dashed line in the visualizations.

Second, we compute the squared differences between the correlation matrices of the original and synthetic datasets. This metric quantifies the extent to which the synthetic data replicates the pairwise correlations present in the original data. Finally, we use the propensity score mean-squared error (pMSE), which is a metric used to evaluate the utility of synthetic data by measuring the distinguishability between real and synthetic datasets. It is defined as:

Where $\hat{e}_i$ represents the estimated propensity score for the i-th observation, which measures the probability of a sample being synthetic rather than real. The goal of synthetic data generation is to create data so realistic that the model cannot easily distinguish between synthetic and real samples. Therefore, lower pMSE values indicate better performance, as they imply a higher degree of similarity between the real and synthetic datasets. A pMSE value close to 0.25 (the maximum achievable value when synthetic and real datasets are highly distinguishable) suggests bad synthetic data generation [33]. Normalizing this metric by dividing it with 0.25 leads to values between 0 (indistinguishable) and 1 (highly distinguishable).

Variable Importance Measures

Python machine learning libraries, for example, sklearn, typically provide various methods to calculate variable importance (VIMP). The main two approaches are (1) Gini importance and (2) permutation importance [34]. Gini importance measures the reduction in Gini impurity when a feature is used to split a node. The feature's importance is quantified by the total decrease in impurity across all trees. Features that contribute more to impurity reduction are considered more important, although this method can be biased toward features with more categories or higher cardinality.

Alternatively, permutation importance evaluates a feature's significance by measuring the drop in model performance, typically accuracy, when the feature's values are randomly shuffled. The importance score is derived from the change in performance on out-of-bag samples before and after shuffling. A larger decrease in accuracy indicates greater importance. This method is more robust, accounting for feature interactions and reducing biases, but is computationally more demanding.

Using both Gini importance and permutation importance provides complementary insights: Gini impurity reflects a feature's contribution to better splits within trees, while permutation-based importance directly measures a feature's impact on overall prediction accuracy. Combining both methods offers a more balanced assessment of feature relevance.

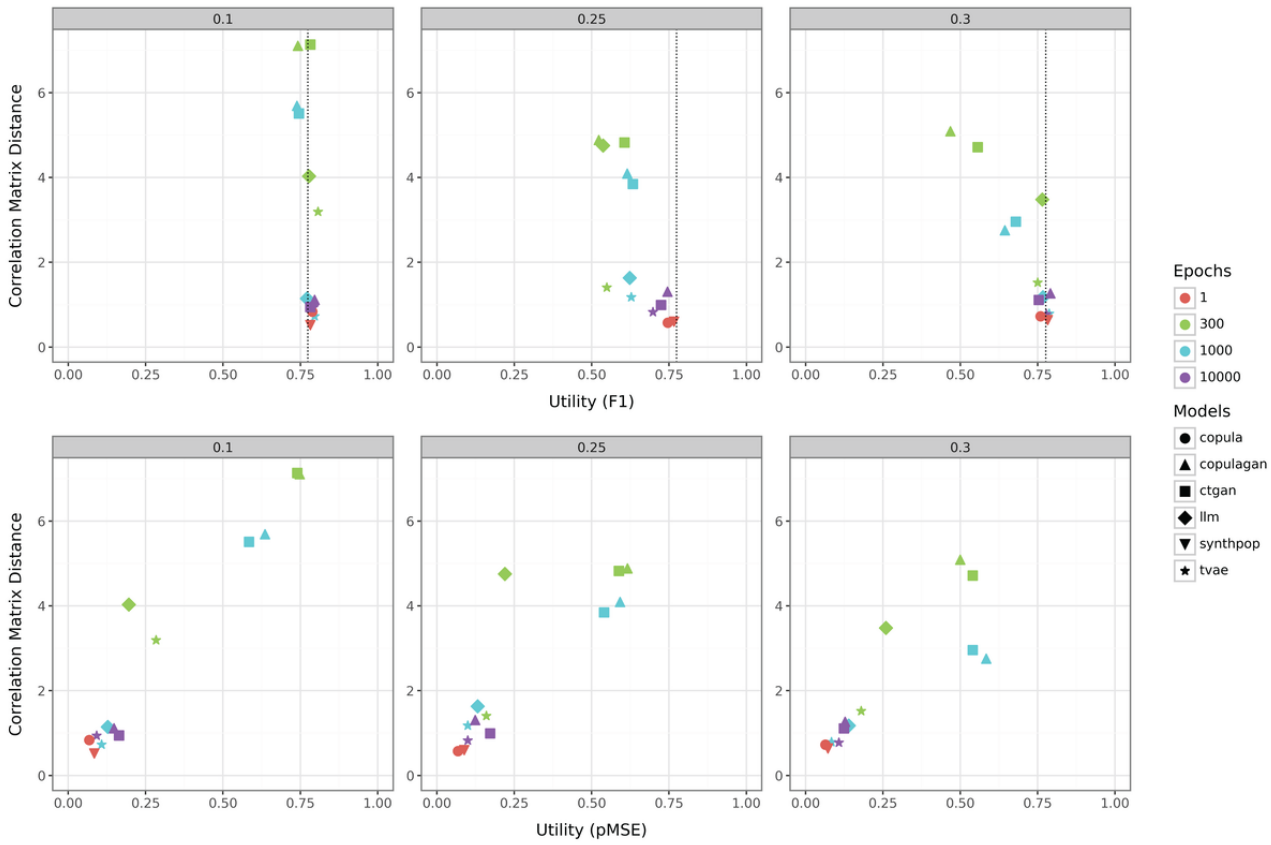
Evaluation Design

We conduct 10 sampling iterations for each combination of SDG methods. For deep learning approaches, we evaluate training epoch sizes of 300, 1000, and 10,000 on both simulated and real datasets. For LLMs, we limit the epoch sizes to 300

XSL•FO
RenderX

and 1000 due to significantly higher resource demands and previous findings indicating no performance improvement with larger epoch counts [35]. The batch size is fixed at 500 for the deep learning SDV methods and 64 for LLMs. Specifically, we compute the mean F_1-score and correlation matrix differences across the 10 samples for each SDG method and epoch size. For the most notable results, we visualize the correlation matrix differences and calculate the VIMP scores for the best and worst-performing methods.

Results



We will first present the results for the simulated data, followed by those for the real data. Since the results from eXtreme Gradient Boosting and Gated Additive Tree Ensembles are nearly identical to those from Random Forest and provide no additional insights, we have omitted them here (Multimedia Appendix 1). Although we anticipated this outcome, we sought to empirically validate it. The analysis will then continue with an examination of the VIMP scores and visualization of the correlation distances for the most notable case, which simulated data consisting of 10,000 samples with an alternating decay parameter of 0.25. This scenario is chosen because it illustrates a case where, despite a large sample size, there is a considerable performance gap between the best- and worst-performing methods.

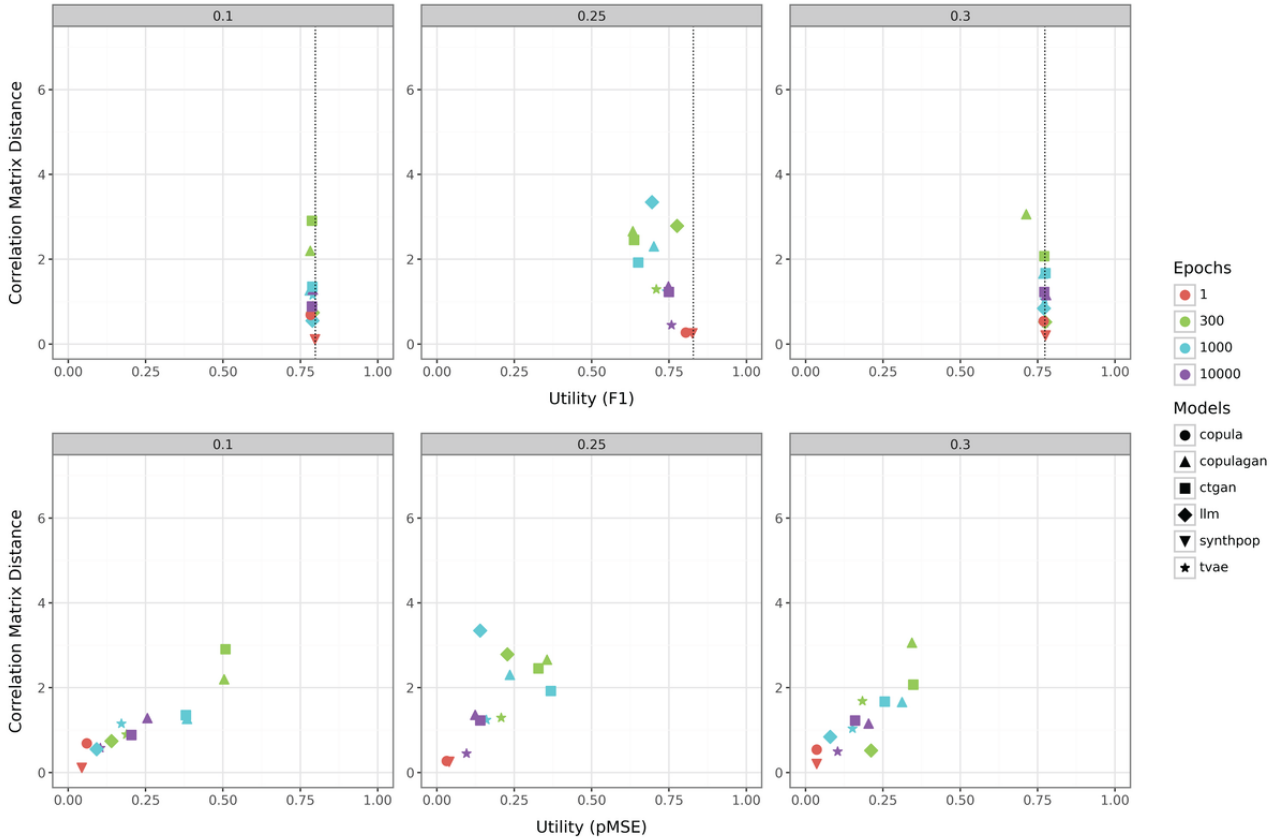
Correlation Distance and Utility Comparison

Simulated Data

Figure 4 presents the results of our methods on the smallest simulated dataset with 500 samples. For the case of strong positive correlations (0.1), there is virtually no difference in utility between generated and original simulated data. In other words, most models cluster tightly around a RF utility of approximately 0.75. Some models (eg, ctgan and copulagan at 300 and 1000 epochs) have higher correlation matrix distances, indicating weaker preservation of correlation structures. Deep learning models trained with more epochs (eg, 1000 or 10,000, indicated by blue and purple) perform better in terms of correlation matrix distances compared to models with 300 epochs. In terms of utility, epoch sizes do not have a significant effect in this scenario because the data complexity seems not high enough to require prolonged training. The observation that utility remains unaffected by high correlation matrix distances highlights that a poor approximation of the correlation structure is problematic only under specific conditions.

Figure 4. Comparison of the correlation matrix distance and utility metrics (F_1-score in the top row; pMSE in the bottom row) for the simulated dataset with a sample size of 500. ctgan: Conditional Tabular Generative Adversarial Network; LLM: large language model; pMSE: Propensity Score Mean-Squared Error; synthpop: Synthetic Populations in R; tvae: Tabular Variational Autoencoder.

In the scenario with moderate positive correlations (0.3), the higher correlation distance of ctgan and copulagan at low epoch counts now also negatively affects the RF utility, despite the correlation matrix distance being lower than in the case of 0.1. The pMSE values are overall lower, suggesting that the increased complexity primarily affects the RF utility. Models trained with 10,000 epochs again demonstrate improved performance, characterized by lower correlation matrix distances and enhanced RF utility, although the pMSE values are higher. The relationship between pMSE values, correlation matrix



XSL•FO
RenderX

differences, and RF utility is demonstrated by comparing LLM with 300 epochs and ctgan with 1000 epochs: while LLM exhibits a higher correlation matrix difference, its superior utility results in a significantly lower pMSE value overall. As observed in the 0.1 case, tvae and LLM with high training epochs again rank among the top-performing methods in this scenario, with copula and synthpop achieving the highest performance. The same necessity for extended training epochs as in the 0.1 case suggests that deep learning models likely struggle due to insufficient training data.

In the most complex scenario (0.25), the performance of each SDG method in RF utility is worse than with the original data. This is particularly evident as the tvae and LLM models deviate more significantly from the baseline even with 10,000 epochs. However, these differences have minimal impact on the pMSE values, where copula and synthpop consistently emerge again as the best-performing methods. The high complexity of this simulated dataset primarily manifests as reduced RF utility rather than increased pMSE. However, the differences compared with the 0.3 scenario are not substantial. Notably, well-performing methods show remarkable robustness, while deep learning approaches with fewer epochs, typically recommended as default settings for practical applications, perform surprisingly poorly by comparison.

Figure 5 illustrates the results obtained on the simulated dataset containing 5000 samples. It is evident that the increased dataset size improves the performance across all cases. Correlation matrix differences are smaller, and in the 0.3 case, almost all methods achieve similarly high levels of performance in terms of RF utility. Notably, the 0.25 case differs significantly from the other two cases, although its results are not substantially different from those observed with the 500-sample dataset. The most notable change is that copulagan and synthpop now emerge more clearly as the leading methods, whereas previously, tvae with high epochs had delivered comparable results. Overall, while deep learning methods benefit from the larger dataset, they still require a high number of epochs to perform well and do not yet match the performance levels of statistical methods.

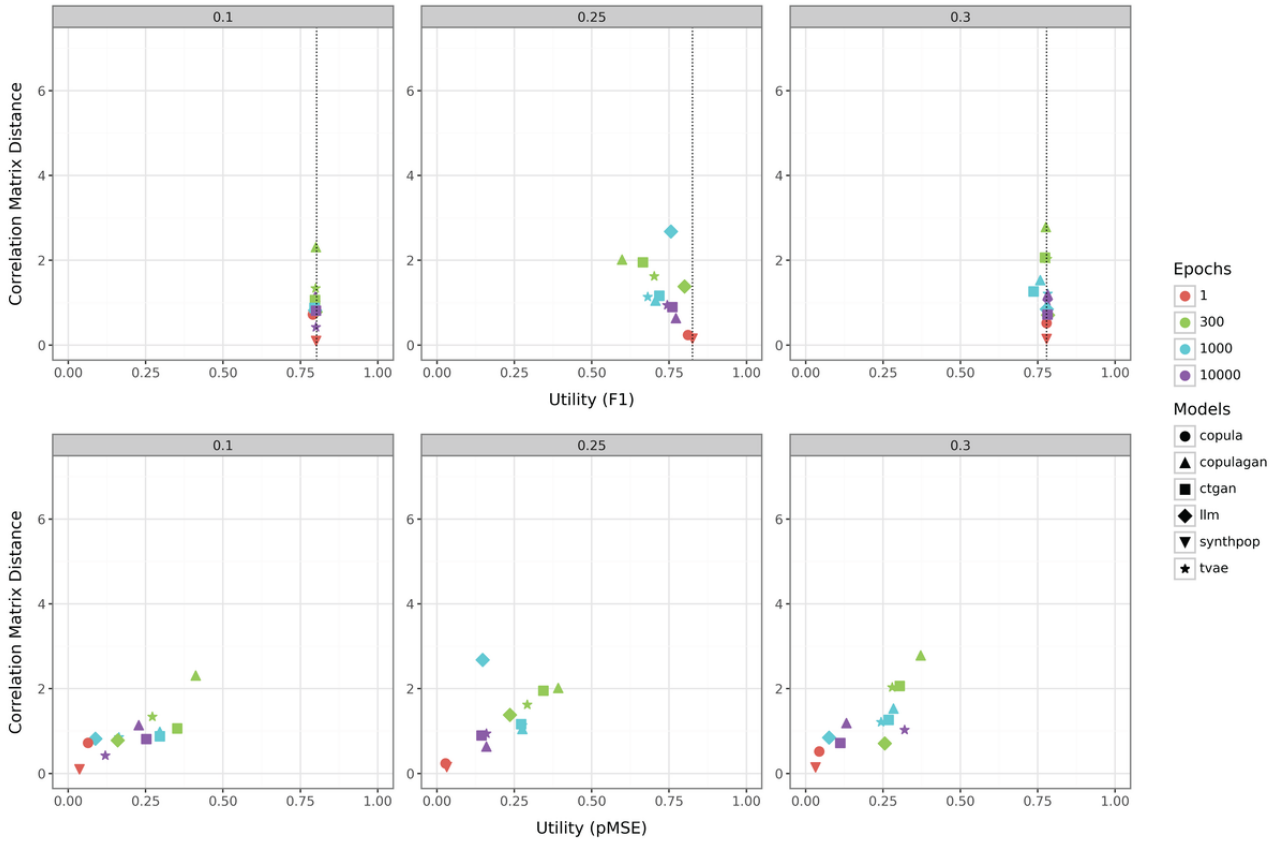


Figure 5. Comparison of the correlation matrix distance and utility metrics (F_1-score in the top row; pMSE in the bottom row) for the simulated dataset with a sample size of 5000. ctgan: Conditional Tabular Generative Adversarial Network; LLM: large language model; pMSE: Propensity Score Mean-Squared Error; synthpop: Synthetic Populations in R; tvae: Tabular Variational Autoencoder.

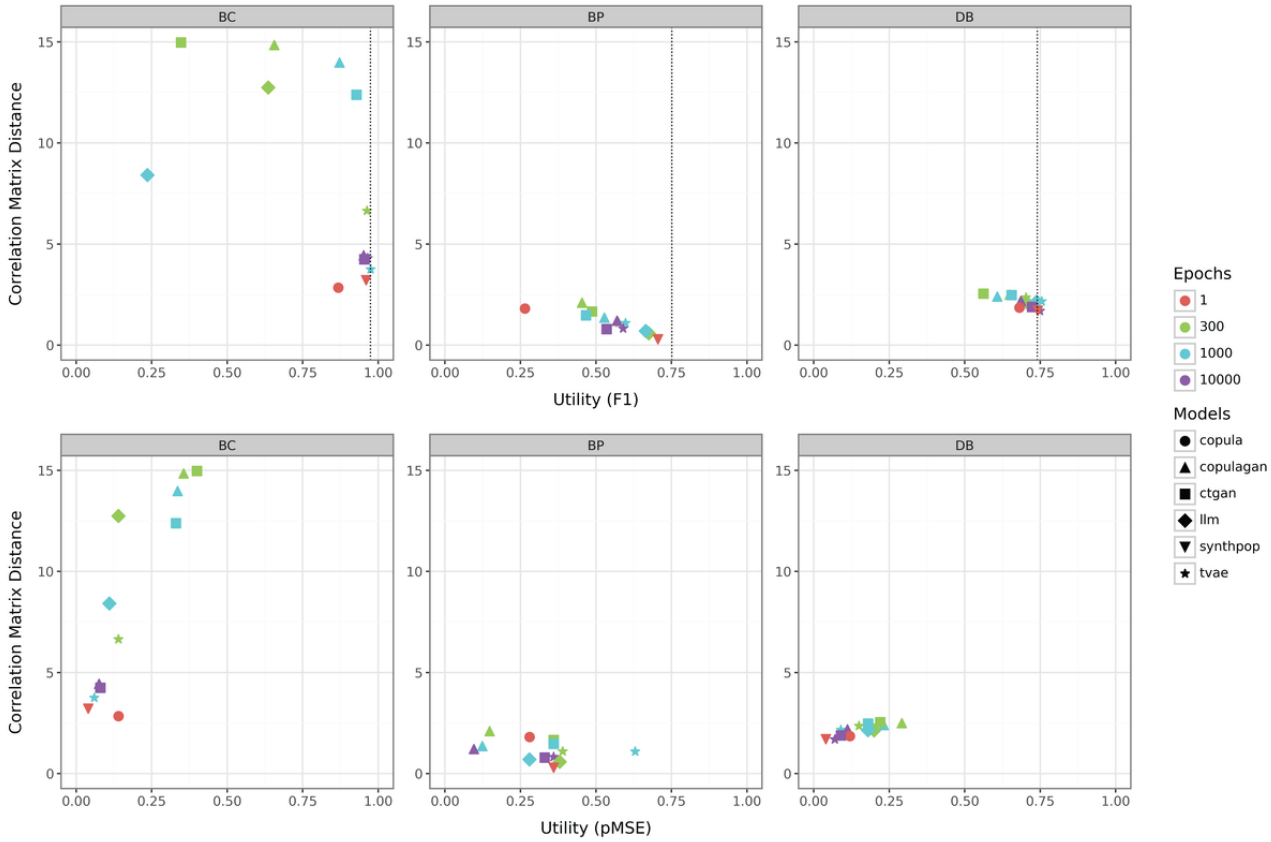
In the results of the simulation dataset comprising 10,000 samples, illustrated in Figure 6, the correlation matrix differences decrease slightly further. In addition, the performance of most deep learning methods improves in terms of RF utility and pMSE values when trained with 300 and 1000 epochs. Increasing the number of training epochs enhances the performance of deep learning methods more compared with 5000 samples but less compared to 500 samples. Otherwise, the results closely resemble those obtained with the 5000-sample dataset. This suggests that using a larger dataset for synthesis does not yield significant benefits unless the goal is to use deep learning methods with a limited number of epochs. However, the overall results indicate that such methods are generally not advantageous for datasets with a structure similar to that of our simulation study.

XSL•FO
RenderX

Figure 6. Comparison of the correlation matrix distance and utility metrics (F_1-score in the top row; pMSE in the bottom row) for the simulated dataset with a sample size of 10,000. ctgan: Conditional Tabular Generative Adversarial Network; LLM: large language model; pMSE: Propensity Score Mean-Squared Error; synthpop: Synthetic Populations in R; tvae: Tabular Variational Autoencoder.

Real-World Data



Due to the larger number of columns and a broader variety of data types in these datasets, the outcomes naturally exhibit some differences (Figure 7). Regarding the impact of dataset size, the results align closely with those observed in the simulated data for key trends. Specifically, smaller datasets exhibit significantly greater variability across all metrics. For the BC dataset, the copula method captures correlations most effectively, whereas synthpop achieves the best results in terms of RF utility and pMSE. BC is also the dataset where increasing the number of epochs benefits deep learning methods the most. This observation is consistent with findings from the simulated data, despite the real datasets featuring a considerably higher number of columns.

On the BP dataset, an initial observation reveals that copulagan achieves unexpectedly favorable pMSE values. This outcome becomes more comprehensible upon examining the dataset's structure. While BP officially comprises 2 categorical variables (gender and class), it also includes sit-up counts, which is an integer variable that pose statistical modeling challenges. Estimating marginals using diverse distributions, such as the Beta distribution, as a preprocessing step for GANs, proves advantageous in this scenario, especially given the ample data available for these estimations. However, this does not translate into superior RF utility. The association between target and features is not adequately captured by copulagan, resulting in poor RF utility scores. In contrast, synthpop demonstrates the best RF utility and correlation matrix difference performance, although it struggles with achieving competitive pMSE due to the complexity of modeling integer variables. Copula, on the other hand, fails entirely to learn meaningful target-feature associations, yielding extremely low RF utility.

The DB dataset presents the fewest challenges to the methods overall, primarily due to the limited number of continuous variables it contains. All methods perform relatively similarly, reflecting the dataset's inherent simplicity. Compared to the corresponding simulated dataset, one notable difference is that even methods with fewer epochs achieve relatively good performance. Otherwise, the insights gained from the 0.3 case simulation with 500 samples are largely transferable to this real-world scenario. Among the methods tested, synthpop and tvae demonstrate the best performance across all metrics, with synthpop again emerging as the most effective.

Detailed Analysis of a Notable Result

We focus on the two least effective methods in terms of correlation matrix difference (ctgan with 300 epochs and LLM with 1000 epochs) and the best-performing method across all metrics (synthpop) on the 0.25 case of the simulated data consisting of 10,000 samples.

Figures 8-10 display the original correlations, those of the synthetic data, and the resulting correlation matrix differences for synthpop, ctgan, and LLM, respectively. While synthpop generates near-perfect synthetic data, both ctgan and LLM struggle, particularly with high absolute feature-feature correlations, which are often underestimated. In the case of LLM, this issue also extends to feature-target correlations, while ctgan exhibits feature-target correlations that exceed those in the original data. Overall, the underestimation of correlations is more pronounced in LLM than the mixed under- and overestimation seen in ctgan, which explains the larger correlation matrix differences observed in LLM. However, since the relative correlation ratios in LLM more closely resemble those in the original dataset, it performs better than ctgan in terms of RF utility and pMSE. Figure 11-13 display the VIMP scores (Gini and permutation importance) for synthpop, ctgan, and LLM, respectively. Synthpop shows near-identical results to the original data. The Gini importance for ctgan is promising, but the permutation importance reveals that feature 3 becomes entirely irrelevant. Features 7 and 9, due to their higher correlations with the target, are now relevant. For the LLM, feature 1 becomes nearly irrelevant. However, since feature 3 holds greater significance for the target variable, and no other irrelevant features exhibit substantial permutation importance, this does not detrimentally impact the RF utility or pMSE as severely as observed with the ctgan model. Overall, we conclude that large discrepancies in correlations harm utility only when the ratios between target and feature correlations shift significantly.

Discussion

Principal Findings

The central finding of our simulation study, which is largely transferable to real-world datasets, is that statistical methods such as copula and synthpop consistently outperform deep learning-based approaches across varying sample sizes and correlation complexities. Notably, synthpop emerged as the most effective method. These techniques demonstrate robust performance with minimal reliance on dataset size or extensive training, highlighting their reliability in preserving statistical properties and utility. However, our analysis of real-world datasets revealed that the copula method struggles when handling integer variables and increasing sample sizes does not mitigate this limitation.

In contrast, deep learning methods yield mixed results. While they benefit from larger datasets and extended training epochs, their performance often falls short of statistical methods, especially when trained with fewer epochs or on smaller datasets. These models struggle to capture the correlation structures, leading to higher pMSE values and diminished utility for downstream tasks. This suggests that deep learning models require careful tuning, including sufficient data and training time, to match the performance of statistical approaches. While the potential for deep learning models to handle datasets with diverse types is promising, the results presented here do not provide sufficient evidence to confirm this advantage over statistical methods. In addition, high performance observed for some deep learning-based approaches may be influenced by overfitting rather than genuine generalization.

The results obtained using the LLM method are somewhat disappointing. Despite a large sample size (≥10,000), this approach does not match the performance of synthpop. While the results are generally acceptable, they highlight that the sheer number of parameters in LLM models is not a decisive factor. Instead, methods specifically designed to directly replicate statistical properties and correlations are often more efficient and effective for tabular data. The probabilistic modeling of LLMs via next-token prediction reaches limitations, particularly when it comes to accurately replicating numerical dependencies. Although the attention mechanism offers promising potential, it does not directly address the preservation of distributions and correlations that are crucial for tabular data. In addition, the significantly longer runtime (hours instead of seconds or minutes), even with 2 high-performance NVIDIA H100 Graphics Processing Units, makes the use of the LLM method difficult to justify for our datasets. However, in cases where tabular data contains many features (more than 30), such as high-dimensional datasets, the runtime of synthpop (which runs on CPU) can become prohibitive when using classification and regression trees. In these cases, the runtime of LLMs may be comparable or even shorter, particularly as the number of rows increases.

Our detailed analysis of correlation matrix differences, VIMP scores, and utility uncovers one central mechanism that leads to either good or poor model performance. We find that a model's utility is primarily influenced by the preservation of relative correlations between features and the target variable, rather than by large correlation matrix differences themselves. Although LLM exhibits greater correlation matrix differences

XSL•FO
RenderX

after 1000 epochs compared to ctgan after 300 epochs, this does not result in worse utility. This is because LLM better preserves the relative correlations, particularly those between the features and the target, which leads to improved RF utility and pMSE. In contrast, while ctgan shows good Gini importance values, its less accurate representation of the correlation value ratios has a greater negative impact on utility. Overall, our findings demonstrate that it is not the absolute magnitude of correlation matrix differences, but the relative correlations between features and the target variable that are critical for model utility.

Our results confirm those found in the literature [36,37] but extend them by incorporating LLMs for the first time and using a simulation approach to assess the impact of various correlation structures on the outcomes. Statistical techniques, such as copula and synthpop, are widely recommended for medical datasets with characteristics similar to those in this study. However, our analysis of the BP dataset highlights the potential usefulness of deep learning methods, particularly when handling multiple variables of diverse data types. In these scenarios, deep learning approaches are anticipated to be able to outperform both synthpop and copula-based methods.

Limitations

A key limitation of this study is that our simulation focused primarily on pairwise correlations. This decision was intentional, as we aimed to restrict our exploration to a small set of scenarios to maintain manageable complexity and derive initial insights. While many of our findings translated well to real-world data, the BP dataset highlighted an important challenge: when dealing with more complex scenarios involving a larger number of variables, diverse data types, and intricate interaction patterns, such as those commonly found in omics or high-dimensional datasets, it becomes essential to design advanced simulation studies that better capture these complexities [38]. In such cases, conventional approaches like Cholesky decomposition or even copula-based methods may no longer suffice [39].

Another limitation of our work is the exclusion of more recent and potentially transformative methods, such as diffusion models [40]. These models have demonstrated exceptional performance in generating high-quality synthetic data, particularly for images, and their application to tabular data represents a promising direction for future research. Moreover, we did not extensively evaluate how our chosen methods perform under scenarios involving temporal or longitudinal data, multimodal datasets, or extreme imbalance in class distributions, challenges that are increasingly relevant in modern data science applications. Addressing these aspects would provide a more comprehensive understanding of the strengths and limitations of SDG methods in diverse contexts.

Further, privacy considerations were not evaluated as part of the synthetic data generation process. While the generative models aimed to preserve data utility and structural similarity, privacy risks such as data leakage or membership inference attacks were not assessed due to our focus in the relationships between correlation structure and utility under different scenarios.

Finally, in synthetic data generation, it is critical to account for biases. If the original data contains biases, the synthetic data is likely to mirror these, potentially leading to discriminatory health care outcomes, particularly for marginalized or underrepresented groups. To mitigate such risks, bias detection and adjustment techniques, such as reweighting, oversampling, and fairness constraints, should be integrated into the data generation process. Beyond bias, ethical concerns also include privacy, informed consent, and accountability. For instance, transparency in the data generation process and clear, informed consent from data contributors are essential for maintaining ethical standards. Regular audits of the synthetic data and associated models are necessary to identify and correct emerging biases and privacy breaching risks.

Conclusions

Statistical methods, particularly synthpop, consistently outperform deep learning–based approaches in preserving statistical properties and utility across diverse datasets, establishing their robustness and reliability. Copula methods show promise but struggle with integer variables, limiting their application in real-world scenarios. Deep learning methods, while resource-intensive and sensitive to hyperparameters, may outperform statistical approaches in handling highly complex datasets with mixed variable types when sufficient training samples and computational resources are available. LLMs, despite their theoretical potential, demonstrated suboptimal performance and high computational costs for the datasets analyzed in this study. Overall, these findings underscore the dominance of statistical methods for synthetic data generation for tabular data, while highlighting the niche potential of deep learning approaches for highly complex datasets, provided adequate resources and tuning.

Acknowledgments

This study was funded by BRIDGE, a joint program of the Swiss National Science Foundation SNSF and Inno Suisse (grant 211751).

Data Availability

Data are deposited in publicly available repositories (where available and appropriate).

Authors' Contributions

MS conceptualized and supervised the study. MM implemented the models and further refined the methodological ideas. MS drafted the manuscript, with both authors reviewing and approving the final version.
